3. Is there a sequence of reals with $\sum a_i^4 = 2$, $\sum a_i^5 = 3$ and $\sum a_i^6 = 3$? *Answer:* no, the same split shifted to $u_i = a_i^2$, $v_i = a_i^3$ gives $9 \leq 6$, false.

16.8 B2. smallest integer side of a lattice triangle

Given that A, B, and C are noncollinear points in the plane with integer coordinates such that the distances AB, AC, and BC are integers, what is the smallest possible value of AB?

Read it out loud

Read this out loud: three lattice points, pairwise integer distances, not collinear, and you are asked for the smallest a single labelled side can be. The fields wired in are geometry, since you are working with lattice points and the triangle inequality, and number theory, since integer coordinates force $x^2 + y^2$ type expressions to be perfect squares wherever a distance is required to be an integer. This is a Heronian triangle question in disguise, a triangle with integer sides that also happens to sit on the integer lattice, and "smallest possible value of AB" is an extremal command term: you are not asked to classify every such triangle, only to pin down one number.

Within thirty seconds you should have done two things. First, hunt for a small example to know what you are aiming to prove is best possible: the right angled triangle with legs 3 and 4 and hypotenuse 5 sits on the lattice at $(0,0)$, $(3,0)$, $(0,4)$ with all three sides integers, giving a candidate answer of 3. Second, notice that AB being genuinely small, 1 or 2, is a very restrictive condition once you also demand A, B, C are not collinear, because the reverse triangle inequality $|AC - BC| < AB$ then leaves the other two sides almost no room to differ. That second observation, not the example, is the real key: it converts a geometry question into an integer rigidity question with almost no free choices left.

Approaches, ranked worst to best

1. **brute force coordinate search.** *Cue:* integer coordinates invites literally trying small lattice triangles. *Circuit:* systematic or hand enumeration of nearby lattice points. (even a search that correctly finds no working triangle with $AB \in \{1,2\}$ among the cases you tried never proves impossibility for the lattice points you did not check, so it cannot stand alone as a proof and costs unbounded ink.)

2. **Heron's formula together with the lattice area lemma.** *Cue:* integer sides make the triangle Heronian, and integer coordinates force twice the area to be an integer. *Circuit:* Heron's formula combined with the shoelace determinant fact. (for $AB = 1$ the two remaining sides are forced equal by the triangle inequality, and Heron's formula closes quickly via a difference of squares factorisation; but for $AB = 2$ the remaining sides can differ by 1, and Heron's formula then produces a quadratic Diophantine condition with no clean factorisation. This route terminates, unlike brute search, but one branch costs far more ink than the route below.)

3. **reverse triangle inequality rigidity plus the perpendicular bisector.** *Cue:* AB is forced tiny, leaving almost no room between $|AC - BC|$ and AB. *Circuit:* the equality case of the triangle inequality is exactly collinearity, which the hypothesis excludes. (place A and B using the fact that the only lattice points at distance 1 or 2 from a fixed lattice point are axis aligned; then $|AC - BC| < AB$ forces $AC = BC$ outright for $AB = 1$, and after one short parity check forces the same for $AB = 2$. In both cases C is pinned to the perpendicular bisector of AB, where integrality kills it in one further line. This is the ideal route: every step is forced, and the only casework is a single parity check.)

The ideal solution

The smallest possible value of AB is $\boxed{3}$, achieved by $A = (0,0)$, $B = (3,0)$, $C = (0,4)$: here $AB = 3$, $AC = 4$, $BC = 5$, all integers, and the three points are not collinear.

It remains to rule out $AB = 1$ and $AB = 2$.

Two facts do all the work. First, since A, B, C are not collinear, the reverse triangle inequality is strict:

$$|AC - BC| < AB,$$

because equality in $|AC - BC| \leq AB$ holds exactly when one of A, B, C lies on the segment joining the other two, which is a case of collinearity. Second, since A and B have integer coordinates and $AB \in \{1, 2\}$, the only lattice points at distance AB from A are obtained from A by moving along a single coordinate axis: the equation $x^2 + y^2 = 1$ forces $(x, y) \in \{(\pm 1, 0), (0, \pm 1)\}$ and $x^2 + y^2 = 4$ forces $(x, y) \in \{(\pm 2, 0), (0, \pm 2)\}$, since neither 1 nor 4 has any other representation as a sum of two integer squares. Translating A to the origin and applying a quarter turn about it, both of which preserve the lattice and every distance, you may therefore place $A = (0, 0)$ and $B = (AB, 0)$ without loss of generality.

Case $AB = 1$**.** Write $A = (0, 0)$, $B = (1, 0)$, $C = (x, y)$ with $x, y \in \mathbb{Z}$. Since $|AC - BC| < 1$ and AC, BC are integers, $AC = BC$. Then C lies on the perpendicular bisector of AB, the line $x = \frac{1}{2}$; but x is an integer, so $x \neq \frac{1}{2}$, a contradiction. So $AB = 1$ is impossible.

Case $AB = 2$**.** Write $A = (0, 0)$, $B = (2, 0)$, $C = (x, y)$ with $x, y \in \mathbb{Z}$. Then

$$BC^2 - AC^2 = \left((x - 2)^2 + y^2\right) - \left(x^2 + y^2\right) = 4 - 4x,$$

which is even, so $AC^2 \equiv BC^2 \pmod 2$. Since an integer and its square always share parity, $AC \equiv BC \pmod 2$, so $AC - BC$ is even. On the other hand $|AC - BC| < AB = 2$ forces $|AC - BC| \in \{0, 1\}$, and the only even value available is 0, so again $AC = BC$. Then C lies on the perpendicular bisector $x = 1$, so write $C = (1, y)$. Now $AC^2 = 1 + y^2$ must be a perfect square, say $AC = k$ for a positive integer k, so $k^2 - y^2 = 1$, that is $(k - y)(k + y) = 1$. Both factors are integers, so either $k - y = k + y = 1$, giving $y = 0, k = 1$, or $k - y = k + y = -1$, giving $k = -1$, impossible since $k > 0$. So $y = 0$ and $C = (1, 0)$, which lies on the line through A and B, contradicting noncollinearity. So $AB = 2$ is impossible.

Since $AB = 1$ and $AB = 2$ are both impossible and $AB = 3$ is achieved, the smallest possible value of AB is 3.

Layer 1: WHAT

Block 1: exhibit the $3, 4, 5$ triangle on the lattice to fix a target value and confirm 3 is achievable.

Block 2: extract the two governing facts, the strict reverse triangle inequality from noncollinearity, and the fact that lattice points at distance 1 or 2 from a fixed lattice point are forced onto the coordinate axes, which licenses a clean placement of A and B.

Block 3: run $AB = 1$: the strict inequality alone forces $AC = BC$, and the perpendicular bisector together with integer coordinates finishes it in one line.

Block 4: run $AB = 2$: the strict inequality only narrows $|AC - BC|$ to two candidate values, so a short parity argument on $AC^2 - BC^2$ is needed to knock out the value 1 before the same perpendicular bisector idea closes it, this time via a difference of squares factorisation rather than a bare fraction.

The nominal route reaches for Heron's formula and the lattice area identity, or for brute enumeration; the ideal route reaches for the reverse triangle inequality's equality case. The bifurcation point sits right after noticing AB is forced small: whether you reach for an area formula, which keeps both unknown sides present and produces a genuine two variable Diophantine condition in the $AB = 2$ branch, or for the reverse triangle inequality, which converts "the two other sides are close in value" directly into "they are equal," collapsing a whole degree of freedom in a single line.

Layer 2: HOW

Block 1. Cue. The problem asks for the smallest possible value of a specific side. **Why natural.** An extremal existence question is answered by pairing a construction, giving an upper bound on

how small the answer could be, with a proof that nothing smaller works; writing down a candidate construction first tells you exactly what you need to rule out. **Link to the next block.** The $3, 4, 5$ triangle fixes the target as 3 and tells you the remaining work is to eliminate $AB = 1$ and $AB = 2$ only.

Block 2. Cue. Noncollinear points with a very small integer distance between two of them. **Why natural.** Noncollinearity is precisely the strict case of the triangle inequality, so smallness of AB combined with noncollinearity is definitionally a statement that AC and BC are forced close together; separately, integer coordinates at a fixed small integer distance restrict to finitely many lattice directions, since $x^2 + y^2 = 1$ or 4 have only axis aligned solutions. **Link to the next block.** These two facts jointly let you place A, B concretely and immediately convert "AB small" into a rigid constraint on $AC - BC$.

Block 3. Cue. For $AB = 1$, the strict inequality gives $|AC - BC| < 1$ with both sides integers. **Why natural.** An integer strictly between -1 and 1 can only be 0, so $AC = BC$ is not a deduction to search for, it is forced immediately by integrality. **Link to the next block.** Equidistance from two fixed points is the definition of the perpendicular bisector, so C's x coordinate is pinned to a half integer, clashing with C being a lattice point.

Block 4. Cue. For $AB = 2$, the same inequality only narrows $|AC - BC|$ to $\{0, 1\}$, leaving one extra case to remove. **Why natural.** $AC - BC$ shares the parity of $AC^2 - BC^2$ exactly because an integer and its square always share parity, and $AC^2 - BC^2$ is directly computable from the coordinates as $4 - 4x$, visibly even; this rules out $|AC - BC| = 1$ without any further search. **Link to the next block.** With $AC = BC$ re established, the perpendicular bisector argument returns, now needing a factorisation $(k - y)(k + y) = 1$ rather than a bare non integer, because the bisector $x = 1$ is itself a lattice line this time.

Layer 3: WHY

The underlying truth is that noncollinearity is not a separate geometric condition to check at the end, it is the strict case of the triangle inequality itself, so any problem that pairs "noncollinear" with "a very small integer side" is handing you a rigidity statement for free: the other two sides are forced within one unit of each other before you do any work. The discernment mechanism to train is to test, immediately after reading a lattice distance problem, whether the given or requested side length is small enough that the triangle inequality alone, rather than an area formula, which treats all three sides symmetrically and loses this rigidity, pins down a relation between the other two sides. When it does, the triangle inequality route is essentially always cheaper, because it removes a degree of freedom outright rather than producing a further equation to solve.

The second truth worth training is about the lattice itself: a lattice point at a fixed small integer distance from another lattice point is not free to sit anywhere on the corresponding circle, it is constrained to the finitely many lattice points on that circle, and for the two smallest integer radii, 1 and 2, that finite set happens to be exactly the four axis aligned points, which is what licenses the WLOG placement rigorously rather than by appeal to intuition. This stops holding at distance 5, where $(3, 4)$ and its images also lie on the circle, so the placement trick is specific to small radii and you should check, not assume, that it applies before using it.

What the examiners were nudging toward is the phrase "noncollinear": it is doing far more work than excluding a degenerate picture, it is the entire mechanism that makes $AB = 1$ and $AB = 2$ impossible, and a candidate who treats it as a throwaway hypothesis rather than the engine of the proof will reach for Heron's formula and pay for it in the $AB = 2$ case.

Revolving concepts

Reverse triangle inequality and its equality case. For any three points, $|AC - BC| \leq AB$, with equality exactly when A, B, C are collinear with one of them between the other two; strict inequality is therefore equivalent to noncollinearity. See Book 1, field: Geometry, topic: triangle inequality.

Sum of two squares representations. An integer n can be written as $x^2 + y^2$ with x, y integers according to the prime factorisation of n in the Gaussian integers; the count and shape of such representations is why 1 and 4 admit only axis aligned lattice points at that distance from the origin, while 25 admits both axis aligned and genuinely diagonal ones. See Book 1, field: Number theory, topic: sums of two squares.

Heronian triangles and the lattice area lemma. A Heronian triangle has integer sides and rational area; a triangle with integer coordinate vertices automatically has an area equal to half an integer, by the shoelace determinant formula, so an integer sided lattice triangle is automatically Heronian. This is the mechanism behind the alternative, costlier approach, and it generalises the whole problem: no Heronian triangle at all, lattice or not, can have a side of length 1 or 2. See Book 1, field: Geometry, topic: Heronian triangles and Pick's theorem.

Lattice symmetries. Translations by integer vectors and rotations by a multiple of a right angle about a lattice point both preserve the set of lattice points and every pairwise distance; this is the precise justification for placing A at the origin and B on an axis, rather than an unexamined appeal to symmetry. See Book 1, field: Geometry, topic: lattice point symmetries.

Circuit Bank

- **WHEN** a problem pairs noncollinear points with a small integer side length **DO** apply the reverse triangle inequality immediately, before reaching for an area formula **BECAUSE** noncollinearity is exactly the strict case of the triangle inequality, so it directly restricts the other two sides once the given side is small, without introducing any new unknowns
- **WHEN** two lattice points are known to be equidistant from a third **DO** place the equidistant point on the perpendicular bisector and use integrality of coordinates or of the resulting distance to finish **BECAUSE** equidistance is the definition of the perpendicular bisector, and a lattice point restricted to a specific line is usually one short check away from a contradiction
- **WHEN** you need to compare the parity of two integer distances without computing either one **DO** compute the difference of their squares directly from coordinates and check its parity, since an integer and its square always share parity **BECAUSE** this avoids ever solving for the distances themselves, replacing a square root computation with a one line algebraic identity

Backtesting

1. First useful cue: the phrase noncollinear sitting next to a request for the smallest integer side.
2. Method the expression suggested: the reverse triangle inequality, since a small AB leaves almost no room between AC and BC.
3. Where you would hesitate, and the thought to reinforce: whether placing A and B on an axis is really justified for a general lattice point; reinforce by checking explicitly which lattice points sit at the given distance, rather than assuming rotational freedom.
4. The trap the question sets: reaching for Heron's formula on the strength of "integer sides" alone, which works but buries you in a quadratic Diophantine condition in the $AB = 2$ case that the triangle inequality route avoids entirely.

5. What makes you recognise it faster next time: any lattice distance problem where noncollinearity is stated explicitly should trigger a check of the reverse triangle inequality before any area formula.
6. The reusable decision rule: when a side length is small and the points are noncollinear, use the triangle inequality to force the other two sides equal, or nearly equal, before doing anything else.

Mirror drills

1. Show that no Heronian triangle, lattice or not, can have a side of length 1. *Answer:* the other two sides are forced equal by the triangle inequality, then Heron's formula reduces to a difference of squares equation with no integer solution.
2. Three lattice points have pairwise integer distances and are noncollinear; show $AB = 2$ still forces $AC = BC$ using only a coordinate parity argument, without first bounding $|AC - BC|$ by the triangle inequality. *Answer:* compute $AC^2 - BC^2$ from coordinates, observe it is always even, and conclude $AC \equiv BC \pmod 2$, so the odd difference is impossible regardless of the inequality bound.
3. Four lattice points, no three collinear, have all six pairwise distances integers; what is the smallest possible value of the shortest of the six distances? *Answer:* still at least 3, since each distance is a side of some noncollinear triangle among the four points and the identical argument applies; a matching example can be built by extending the $3, 4, 5$ triangle with a fourth suitably placed integer point.

16.9 B3. the threshold for redistributing balls to uniform

There are 2010 *boxes labeled* $B_1, B_2, \ldots, B_{2010}$*, and* 2010$n$ *balls have been distributed among them, for some positive integer* n*. You may redistribute the balls by a sequence of moves, each of which consists of choosing an* i *and moving* exactly i *balls from box* B_i *into any one other box. For which values of* n *is it possible to reach the distribution with exactly* n *balls in each box, regardless of the initial distribution of balls?*

Read it out loud

Read this out loud and notice the one detail that decides the whole problem: a move at index i does not let you choose how many balls to send, it forces you to send exactly i balls, and only out of box B_i itself. The fields wired in are combinatorics and counting, specifically the pigeonhole principle used not in its usual two pigeons one hole form but as a capacity bound: if every box is required to stay below its own label's threshold, there is a hard cap on the total number of balls that configuration can hold. The command term "for which values of n, regardless of the initial distribution" is asking for a threshold that works against an adversary who chooses the starting mess, so you need both a construction that succeeds above the threshold and a stuck configuration that fails below it.

Within thirty seconds you should have written down the quantity $\sum_{i=1}^{2010}(i-1)$, the total number of balls a distribution could hold while every single box B_i sits strictly below its own threshold i, since a box below threshold cannot originate any move at all and such a configuration is completely frozen. That sum is $\frac{2009\times 2010}{2} = 2010 \times 1004.5$, exactly half a box count short of a clean multiple of 2010, and this single number is doing all the work: below it a frozen starting configuration exists, and above it no configuration can freeze every box simultaneously, so some move is always available.

Approaches, ranked worst to best

1. **small case brute force.** *Cue:* 2010 boxes and an arbitrary n are unwieldy, so shrink both. *Circuit:* pattern hunting on a handful of boxes. (useful only for conjecturing the threshold; it proves nothing about 2010 boxes on its own and still needs a general argument bolted on afterwards.)

2. **hunting for a preserved residue or colouring invariant.** *Cue:* "for which n is it possible" reads like a classic invariant question. *Circuit:* parity or modular invariants under the move. (the move set here does not preserve any fixed modulus in a useful way, since a move at index i changes two box counts by exactly $\mp i$, and i itself varies from move to move; you can chase candidate invariants for a long time without finding one that pins down 1005 exactly, and time is lost before falling back to a direct counting argument.)

3. **capacity or pigeonhole obstruction for impossibility, paired with an explicit router box construction for sufficiency.** *Cue:* a move is only ever legal from a box holding at least its own label, and box B_1 is the unique box whose native move size is a single ball. *Circuit:* the frozen everywhere configuration bounds the threshold from below, and routing every ball through B_1 realises it from above. (the threshold falls out of one inequality, $\sum_{i=1}^{2010}(i-1)$ against 2010n, and the construction needs nothing more exotic than repeatedly emptying the largest eligible box through B_1. This is the ideal route.)

The ideal solution

The answer is $\boxed{n \geq 1005}$.

Why $n \le 1004$ fails. For $i = 1, \dots, 2010$, choose integers c_i with $0 \le c_i \le i-1$, so $c_1 = 0$, summing to exactly $2010n$; this is possible whenever $2010n \le \sum_{i=1}^{2010}(i-1) = \frac{2009\times 2010}{2} = 2010 \times 1004.5$, in particular whenever $n \le 1004$, since the allowances $[0, i-1]$ for $i = 1, \dots, 2010$ can realise any integer total from 0 up to that cap. Start with B_i holding c_i balls. Every box satisfies $B_i \le i-1 < i$, so no move is legal anywhere: a move at index i needs $B_i \ge i$. The distribution is frozen, and since $c_1 = 0 < n$, box B_1 can never reach its target of $n \ge 1$ balls. So for $n \le 1004$ the uniform distribution is not reachable from every start.

Why $n \ge 1005$ suffices. First, an invariant that holds at every distribution with total $2010n$, not only the initial one, since the total never changes under a move: some index i is always *eligible*, meaning $B_i \ge i$. Indeed if every $B_i \le i-1$ at once, the total would be at most $2010 \times 1004.5 < 2010 \times 1005 \le 2010n$, a contradiction.

Run the following three phases from an arbitrary starting distribution.

Phase 1, collect. While some index $i \ge 2$ is eligible, take the largest such i and move i balls from B_i into B_1. Each move strictly reduces the total held in boxes 2 through 2010 by at least 2, so after finitely many moves no index $i \ge 2$ remains eligible: every B_i for $i \ge 2$ now satisfies $B_i \le i-1$.

Phase 2, flush. Process the indices $j = 2010, 2009, \dots, 2$ in turn. Let v_j denote the value of B_j left by phase 1, unchanged while larger indices are processed since only B_1 and the current B_j are touched, so $0 \le v_j \le j-1$. Move 1 ball from B_1 to B_j, repeated $j - v_j$ times, bringing B_j up to exactly j; this makes B_j eligible, so move j balls from B_j back to B_1, leaving $B_j = 0$. Move on to the next smaller index.

This phase never asks B_1 for a ball it does not have, precisely because $n \ge 1005$. Right before processing index j, boxes $2010, \dots, j+1$ are already empty and boxes $2, \dots, j$ still hold their original phase 1 values, so

$$B_1 = 2010n - \sum_{k=2}^{j} v_k.$$

The largest single withdrawal you make before any repayment, while processing index j, is $j - v_j$ balls, so legality at this step needs

$$2010n - \sum_{k=2}^{j} v_k \;\ge\; j - v_j \quad\Longleftrightarrow\quad 2010n \;\ge\; j + \sum_{k=2}^{j-1} v_k.$$

Bounding every $v_k \le k-1$, the right side is at most $j + \frac{(j-2)(j-1)}{2}$, an expression that increases by exactly j each time j increases by 1, so it is largest over $j = 2, \dots, 2010$ at $j = 2010$, where it equals $2010 + \frac{2008\times 2009}{2} = 2010 + 2017036 = 2019046$. Since $2010n \ge 2010 \times 1005 = 2020050 > 2019046$, the required inequality holds at $j = 2010$, and therefore at every smaller j too. So phase 2 completes legally, leaving every box empty except $B_1 = 2010n$.

Phase 3, distribute. For $i = 2, \dots, 2010$ in turn, move 1 ball from B_1 to B_i, repeated n times for each i. Legal throughout, since B_1 decreases monotonically from $2010n$ down to $2010n - 2009n = n$ and never needs to supply more than it holds. At the end $B_i = n$ for every $i \ge 2$, and $B_1 = n$ too.

The target is reached from an arbitrary start, so $n \ge 1005$ suffices, and combined with the impossibility direction the answer is exactly $n \ge 1005$.

Layer 1: WHAT

Block 1: notice the move size at index i is pegged to the box's own label, so a box below its label is completely frozen, which immediately suggests a capacity bound: what is the largest total achievable while every box is simultaneously frozen.

Block 2: turn that into the exact threshold, $\sum_{i=1}^{2010}(i-1) = 2010 \times 1004.5$, splitting the integers n into $n \le 1004$, where a frozen starting configuration with this total exists, and $n \ge 1005$, where no configuration can freeze every box at once, so some move is always available.

Block 3: for sufficiency, notice box B_1 is the only box whose native move size is a single ball, so route everything through it: collect every eligible box into B_1 working from the largest index down, then re inject one ball at a time to flush whatever remains, then hand out exactly n balls to everyone.

Block 4: verify the flush phase never overdraws B_1 by checking the single worst case, the largest index processed first, against the very same threshold from block 2, closing the argument exactly at $n = 1005$ with no gap between the impossibility bound and the construction.

The nominal route hunts for a preserved residue or colouring invariant, or brute forces small cases; the ideal route never asks what is preserved, only what is achievable while every legality threshold simultaneously fails. The bifurcation point sits right after reading "moving exactly i balls": whether you treat this as a hint to search for an invariant, the usual reflex for "for which n" questions, or as a rigidity statement about which moves are even available, which is a plain counting question and the one that actually closes this problem.

Layer 2: HOW

Block 1. **Cue.** A move at index i moves exactly i balls, and is available only when $B_i \geq i$ already. **Why natural.** This is a threshold condition tied to each box's own label, and thresholds tied to labels are answered by asking what happens if every box sits just under its own threshold at once, which is a pure counting question, not a structural one. **Link to the next block.** That question is exactly $\sum_{i=1}^{2010}(i-1)$, the capacity of the frozen everywhere configuration.

Block 2. **Cue.** The capacity 2010×1004.5 sits exactly halfway between two multiples of 2010. **Why natural.** The total balls is always an integer multiple of 2010, namely $2010n$, so it either sits at or below 2010×1004, which realises the frozen cap or falls short of it, or it sits at 2010×1005 or above, which strictly exceeds the cap; there is no integer n landing on the cap itself, so the two cases meet with no ambiguous boundary to resolve. **Link to the next block.** This tells you $n = 1004$ is the last impossible value and $n = 1005$ is the first value where some move is always available, which is exactly the opening a construction needs.

Block 3. **Cue.** Among all 2010 boxes, only B_1's own move size is 1. **Why natural.** Any box with label $i \geq 2$ forces batches of i balls at a time, too coarse to land exactly on a target of n balls per box in general, so atomic control is only ever available at B_1. **Link to the next block.** This fixes the shape of the whole construction before a single move is written: collect everything reachable into B_1, then dispense it back out one ball at a time.

Block 4. **Cue.** The collect phase can strand up to $i-1$ balls in each box i that never became eligible on its own. **Why natural.** Those stranded balls still have to reach B_1 eventually, and the only way to move fewer than i balls out of box i is to first top it up to exactly i balls, borrowing the shortfall from B_1 before getting it back. **Link to the next block.** This makes the flush phase a sequence of loans against B_1, and the only remaining question is whether B_1 can always afford the loan, answered by the same capacity inequality from block 2, now checked at the single worst moment, the largest box, processed first, when the loan is biggest and nothing has yet been repaid.

Layer 3: WHY

The underlying truth is that this is a counting argument dressed as a token game: the impossibility direction and the sufficiency direction are both proved by reading the same inequality, $2010n$ against $\sum_{i=1}^{2010}(i-1)$, in opposite directions, which is why the threshold comes out as one clean integer rather than needing two unrelated techniques that happen to meet in the middle. The discernment mechanism to train is this: whenever a move in a combinatorial construction is legal only once a counter's value crosses a threshold tied to its own label, ask first what the maximum achievable total

is while every threshold fails at once, and compare that number to the actual total; the comparison usually is the answer, or is one integer step away from it.

The second truth worth training is about where fine control comes from: when the native move sizes in a construction are coarse and tied to position, the only place you ever get atomic, one unit control is wherever the move size happens to be 1, and any construction with an exact numerical target has no real alternative to routing through that one component. Recognising this before writing a single move is what turns the construction from a search into a fixed three step procedure.

What the examiners were nudging toward is the word "exactly" in "moving exactly i balls": it is the entire content of the problem, since a version of this question where you could move any number of balls up to i would collapse instantly to direct balancing with no threshold at all, and a candidate who treats that word as incidental phrasing rather than the whole obstruction will spend their time hunting for an invariant that does not exist. This problem is a small instance of chip firing, also called the abelian sandpile model when firing is forced once a threshold is crossed, a named area of algebraic combinatorics; recognising the family is what turns this from a from scratch construction into an application of a known shape.

Revolving concepts

Pigeonhole as a capacity bound. If nonnegative integers $x_1, \ldots, x_k$ satisfy $x_i \leq c_i$ for fixed caps c_i, then $\sum x_i \leq \sum c_i$; contrapositively, if the actual total of such a family exceeds $\sum c_i$, some x_i exceeds its own cap. This is the two directions of the whole proof, read forwards for the construction and backwards for the counterexample. See Book 1, field: Combinatorics, topic: pigeonhole as a counting bound.

Chip firing and the abelian sandpile model. A chip firing game places tokens on the vertices of a labelled structure and allows a vertex to fire, sending tokens elsewhere, once its token count reaches a threshold tied to that vertex; questions of termination and the shape of the eventual stable state form a developed area of algebraic combinatorics, of which this problem is a specific instance. See Book 1, field: Discrete structures and graphs, topic: chip firing games.

Triangular numbers and their parity relative to the count. $\sum_{i=1}^{k}(i-1) = \binom{k}{2} = k \times \frac{k-1}{2}$, an integer multiple of k exactly when k is odd, and a half integer multiple of k when k is even. This is why 2010, an even count, produces a threshold sitting exactly between two integers with no ambiguous boundary case to resolve, whereas an odd count lands the capacity exactly on a multiple of the count and needs a separate check at equality, as in mirror drill two. See Book 1, field: Combinatorics, topic: triangular numbers.

Greedy processing against a monotonic bound. When a construction must clear a sequence of requirements against a shared, partially replenished reserve, and the reserve needed for each requirement is monotonic across the processing order, it suffices to verify the single extremal requirement rather than checking every step; this recurs across scheduling and resource allocation constructions generally, not only here. See Book 1, field: Sequences and recurrences, topic: extremal case verification.

Circuit Bank

- **WHEN** a move or operation is legal only once a counter's current value crosses a threshold tied to its own label or index **DO** compute the total achievable while every threshold simultaneously fails, and compare it to the actual total **BECAUSE** if the actual total exceeds that capacity, some threshold must be exceeded somewhere at all times, which seeds both the impossibility bound below the capacity and the construction above it
- **WHEN** a construction needs to move an arbitrary, exact amount out of a structure whose native move sizes are coarse and tied to position **DO** find the one component whose native move size is the smallest possible, typically 1, and route everything through it **BECAUSE**

atomic control only ever exists at the finest native step size, so any construction with an exact numerical target has no alternative to funnelling through that component

- **WHEN** a multi phase construction repeatedly borrows from a shared reserve before repaying it **DO** check the reserve's sufficiency only at the single worst case, largest debt, earliest in the processing order, rather than summing every phase **BECAUSE** when the required bound is monotonic across the processing order, the extremal case implies every other case for free, and re deriving each phase separately wastes ink

Backtesting

1. First useful cue: the move size at index i is exactly i, not a free choice.
2. Method the expression suggested: a capacity or pigeonhole bound on the configuration where every box sits simultaneously below its own label.
3. Where you would hesitate, and the thought to reinforce: worrying whether B_1 can run out of balls midway through the flush phase; reinforce by checking only the single largest withdrawal against the same capacity inequality that gave the threshold.
4. The trap the question sets: 2010 boxes and an arbitrary n invite a hunt for a residue or colouring invariant that simply is not there, since the real obstruction is a plain counting bound.
5. What makes you recognise it faster next time: any competition problem where a move is described as "exactly" some label dependent amount should trigger the frozen configuration capacity check before anything else.
6. The reusable decision rule: when a move's legality depends on crossing a label tied threshold, compare the actual total to the capacity of the everyone frozen configuration; that comparison typically is the answer.

Mirror drills

1. With 6 boxes $B_1, \ldots, B_6$ and $6n$ balls under the identical move rule, for which n can you always reach n in every box? *Answer:* by the same bound, $\sum_{i=1}^{6}(i-1) = 15 = 6 \times 2.5$, so $n \geq 3$.
2. Redo the setup with 2011 boxes instead of 2010, so that $\sum_{i=1}^{2011}(i-1) = \frac{2010 \times 2011}{2} = 2011 \times 1005$ lands exactly on an integer multiple of the box count. *Answer:* at $n = 1005$ the frozen everywhere configuration is achievable with total exactly 2011×1005, so this boundary value is impossible too, and the threshold is $n \geq 1006$, one more than the naive halving suggests, because an odd box count removes the half integer gap that made 2010 unambiguous.
3. A row of N boxes holds $2N$ balls; the rule is "move exactly 2 balls from any box holding at least 2, into any other box," the same fixed amount regardless of the source box's label. For which starting distributions can you reach 2 balls in every box? *Answer:* exactly those where every box starts with an even number of balls: each move changes a box's count by ± 2, so every box's parity is invariant throughout, ruling out any start with an odd box; when every box starts even, repeatedly moving from a box above target to one at zero terminates at uniformity. This drill checks that removing the label dependence swaps the capacity obstruction for a parity obstruction, it does not remove every obstruction.

16.10 B4. Casoratian equal to one forces linear

Find all pairs of polynomials $p(x)$ and $q(x)$ with real coefficients for which

$$p(x)q(x+1) - p(x+1)q(x) = 1.$$

Read it out loud

Say the left side aloud before you touch a coefficient: p evaluated at x times q evaluated at $x+1$, minus the same product with the roles of p and q swapped. Two structural features are on the surface. The expression is bilinear, linear in p for fixed q and linear in q for fixed p. And it is antisymmetric: swap p and q and the whole thing changes sign. Bilinear and antisymmetric in two arguments is the definition of a 2×2 determinant, so inside thirty seconds you should have written

$$p(x)q(x+1) - p(x+1)q(x) = \det \begin{pmatrix} p(x) & p(x+1) \\ q(x) & q(x+1) \end{pmatrix} = 1.$$

That is not decoration. The instant the expression is a determinant you own a free move: adding a constant multiple of one row to the other does not change the value.

Read the columns next. They are the same two polynomials evaluated at x and at $x+1$, so the forward shift is wired into the question, not the derivative. This object has a name. It is the Casoratian of p and q, the discrete Wronskian, the exact analogue of $pq' - p'q$ with the derivative replaced by the shift. The fields embedded here are polynomial algebra, finite differences, and one line of 2×2 linear algebra. There is no analysis in this problem and you should refuse to import any.

What is really being tested is two reflexes. First, can you run a degree count on an expression whose top term cancels for free? The coefficient of x^{m+n} on the left is $p_m q_n - p_m q_n = 0$ automatically, so all of the information sits one degree down, at x^{m+n-1}, and you must compute that coefficient in general rather than in examples. Second, do you remember that the one configuration which kills a leading coefficient argument, namely $\deg p = \deg q$, is exactly the configuration a row operation dissolves? The problem is built out of that pairing.

One more free line before you start. The right side is a nonzero constant, so neither p nor q is the zero polynomial, and any common polynomial factor of p and q divides 1, hence $\gcd(p, q) = 1$. Record it. You will not need it on the winning route, but it is the fuel for the second best route and it costs nothing.

Approaches, ranked worst to best

1. **Guess the linear family and stop.** *Cue:* the equation looks as though only small solutions can survive. *Circuit:* pattern matching with no exclusion. Substituting $p = ax + b$, $q = cx + d$ takes one line and returns $bc - ad = 1$. That is the correct family and it is worth close to nothing, because the command term is *find all*. A family with no proof that nothing else works is a conjecture, and the Putnam pays for classification, not for examples.

2. **Full coefficient comparison.** *Cue:* a polynomial identity, so expand and equate coefficients. *Circuit:* binomial expansion of $p(x+1)$ and $q(x+1)$, then a descending induction on the minors $p_i q_j - p_j q_i$. This does close. The coefficient of x^k on the left is a double sum of binomial differences multiplied by the 2×2 minors $p_i q_j - p_j q_i$, and a descending induction shows every minor vanishes, which makes p and q proportional and the left side zero. Cost: a page of indices for a problem whose answer is two lines. It ranks low not because it is wrong but because ink is time and every index is an error site.

3. **Telescoping the ratio.** *Cue:* divide by $q(x)q(x+1)$ and a difference of a rational function appears. *Circuit:* convert to $\frac{p(x)}{q(x)} - \frac{p(x+1)}{q(x+1)} = \frac{1}{q(x)q(x+1)}$ and telescope over the integers. Informative but overweight. If $\deg q \geq 1$ the right side is summable, so $p(N)/q(N)$ converges as N runs through the integers, which forces $\deg p \leq \deg q$, and antisymmetry gives the reverse. You get $\deg p = \deg q$ cheaply, and then you still have to break the tie. You also imported convergence into a problem that is pure algebra, which is the wrong kind of borrowing.

4. **Shift and subtract.** *Cue:* the identity holds for every x, so it also holds at $x-1$. *Circuit:* eliminate the mixed terms by subtracting two instances, then run coprimality against a degree count. Subtracting the instance at $x-1$ from the instance at x gives $p(x)\big(q(x+1)+q(x-1)\big) = q(x)\big(p(x+1)+p(x-1)\big)$. Since $\gcd(p,q) = 1$, p divides $p(x+1)+p(x-1)$; that quotient has degree 0 and leading coefficient 2, so $p(x+1)+p(x-1) = 2p(x)$, the second difference of p vanishes, and p is linear. A first class route. It costs one extra idea (coprimality) and one extra object (the second difference) compared with the winner.

5. **Casoratian row reduction.** *Cue:* the left side is a determinant, and a determinant only ever needs a degree count plus a row operation. *Circuit:* compute the first surviving coefficient in general, then use invariance under a row operation to force the degrees apart. One lemma, one line of algebra, no induction, no divisibility, and it explains the answer rather than merely confirming it. This is the route to install.

The ideal solution

Write $D(p,q)(x) = p(x)q(x+1) - p(x+1)q(x)$ for the Casoratian of the pair.

Lemma 16.10.1. *Let p and q be nonzero polynomials of degrees m and n with leading coefficients p_m and q_n, and suppose $m+n \geq 1$. Then* $\deg D(p,q) \leq m+n-1$, *and the coefficient of x^{m+n-1} in $D(p,q)$ equals $(n-m)p_m q_n$.*

Proof. Write $p(x) = p_m x^m + p_{m-1}x^{m-1} + \cdots$ and $q(x) = q_n x^n + q_{n-1}x^{n-1} + \cdots$. Expanding the shift, $q(x+1) = q_n x^n + (nq_n + q_{n-1})x^{n-1} + \cdots$ and $p(x+1) = p_m x^m + (mp_m + p_{m-1})x^{m-1} + \cdots$, since only the top two terms of a binomial expansion can reach degree $n-1$ or $m-1$. Hence the coefficient of x^{m+n} in $D(p,q)$ is $p_m q_n - p_m q_n = 0$, and the coefficient of x^{m+n-1} is

$$\big(p_m(nq_n + q_{n-1}) + p_{m-1}q_n\big) - \big((mp_m + p_{m-1})q_n + p_m q_{n-1}\big) = (n-m)p_m q_n. \qquad \square$$

Lemma 16.10.2. *For every real constant t, $D(p,\, q - tp) = D(p,q)$.*

Proof. Expanding, $D(p, q-tp) = D(p,q) - t\big(p(x)p(x+1) - p(x+1)p(x)\big) = D(p,q)$. $\square$

Now suppose $D(p,q) = 1$ identically. Neither p nor q is the zero polynomial, since D would then be identically zero. Put $m = \deg p$ and $n = \deg q$.

Suppose first $m = n$. Set $t = q_n/p_m$ and $q_1 = q - tp$. By Lemma 2, $D(p,q_1) = 1$, so q_1 is not the zero polynomial, and by construction its leading term has been cancelled, so $n_1 := \deg q_1 < m$. Apply Lemma 1 to the pair (p,q_1), whose degrees are now different. Since $n_1 \neq m$ and $p_m \neq 0$ and the leading coefficient of q_1 is nonzero, the coefficient of x^{m+n_1-1} in $D(p,q_1)$ is nonzero, provided $m+n_1 \geq 1$. As $D(p,q_1) = 1$ has degree 0, this forces $m+n_1-1 = 0$, that is $m+n_1 = 1$. Note $m+n_1 = 0$ is impossible: it would mean $m = n_1 = 0$, and two nonzero constants have $D = 0$. From $m+n_1 = 1$ with $n_1 < m$ we get $m = 1$ and $n_1 = 0$, so $m = n = 1$.

Suppose instead $m \neq n$. Then $m+n \geq 1$, and Lemma 1 gives $\deg D(p,q) = m+n-1$ exactly, so $m+n = 1$ and $\{m,n\} = \{0,1\}$.

In both cases $\deg p \leq 1$ and $\deg q \leq 1$. Write $p(x) = ax+b$ and $q(x) = cx+d$ with a,b,c,d real, allowing a or c to vanish. Then

$$D(p,q) = (ax+b)\big(c(x+1)+d\big) - \big(a(x+1)+b\big)(cx+d)$$

$$= \big(acx^2 + (ac + ad + bc)x + bc + bd\big) - \big(acx^2 + (ac + ad + bc)x + ad + bd\big)$$
$$= bc - ad,$$

a constant. So the identity holds precisely when $bc - ad = 1$, and every such pair does satisfy it. The complete answer is

$$\boxed{p(x) = ax + b, \quad q(x) = cx + d, \quad bc - ad = 1}$$

with $a, b, c, d \in \mathbb{R}$. Equivalently, $\det \begin{pmatrix} p(0) & p(1) \\ q(0) & q(1) \end{pmatrix} = 1$: for polynomials of degree at most 1, the single instance of the identity at $x = 0$ already implies all the others.

Layer 1: WHAT

Block 1. Name the left side as the determinant of the 2×2 matrix with rows $\big(p(x), p(x+1)\big)$ and $\big(q(x), q(x+1)\big)$.

Block 2. Degree count in general: the x^{m+n} coefficient cancels for free, and the coefficient of x^{m+n-1} is $(n - m)p_m q_n$.

Block 3. Consequence: if $\deg p \neq \deg q$ then the Casoratian has degree exactly $m + n - 1$, so being equal to 1 forces $m + n = 1$.

Block 4. The blocked case $\deg p = \deg q$ is not a case, it is a degeneracy: a row operation $q \mapsto q - tp$ leaves the determinant untouched and strictly drops the degree, sending you back into Block 3.

Block 5. Both degrees are at most 1; substitute and read off $bc - ad = 1$; verify the family.

The nominal route splits from this at Block 1. The zombie move is to expand $p(x)q(x+1)$ and $p(x+1)q(x)$ in coordinates, collect the coefficient of x^k, and start comparing. That route is not wrong, it is expensive, and its expense is entirely caused by refusing to name what the expression is. The bifurcation point is the very first line you write: either you write out $\sum_i \sum_j$ with binomial coefficients, or you write det. Everything downstream is determined by that choice. Once the word determinant is on the page, you automatically ask the determinant question, which is not what are the coefficients but which operations preserve the value, and the answer to that question is the whole solution.

Layer 2: HOW

Block 1. Cue. Bilinear in p and q, and antisymmetric under swapping them. In A-level Further Maths you met exactly one bilinear antisymmetric gadget on pairs, the 2×2 determinant, and it is defined by those two properties together with its value on the identity. **Why natural.** Naming an expression by its structural type is not cosmetic. A determinant carries a group of symmetries with it (row operations, transposition, multilinearity), and symmetries are free information. An unnamed polynomial expression carries nothing. **Link to the next block.** Once it is a determinant you want to normalise the rows, but before normalising you must know what quantity the rows control. That quantity is degree, so you count degrees next.

Block 2. Cue. The identity is pinned to a constant, and constants are the degree 0 objects. Any argument that controls the degree of the left side finishes the problem, so compute the degree. **Why natural.** The natural first attempt, look at the top coefficient, dies immediately because the top coefficient is $p_m q_n - p_m q_n = 0$. That death is the signal, not a setback: whenever an antisymmetric combination annihilates its own leading term, the first surviving coefficient is where the content lives, so you compute it in full generality. This is a general habit: in any expression built to cancel, differentiate your attention one order down. **Link to the next block.** The formula $(n - m)p_m q_n$ has a visible zero set. It vanishes exactly when $m = n$. So the degree count settles everything except one case, and you now know precisely which case to attack.

Block 3. Cue. A nonzero coefficient at x^{m+n-1} pins the degree of the left side to $m+n-1$, and the right side has degree 0. **Why natural.** This is the cheapest kind of argument on the Putnam: an equation between polynomials is an equation between degrees first. You get $m+n=1$, so one of the two polynomials is a nonzero constant and the other is genuinely linear. **Link to the next block.** The only gap left is $m=n$. You do not attack it head on; you remember from Block 1 that you are holding a determinant.

Block 4. Cue. Equal leading degrees plus a determinant is the classic setup for row reduction. This is the first step of Gaussian elimination and the first step of the Euclidean algorithm, and both are triggered by the same cue: two objects with the same leading behaviour. **Why natural.** The row operation $q \mapsto q - tp$ with t constant leaves D unchanged, because the correction term is $t\,p(x)p(x+1)$ in both products and cancels. It is essential that t is constant: with a polynomial multiplier $r(x)$ the correction is $p(x)p(x+1)\big(r(x+1)-r(x)\big)$, which survives unless r is constant. That is why this is one row operation, not a full Euclidean descent. **Link to the next block.** Killing the leading term drops $\deg q$ strictly, which places you back in Block 3, and Block 3 then forces $\deg p = 1$.

Block 5. Cue. Both degrees are at most 1, so the whole problem is now four unknown real numbers and one identity. **Why natural.** At this point substitution is the correct move, not a fallback. Substituting into a bounded, tiny parametrisation is honest work; substituting into an unbounded family of coefficients was the zombie route. The verification also matters for marks: you must show the family really does satisfy the identity, since *find all* demands both inclusions. **Link to the next block.** Nothing follows; the classification is complete. Finish by noticing the answer is the determinant of the values at 0 and 1, which is the cleanest form to remember.

Layer 3: WHY

The mathematical truth underneath is that D is an alternating bilinear form on the vector space of polynomials, twisted by the shift. Alternating forms have a fixed behaviour you can rely on. They vanish on proportional pairs, they are unchanged when you add a multiple of one argument to the other, and they lose the top order term of any naive size estimate. All three of those facts were used, and none of them required knowing anything about p and q beyond their degrees.

The second truth is the degree formula $(n-m)p_m q_n$, and it deserves a moment. It says the Casoratian of two polynomials of the same degree is smaller than you would expect, and it is exactly this drop that permits nonzero constant Casoratians to exist at all. If the coefficient had been, say, $p_m q_n$ with no factor $(n-m)$, the answer to the problem would have been that no pairs exist. So the entire solution set of the problem is created by one degeneracy, and the row operation is the tool that measures how deep the degeneracy goes. The same phenomenon runs the continuous analogue: for the Wronskian, the coefficient of x^{m+n-1} in $pq' - p'q$ is again $(n-m)p_m q_n$, and the classification of $pq' - p'q = 1$ is again $p = ax+b$, $q = cx+d$ with $bc - ad = 1$. If you learn one of the two you have learned both.

The discernment mechanism, the thing that decides the route before you compute anything, is this: classify the expression by its symmetry type, then use the symmetry group as your move list. Antisymmetric in two objects means determinant means row operations. Symmetric in two objects means elementary symmetric polynomials means Newton or Vieta. Invariant under a shift means finite differences or periodicity. You are not searching for a clever idea; you are looking up which move list the structure hands you. To train it, take any competition expression and before solving it, write one line naming its symmetry type and one line naming the associated move list. That drill is fast, it is boring, and it is the difference between seeing the determinant in ten seconds and never seeing it.

The examiners nudged in three ways and you should be able to name all three. They wrote $q(x+1)$ rather than $q(y)$, which plants the shift. They put a nonzero constant on the right rather than 0, which plants coprimality and rules out the proportional pairs. And they asked for pairs of polynomials, which plants a two row object. A question asking for a single polynomial would not have had a determinant in it.

Revolving concepts

Casoratian (discrete Wronskian). For functions f, g define $C(f,g)(x) = f(x)g(x+1) - f(x+1)g(x)$. It is bilinear and alternating, it satisfies $C(f, g+tf) = C(f,g)$ for constant t, and for polynomials it vanishes identically if and only if p and q are proportional. That last claim is worth proving once: if $C(p,q) = 0$ then $p(x)q(0) - p(0)q(x)$ vanishes at every integer, since p/q is unchanged by the shift, so the polynomial $p(x)q(0) - p(0)q(x)$ has infinitely many roots and is identically zero. See Book 1, field: Polynomials, topic: Casoratian and Wronskian.

Second order linear recurrences and the Casoratian identity. If two sequences f_k and g_k both satisfy $u_{k+1} = \alpha_k u_k + \beta_k u_{k-1}$, then their Casoratian $C_k = f_k g_{k+1} - f_{k+1} g_k$ satisfies the first order recursion $C_{k+1} = -\beta_k C_k$, hence

$$C_k = C_0 \prod_{j=0}^{k-1} (-\beta_j).$$

This is the generalised recursion behind the problem: a constant Casoratian is exactly the case $\beta_j = -1$ for all j, and an alternating Casoratian is the case $\beta_j = 1$, which is the Fibonacci recursion and gives the Cassini identity $F_{k+1}F_{k-1} - F_k^2 = (-1)^k$. Whenever you meet a bilinear alternating combination of two solutions of the same linear recursion, compute how it transforms in one step; it always satisfies a first order recursion, which you can always solve as a product. See Book 1, field: Sequences and recurrences, topic: second order linear recurrences.

Finite differences. $\Delta f(x) = f(x+1) - f(x)$ lowers the degree of a polynomial by exactly one, so $\Delta^{k+1} p = 0$ if and only if $\deg p \le k$. The relation $p(x+1) + p(x-1) = 2p(x)$ that appears on the shift and subtract route is exactly $\Delta^2 p = 0$ evaluated one step back, hence p is linear. The general expansion is Newton's forward difference formula $p(x) = \sum_{k \ge 0} \Delta^k p(0) \binom{x}{k}$, the discrete Taylor series, which terminates for polynomials. See Book 1, field: Polynomials, topic: finite differences.

Coprimality and Bezout in $\mathbb{R}[x]$. $\mathbb{R}[x]$ is a Euclidean domain, so gcd exists and $\gcd(p,q) = 1$ if and only if $up + vq = 1$ for some polynomials u, v. Our identity is literally a Bezout relation with $u(x) = q(x+1)$ and $v(x) = -p(x+1)$, which is why the problem feels like a unimodularity condition. See Book 1, field: Polynomials, topic: Euclidean algorithm and Bezout.

Unimodular pairs. For integers, $bc - ad = 1$ is membership of $SL_2(\mathbb{Z})$ and is the engine behind continued fractions, Farey neighbours and the Stern and Brocot tree. The polynomial statement here is the same condition read one level up: the pair (p,q) is a unimodular pair for the shift. See Book 1, field: Matrices and determinants, topic: unimodular matrices.

Circuit Bank

- **WHEN** an expression is bilinear and antisymmetric in two objects **DO** write it as a 2×2 determinant and immediately list the operations that preserve it **BECAUSE** a determinant hands you a free normalisation, and normalising is always cheaper than computing
- **WHEN** the leading coefficient of an expression cancels identically **DO** compute the next coefficient in full generality, with letters, not examples **BECAUSE** a structure built to cancel stores all of its information in the first surviving coefficient
- **WHEN** a degree count is blocked only by the equal degree case **DO** use a row operation or a subtraction of leading terms to break the tie **BECAUSE** equal leading behaviour is a degeneracy to dissolve, not a case to fight

- **WHEN** a polynomial identity equals a nonzero constant **DO** write down at once that neither polynomial is zero and that they are coprime **BECAUSE** any common factor divides the constant, and this line is free
- **WHEN** a relation says a second difference or second derivative vanishes **DO** conclude the object is linear and stop **BECAUSE** $\Delta^2 p = 0$ and $p'' = 0$ each characterise degree at most one

Backtesting

1. First useful cue: the left side changes sign when p and q are swapped, and it is linear in each, so it is a 2×2 determinant with columns indexed by x and $x+1$.
2. Method the expression suggested: control the degree of the determinant, then remove the one obstruction to that control with a row operation.
3. Where you would hesitate, and the thought to reinforce: at the case $\deg p = \deg q$, where the leading coefficient argument dies. Reinforce this: the death of a leading coefficient argument at equal degrees is the standard prompt for elimination, in Gaussian elimination, in the Euclidean algorithm, and here.
4. The trap the question sets: *find all* invites you to produce the linear family from a one line substitution and feel finished. Producing the family is worth almost nothing; excluding everything else is the whole problem.
5. What makes you recognise it faster next time: the phrase Casoratian. Say it out loud when you see $f(x)g(x+1) - f(x+1)g(x)$, and the whole theory of alternating forms and second order recurrences arrives with it.
6. The reusable decision rule: classify by symmetry type first, then use the symmetry group as your move list, and only then compute.

Mirror drills

1. Find all pairs of real polynomials with $p(x)q'(x) - p'(x)q(x) = 1$. *Answer:* the same family, $p = ax + b$, $q = cx + d$ with $bc - ad = 1$. The degree lemma is identical: the coefficient of x^{m+n-1} in $pq' - p'q$ is $(n-m)p_m q_n$, and $q \mapsto q - tp$ again preserves the form.
2. Prove that $p(x)q(x+1) - p(x+1)q(x) = 0$ identically forces p and q to be proportional. *Answer:* the relation says p/q is invariant under the shift, so $p(x)q(0) - p(0)q(x)$ vanishes at every integer, hence identically.
3. Let f_k and g_k both satisfy $u_{k+1} = u_k + u_{k-1}$. Show $f_k g_{k+1} - f_{k+1} g_k$ alternates in sign with constant modulus, and deduce Cassini's identity $F_{k+1}F_{k-1} - F_k^2 = (-1)^k$. *Answer:* substituting the recursion gives $C_{k+1} = -C_k$; take $f_k = F_{k-1}$, $g_k = F_k$ and evaluate at $k = 1$.

16.11 B5. Iterative differential equation has no increasing solution

Is there a strictly increasing function $f : \mathbb{R} \to \mathbb{R}$ such that $f'(x) = f(f(x))$ for all x?

Read it out loud

This is a differential equation in which the right side is not a function of x and $f(x)$ in the usual sense. The unknown appears at two different arguments at once, at x on the left and at $f(x)$ on the right. That is an iterative differential equation, and the single sentence that describes it is: the growth rate of f at a point equals the value of f at the point f has already reached. It is self referential, and self reference is the whole content. Nothing in the standard toolkit of separable, linear, integrating factor or exact equations touches it, so do not reach for any of them.

The question is a yes or no existence question, so the first two minutes belong to scouting, not to proving. Push the three standard shapes through the relation. Linear: $f = ax + b$ gives $a = a^2x + ab + b$ for all x, so $a^2 = 0$, so $a = 0$ and then $b = 0$; the only linear solution is the zero function, which is not strictly increasing. Power law on a ray: $f = cx^\beta$ gives $c\beta x^{\beta-1} = c^{1+\beta}x^{\beta^2}$, which needs $\beta^2 = \beta - 1$; the discriminant is $1 - 4 = -3$, so there is no real exponent. Exponential: $f = ce^{kx}$ gives $cke^{kx} = ce^{kce^{kx}}$, a double exponential against a single one, impossible. Three natural shapes, three failures, and the middle failure is structural: the exponent equation $\beta^2 = \beta - 1$ is the golden ratio equation with the sign flipped and it has no real root. That is your evidence. Commit to proving the answer is no.

The fields embedded are monotonicity, differentiability and convexity on the real line, plus comparison for a first order differential inequality. What is really tested is bootstrapping: taking a relation you cannot solve and squeezing consequences out of it until one of them is impossible. Within thirty seconds you should have written three free facts. f strictly increasing gives $f' \geq 0$. The right side $f \circ f$ is a composition of increasing functions, hence increasing, so f' is increasing and f is convex. And f' increasing with $f' \geq 0$ gives $f'(x) > f'(x-1) \geq 0$, so $f' > 0$ everywhere. You are already holding a convex, strictly increasing function whose derivative is positive, and you have used nothing but the words in the question.

Approaches, ranked worst to best

1. **Keep hunting for a solution.** *Cue:* the question says is there, so try to build one. *Circuit:* ansatz search over the standard function library. Useful for sixty seconds as scouting and worthless after that. A failed search proves nothing, and the marks are all in the exclusion. If you are still substituting shapes at minute ten you have misread the command term.

2. **Monotonicity bookkeeping with no engine.** *Cue:* f is increasing, so collect sign facts. *Circuit:* convexity, fixed point chasing, tangent line bounds. You will correctly get $f' > 0$, f convex, f above its tangents. Then you stall, because none of those facts is quantitative enough to contradict anything: convex increasing functions exist in abundance. The lesson is that sign information alone never closes an existence problem; you need a rate.

3. **The bound $f(x) \leq x + 1$ by case analysis.** *Cue:* f convex means f lies above a tangent line, and $f' = f(f(x))$ ties that line back to f. *Circuit:* tangent line bound, then a two case argument on whether $f(x_0) < x_0$. This closes and it is the official first route: from $f(x_0) = b$ and $f'(x_0) = a > 0$ you get $f(x) \geq a(x - x_0) + b$, and feeding that back at the point b forces $f(x_0) \leq x_0 + 1$, hence $f' = f \circ f \leq 1$, which then contradicts the linear lower bound. Correct, and it costs a case split that is easy to garble in the arena.

4. **Invert the function.** *Cue:* f is strictly increasing, so it has an inverse. *Circuit:* differentiate $x = g(f(x))$ to get $g'(y) = 1/f(y)$, then compare integrals. Attractive, because $g' = 1/f$ converts the whole problem into the convergence of $\int^\infty dy/f(y)$: since g is unbounded above

on the range, that integral must diverge, so f cannot grow too fast. But to finish you still need a lower bound on the growth of f, which is the work of the winning route. It is the winner plus one extra layer.

5. **Differentiate, bootstrap the growth, then blow up.** *Cue:* the relation defines f', so it can be differentiated for free, and the chain rule turns the composition into a product of two positive increasing factors. *Circuit:* regularity bootstrap, then integrate a positive second derivative twice, then compare against $y' = \alpha y^2$. One direction, no case splits, and every step is a move you already own. This is the route to install.

The ideal solution

The answer is no: no such function exists. Suppose, for contradiction, that $f : \mathbb{R} \to \mathbb{R}$ is strictly increasing and satisfies $f'(x) = f(f(x))$ for all x.

Step 1: $f' > 0$ everywhere. Since f is strictly increasing and differentiable, $f' \geq 0$. Since f is strictly increasing, so is the composition $f \circ f$, and $f \circ f = f'$, so f' is strictly increasing. Hence for every x we have $f'(x) > f'(x-1) \geq 0$.

Step 2: f is twice differentiable, with f'' positive, continuous and increasing. The relation $f' = f \circ f$ exhibits f' as a composition of differentiable functions, so f' is differentiable and the chain rule gives

$$f''(x) = f'\big(f(x)\big)\, f'(x).$$

Both factors are positive by Step 1, so $f'' > 0$. Both factors are also increasing: f' is increasing by Step 1, and $f' \circ f$ is increasing as a composition of increasing functions. A product of two positive increasing functions is increasing, so f'' is increasing. It is continuous because $f' = f \circ f$ is continuous and f'' is a product of continuous functions.

Step 3: quadratic growth. Put $\alpha = f''(0)/4 > 0$, so $f''(x) \geq 4\alpha$ for all $x \geq 0$. Integrating the continuous function f'' from 0 to x gives, for $x \geq 0$,

$$f'(x) = f'(0) + \int_0^x f''(t)\, dt \geq f'(0) + 4\alpha x,$$

and integrating once more,

$$f(x) \geq f(0) + f'(0)x + 2\alpha x^2 \qquad (x \geq 0).$$

The difference $\big(f(0) + f'(0)x + 2\alpha x^2\big) - \alpha x^2 = \alpha x^2 + f'(0)x + f(0)$ is a quadratic with positive leading coefficient, so it is nonnegative for all sufficiently large x. Fix $M \geq 0$ with

$$f(x) \geq \alpha x^2 \qquad \text{for all } x \geq M.$$

Step 4: feed the growth back into the relation. Choose $T \geq M$ with $\alpha T^2 \geq M$; this is possible since $\alpha T^2 \to \infty$. For $x \geq T$ we have $f(x) \geq \alpha x^2 \geq \alpha T^2 \geq M$, so the bound of Step 3 may be applied at the point $f(x)$ itself:

$$f'(x) = f\big(f(x)\big) \geq \alpha f(x)^2 \qquad (x \geq T).$$

Also $f(x) \geq \alpha T^2 > 0$ for $x \geq T$, so $1/f$ is defined and differentiable there.

Step 5: the differential inequality has no global solution. For $x \geq T$,

$$\frac{d}{dx}\left(\frac{-1}{f(x)}\right) = \frac{f'(x)}{f(x)^2} \geq \alpha.$$

Integrating from T to x,

$$\frac{1}{f(T)} - \frac{1}{f(x)} \geq \alpha(x - T) \qquad (x \geq T).$$

Since $1/f(x) > 0$, the left side is strictly less than $1/f(T)$, so

$$\alpha(x - T) < \frac{1}{f(T)} \qquad \text{for every } x \geq T,$$

which is false as soon as $x > T + \dfrac{1}{\alpha f(T)}$. This contradiction shows no such f exists. The answer to the question is $\boxed{\text{no}}$.

Layer 1: WHAT

Block 1. Scout with the three standard shapes, notice the exponent condition $\beta^2 = \beta - 1$ has no real root, and commit to proving nonexistence.

Block 2. Harvest the free monotonicity: $f' \geq 0$, then $f' = f \circ f$ is increasing, then $f' > 0$.

Block 3. Differentiate the relation. The chain rule gives $f'' = f'(f)\, f' > 0$ and increasing, so the equation upgrades its own regularity and its own sign information.

Block 4. Integrate the bound $f'' \geq 4\alpha$ twice from a fixed base point to obtain $f(x) \geq \alpha x^2$ for large x.

Block 5. Substitute that growth back into the original relation at the point $f(x)$, obtaining $f' \geq \alpha f^2$ on a ray.

Block 6. Kill $f' \geq \alpha f^2$ by integrating $(-1/f)' \geq \alpha$: the left side stays negative while the right side grows without bound.

The nominal route is to treat this as a differential equation to be solved: separate variables (impossible, the right side is not a function of $f(x)$ alone in the required sense), try a power series about 0 (the coefficients of $f \circ f$ tangle instantly), or hunt for a closed form. The bifurcation point is the line where you stop asking what f is and start asking what f must satisfy. Concretely it is the decision to differentiate the relation in Block 3. Differentiating an equation you cannot solve feels wrong to a beginner, because differentiation usually makes things harder. Here it makes things easier, because the right side is a composition and the chain rule turns a composition into a product, and products of positive increasing things are positive and increasing. You are trading solvability for sign information, and sign information is what kills existence questions.

Layer 2: HOW

Block 1. **Cue.** The command term is is there, not find. That is a yes or no question, and on a yes or no question the first job is to decide which way to commit, cheaply. **Why natural.** Substituting the three standard shapes is the cheapest possible experiment, and their failure modes are informative rather than blank. The power law forces $\beta^2 = \beta - 1$, an honest quadratic with negative discriminant, so the failure is not an accident of the family; it is a real obstruction living in the exponents. **Link to the next block.** Having committed to no, you need a contradiction, and contradictions in analysis come from quantities that are forced to grow while being forced to stay bounded. So you start collecting growth information.

Block 2. **Cue.** Strictly increasing is a hypothesis, and every hypothesis is free information you must bank before working. **Why natural.** $f' \geq 0$ is immediate. The move worth naming is the next one: since f is increasing, $f \circ f$ is increasing, and the relation says $f \circ f$ *is* f'. So the equation itself upgrades monotonicity of f into monotonicity of f', which is convexity. Then $f'(x) > f'(x - 1) \geq 0$ upgrades a weak inequality into a strict one at no cost, and strictness matters because you will divide by f later. **Link to the next block.** Convexity is qualitative. To get a rate you need a second derivative, and the relation is begging to be differentiated because its right side is a composition of differentiable functions.

Block 3. **Cue.** The relation defines f' explicitly as $f \circ f$, and f is differentiable, so f' is differentiable. Any equation that expresses a derivative in terms of differentiable data can be differentiated again, and doing so is free. **Why natural.** The chain rule converts the composition into the product $f'(f(x))f'(x)$. Sign information multiplies well: positive times positive is positive, increasing times increasing is increasing when both are positive. So one differentiation turns a qualitative statement about f into a quantitative floor on f'', namely $f''(x) \geq f''(0) > 0$ for $x \geq 0$. This is the general phenomenon of regularity bootstrap: an equation of the form $f' = \Phi(f)$ with Φ smooth forces f to be smooth, one derivative at a time. **Link to the next block.** A positive floor on f'' is exactly what integrates into a growth rate, so integrate twice.

Block 4. **Cue.** A constant lower bound on a continuous second derivative on a ray. There is only one move: integrate, twice, from a fixed base point. **Why natural.** Integration converts pointwise sign information into global size information, which is the currency of contradiction arguments. Note the choice of base point 0: any fixed point works, and choosing one immediately avoids all the case analysis that the alternative routes carry. Note also that α is defined as $f''(0)/4$ and not as some abstract constant; you want the quadratic coefficient to be 2α so that after absorbing the linear and constant terms you are left with the clean statement $f(x) \geq \alpha x^2$. **Link to the next block.** You now have a growth rate for f. The relation $f' = f \circ f$ evaluates f at $f(x)$, and $f(x)$ is large when x is large, so the growth rate can be applied a second time, at the inner point.

Block 5. **Cue.** The right side of the relation is f evaluated at $f(x)$, and you have just proved a lower bound for f valid on a ray. Any bound valid on a ray can be applied at any point that lies in the ray, and $f(x)$ does lie there once x is large. **Why natural.** This is the self reference finally working for you rather than against you. The composition, which made the equation unsolvable, is exactly what lets you apply the growth bound twice and square it. The single technical care needed is to choose T so that $f(x) \geq M$, which is why T is chosen with $\alpha T^2 \geq M$, not merely $T \geq M$. **Link to the next block.** You now hold $f' \geq \alpha f^2$ on a ray with $f > 0$, which is a Riccati type differential inequality, and those are lethal.

Block 6. **Cue.** The inequality $y' \geq \alpha y^2$ with $y > 0$. This is the standard blow up template and it has a standard one line kill. **Why natural.** Divide by y^2 and recognise the left side as the derivative of $-1/y$. Integrating a lower bound on a derivative gives a lower bound on the increment, and the increment of $-1/y$ is bounded above by $1/y(T)$ because $-1/y$ is negative throughout. A bounded quantity forced to increase at a constant rate forever is the contradiction. Notice what is not needed: no ODE existence theory, no comparison theorem quoted from a book, no explicit solution. The substitution $y \mapsto -1/y$ is the entire content of the finite time blow up of $y' = \alpha y^2$. **Link to the next block.** Contradiction reached, so the supposed f does not exist and the answer is no.

Layer 3: WHY

The mathematical truth beneath this problem is that superlinear feedback cannot live on the whole line. Write the relation as: the rate of increase of f equals f evaluated further along its own graph. If f ever grows faster than linearly, then $f(x)$ is far to the right of x, so $f(f(x))$ is much larger than $f(x)$, so f' is much larger than f, so f grows even faster. The loop is unstable, and the precise form of the instability is $y' \geq \alpha y^2$, whose solutions satisfy $\frac{1}{y(T)} - \frac{1}{y(x)} \geq \alpha(x - T)$ and therefore cease to exist beyond $x = T + \frac{1}{\alpha y(T)}$. The general principle is Osgood's criterion: for $y' \geq g(y)$ with g positive, the solution blows up in finite time whenever $\int^{\infty} \frac{dy}{g(y)}$ converges. With $g(y) = \alpha y^2$ that integral converges, so the domain $\mathbb{R}$ demanded by the problem is impossible. Everything else in the solution exists only to prove that the feedback really is superlinear.

The second truth is the bootstrap. An equation of the form $f' = \Phi(f)$ where Φ is built from f itself is not an obstacle to regularity, it is a machine for producing it: f differentiable gives f' differentiable gives f twice differentiable, and by induction f is infinitely differentiable. Each differentiation also multiplies sign information, because the chain rule produces products, and products of positive increasing factors are positive and increasing. So the two things this equation is generous with are smoothness and signs, and the ideal solution spends both.

The discernment mechanism is a two question filter you should run on every existence question in analysis. Question one: can I solve it? If the unknown appears at more than one argument, or inside itself, the answer is essentially always no, and you must stop trying within a minute. Question two: what does the equation force in the limit? Existence on all of $\mathbb{R}$ is a strong hypothesis and it is usually the hypothesis that breaks, because equations that are locally harmless are globally lethal. To train the filter, take any functional or differential equation and immediately ask what it says as $x \to +\infty$ and as $x \to -\infty$, before doing anything else. Here the whole difficulty is at $+\infty$, and the diagnostic that told you so is that the right side is f evaluated at a point that runs off to the right.

The examiners nudged in three ways. They asked is there rather than find, which signals a decision problem. They wrote strictly increasing rather than monotone or continuous, which hands you exactly the sign facts needed to start the bootstrap; a weaker hypothesis would have made the problem harder, so the hypothesis is a gift and you must spend it. And they demanded the domain $\mathbb{R}$, all of it, which is the clue that the contradiction is global rather than local. Every one of those three words was placed to point at the route above.

Revolving concepts

Iterative differential equations. An equation in which the unknown is evaluated at an argument depending on the unknown, such as $f'(x) = f(f(x))$, is called an iterative differential equation. It is not an ordinary differential equation: the standard existence and uniqueness theorems do not apply, because the right side is not a function of $(x, f(x))$ in the required sense. The correct handling is the one used here: extract monotonicity, regularity and growth, and argue globally. See Book 1, field: Functional equations, topic: iterative differential equations.

Regularity bootstrap. If f is differentiable and $f' = f \circ f$, then by induction f is of class C^k for every k: assuming $f \in C^k$, the composition $f \circ f$ is C^k, so $f' \in C^k$, so $f \in C^{k+1}$. This is the general recursion in the problem, and the general form is: for $f' = \Phi(f)$ with Φ of class C^∞ on the relevant range, $f \in C^k \Rightarrow f \in C^{k+1}$, hence $f \in C^\infty$. The same induction is how one proves solutions of analytic differential equations are analytic. See Book 1, field: Real analysis, topic: bootstrapping regularity.

Monotonicity and convexity from composition. If u and v are increasing then $u \circ v$ is increasing; if u, v are positive and increasing then uv is increasing. A differentiable f with increasing f' is convex, and a convex function lies above each of its tangent lines, $f(x) \geq f(x_0) + f'(x_0)(x - x_0)$. This tangent line bound is the engine of the alternative route ranked third, and it is worth carrying because it converts a single derivative value into a global linear floor. See Book 1, field: Real analysis, topic: convexity.

Finite time blow up and Osgood's criterion. If y is positive and differentiable on $[T, \infty)$ with $y' \geq \alpha y^2$, then $(-1/y)' \geq \alpha$, so $\frac{1}{y(T)} - \frac{1}{y(x)} \geq \alpha(x - T)$ and hence $x - T < \frac{1}{\alpha y(T)}$, which bounds the domain. More generally, $y' \geq g(y)$ with $g > 0$ and $\int^\infty dy/g(y) < \infty$ forces blow up in finite time, by the same separation of variables. The recursion to remember is the family $y' = y^{1+\varepsilon}$: every $\varepsilon > 0$ blows up, and $\varepsilon = 0$ (linear growth, the exponential) does not. Superlinear is the threshold. See Book 1, field: Real analysis, topic: differential inequalities and blow up.

Inverse function differentiation. If f is strictly increasing and differentiable with $f' > 0$, its inverse g satisfies $g'(y) = 1/f'(g(y))$; combined with $f' = f \circ f$ this gives the clean relation $g'(y) = 1/f(y)$ on the range of f. Since g is unbounded above, $\int^\infty dy/f(y)$ must diverge, which is

a second and independent way to see that f cannot grow quadratically. See Book 1, field: Calculus and integrals, topic: inverse functions.

Circuit Bank

- **WHEN** a relation gives f' explicitly in terms of f composed with itself **DO** differentiate the relation immediately **BECAUSE** the chain rule turns the composition into a product, and products of positive increasing factors keep every sign you already own
- **WHEN** a question asks is there rather than find **DO** spend sixty seconds on linear, power and exponential ansatzes, then commit **BECAUSE** the failure mode of the power ansatz is usually an honest algebraic obstruction that tells you which way to argue
- **WHEN** you hold a constant positive lower bound on a second derivative **DO** integrate twice from a fixed base point **BECAUSE** that is the only mechanism that converts a pointwise sign into a global growth rate, and choosing a base point removes all case analysis
- **WHEN** you reach $y' \geq \alpha y^2$ with $y > 0$ **DO** write $(-1/y)' \geq \alpha$ and integrate **BECAUSE** the increment of $-1/y$ is bounded above by $1/y(T)$, so a constant rate of increase is immediately impossible, and this is the whole proof of finite time blow up
- **WHEN** an existence question specifies the domain $\mathbb{R}$ rather than an interval **DO** look for the contradiction at infinity, not locally **BECAUSE** equations that are harmless locally are frequently lethal globally, and the stated domain is the examiner naming where to look

Backtesting

1. First useful cue: the unknown appears at two arguments, x and $f(x)$, so this cannot be solved and must be attacked by extracting consequences.
2. Method the expression suggested: bank the monotonicity facts, differentiate the relation to get $f'' = f'(f)f' > 0$, integrate twice for quadratic growth, resubstitute to reach $f' \geq \alpha f^2$, and finish with blow up.
3. Where you would hesitate, and the thought to reinforce: at the decision to differentiate an equation you cannot solve. Reinforce this: differentiation is free whenever the right side is differentiable data, and here it converts a composition into a product, which is a strict gain in sign information.
4. The trap the question sets: spending the whole time trying to construct f, or proving only qualitative facts (convex, increasing, positive derivative) and expecting them to contradict something. They never will; you need a rate.
5. What makes you recognise it faster next time: the shape $f' = f \circ f$ is superlinear feedback, and superlinear feedback on all of $\mathbb{R}$ is impossible. Recognise the family $y' \geq \alpha y^2$ on sight.
6. The reusable decision rule: in an existence question about a function on all of $\mathbb{R}$, extract a growth rate first and look for the contradiction at infinity.

Mirror drills

1. Show there is no differentiable $f : \mathbb{R} \to \mathbb{R}$ with $f'(x) = 1 + f(x)^2$ for every real x. *Answer:* $\big(\arctan f(x)\big)' = f'/(1+f^2) = 1$, so $\arctan f(x) - \arctan f(0) = x$ for all x, while the left side is bounded by π.

2. Prove that any differentiable $f : \mathbb{R} \to \mathbb{R}$ with $f' = f \circ f$ is infinitely differentiable. *Answer:* induct: if $f \in C^k$ then $f \circ f \in C^k$, so $f' \in C^k$ and $f \in C^{k+1}$; the base case is $f \in C^1$ because $f' = f \circ f$ is continuous.
3. Let y be positive and differentiable on $[0, \infty)$ with $y' \geq y^{3/2}$. Show no such y exists. *Answer:* $\left(-2y^{-1/2}\right)' = y'y^{-3/2} \geq 1$, so $2y(0)^{-1/2} \geq x$ for every $x \geq 0$, which fails for large x.

16.12 B6. Entrywise powers matching matrix powers forever

Let A be an $n \times n$ matrix of real numbers for some $n \geq 1$. For each positive integer k, let $A^{[k]}$ be the matrix obtained by raising each entry to the kth power. Show that if $A^k = A^{[k]}$ for $k = 1, 2, \ldots, n+1$, then $A^k = A^{[k]}$ for all $k \geq 1$.

Read it out loud

The problem places two rival meanings of the word power side by side. The algebraic power A^k mixes everything: each entry of A^2 is a sum of n products of entries. The entrywise power $A^{[k]}$ mixes nothing at all: the (i, j) entry of $A^{[2]}$ depends only on the (i, j) entry of A and on no other entry. These two operations have essentially nothing in common, and the hypothesis says they agree for the first $n + 1$ exponents while the conclusion says they agree forever. So this is an induction whose base cases are handed to you on a plate, and the entire problem is the single question: what relation propagates them?

Now read the count. The matrix is $n \times n$ and the hypothesis runs to $n + 1$. The theorem that converts the size n into a linear relation among the powers of A is the Cayley and Hamilton theorem: A satisfies its own characteristic polynomial P, which is monic of degree n, so A^n is a fixed real linear combination of $I, A, \ldots, A^{n-1}$. That relation has an I in it, and an I is poison here, because the entrywise operation does not send the constant polynomial 1 to I; it sends it to the matrix of all ones. So you multiply the relation by A and obtain a relation among $A, A^2, \ldots, A^{n+1}$ with no constant term. There is your $n + 1$. The exponent range in the hypothesis is not decoration, it is the examiner writing down the degree of $xP(x)$ and daring you to notice.

The fields embedded are linear algebra (characteristic polynomial, Cayley and Hamilton), polynomial division in $\mathbb{R}[x]$, and linear recursions with constant coefficients. What is really tested is whether you can see both operations as evaluations of a polynomial and then use only the structure the two evaluations share. The matrix evaluation $g \mapsto g(A)$ is a ring homomorphism. The entrywise evaluation is a ring homomorphism too, but for the wrong multiplication (the entrywise product). The single property they share is linearity in g, so every line of the solution must be linear in g, and you are forbidden from multiplying the two sides of anything.

State the knowledge gaps honestly, because this problem is not approachable without them. You must have installed: the characteristic polynomial $P(x) = \det(xI - A)$ for general n and the Cayley and Hamilton theorem for general n (A-level Further Mathematics gives you at most the 2×2 and 3×3 cases, usually as a verification exercise, and that is not enough); division with remainder in $\mathbb{R}[x]$ and the notion of the ideal generated by a polynomial; and the idea that a matrix identity can be read entrywise as n^2 scalar identities. Without Cayley and Hamilton there is no finite linear relation among the powers, and with no finite relation there is no problem, only an infinite family of unrelated equations. Within thirty seconds you should have written $P(x) = x^n + a_{n-1}x^{n-1} + \cdots + a_0$, then $A\,P(A) = 0$, then the observation that $xP(x)$ has degree $n + 1$ and zero constant term.

Approaches, ranked worst to best

1. **Direct entrywise induction.** *Cue:* it is an induction on k, so assume $A^m = A^{[m]}$ and prove the next case. *Circuit:* expand $(A^{m+1})_{ij} = \sum_\ell (A^m)_{i\ell} A_{\ell j}$ and hope. It dies on the first line. The hypothesis gives you $(A^m)_{i\ell} = A^m_{i\ell}$, so the sum becomes $\sum_\ell A^m_{i\ell} A_{\ell j}$, and there is no reason on earth for that to equal A^{m+1}_{ij}. It also uses only one of the $n + 1$ given cases, which is a guarantee that you have misread the question: an unused hypothesis is a misread hypothesis.

2. **Diagonalise and compare spectra.** *Cue:* powers of a matrix are controlled by eigenvalues. *Circuit:* $A = SDS^{-1}$, so $A^k = SD^kS^{-1}$. Two fatal defects. Nothing says A is diagonalisable, and, far worse, the entrywise power is not a spectral object at all: $A^{[k]}$ has no relationship to

the eigenvalues of A. You would be applying a tool to one side of an equation whose other side the tool cannot see.

3. **Classify the matrices satisfying the hypothesis.** *Cue:* understand the objects before proving anything about them. *Circuit:* small case exploration, 2×2 first. As a proof strategy this is a research programme, not a Putnam route, and you would spend the hour on examples. As scouting it is worth two minutes, because the example $A = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$ turns up quickly and it is exactly the object that shows the threshold $n+1$ is sharp. Scout, then leave.

4. **Cayley and Hamilton plus induction on the exponent.** *Cue:* the count $n+1$ names the degree of $xP(x)$. *Circuit:* show every entry is a root of $xP(x)$, then run the same order n recursion on both sides. This is a complete and short solution. Apply the hypothesis to the relation $A\,P(A) = 0$ to learn that every entry t of A satisfies $tP(t) = 0$; then for $m \geq n$ both A^{m+1} and $A^{[m+1]}$ are the same fixed linear combination of the preceding n terms of their own sequences, and induction closes it.

5. **Two evaluation maps agreeing modulo a common ideal.** *Cue:* both sides are the value of a polynomial, read in two different ways. *Circuit:* linearity in the polynomial, plus division with remainder. Identical content to the previous route, but stated so that the induction disappears into one line of polynomial division. It also answers the two questions the induction leaves unanswered: why you must multiply P by x, and why $n+1$ instances and not n. Install this one.

The ideal solution

For a polynomial $g(x) = \sum_{k \geq 0} c_k x^k$ with real coefficients, define two matrices:

$$E(g) = g(A) = \sum_{k \geq 0} c_k A^k, \qquad F(g) = \text{the matrix whose } (i,j) \text{ entry is } g(A_{ij}).$$

Both E and F are linear maps from $\mathbb{R}[x]$ to the space of $n \times n$ real matrices, since each is defined coefficient by coefficient. For $k \geq 1$ we have $E(x^k) = A^k$ and $F(x^k) = A^{[k]}$. They part company only at $k = 0$: $E(1) = I$ while $F(1) = J$, the matrix all of whose entries are 1. For that reason the whole argument is carried out inside

$$x\mathbb{R}[x] = \{\, g \in \mathbb{R}[x] : g(0) = 0 \,\},$$

the polynomials with zero constant term, which is an ideal of $\mathbb{R}[x]$.

Let $V = \operatorname{span}_{\mathbb{R}}\{x, x^2, \ldots, x^{n+1}\}$, the polynomials of degree at most $n+1$ with zero constant term. The hypothesis says $E(x^k) = F(x^k)$ for $k = 1, \ldots, n+1$, so by linearity

$$E(g) = F(g) \qquad \text{for every } g \in V. \tag{1}$$

The conclusion to be proved is that $E(g) = F(g)$ for every $g \in x\mathbb{R}[x]$, since that includes every monomial x^k with $k \geq 1$.

Step 1: every entry of A is a root of $xP(x)$. Let $P(x) = x^n + a_{n-1}x^{n-1} + \cdots + a_0$ be the characteristic polynomial of A. Then $xP(x)$ is a polynomial of degree $n+1$ with zero constant term, so $xP(x) \in V$. By the Cayley and Hamilton theorem $P(A) = 0$, hence

$$E\big(xP(x)\big) = A\,P(A) = 0.$$

By (1), $F\big(xP(x)\big) = 0$ as well. Reading that matrix identity entrywise, for every pair (i,j) and $t = A_{ij}$,

$$t\,P(t) = 0. \tag{2}$$

Step 2: both maps annihilate every multiple of $xP(x)$. Let $I_0 = xP(x)\,\mathbb{R}[x]$, the ideal of multiples of $xP(x)$. For $g = xP(x)h(x)$ we have

$$E(g) = A\,P(A)\,h(A) = 0,$$

because polynomials in A commute and $P(A) = 0$; and the (i,j) entry of $F(g)$ is $t\,P(t)\,h(t) = 0$ by (2). So E and F both vanish on I_0.

Step 3: V and I_0 together span $x\mathbb{R}[x]$. It suffices to show $x^m \in V + I_0$ for every $m \geq 1$. For $m \leq n+1$ this is immediate. For $m \geq n+2$, divide with remainder by the polynomial $xP(x)$, which is monic of degree $n+1$:

$$x^m = Q(x)\,xP(x) + R(x), \qquad \deg R \leq n.$$

The monomial x^m and the product $Q(x)xP(x)$ are both divisible by x, hence so is R, so R is a linear combination of $x, x^2, \ldots, x^n$ and lies in V. Therefore $x^m = Q(x)xP(x) + R(x) \in I_0 + V$.

Step 4: conclude. The map $E - F$ is linear on $\mathbb{R}[x]$, it vanishes on V by (1), and it vanishes on I_0 by Step 2. Hence it vanishes on $V + I_0$, which by Step 3 is all of $x\mathbb{R}[x]$. In particular, for every $k \geq 1$,

$$A^k - A^{[k]} = (E - F)(x^k) = 0,$$

that is, $A^k = A^{[k]}$ for all $k \geq 1$, as required. ■

Remark 16.12.1. The same content in the language of recursions makes the role of the exponent $n+1$ explicit. Cayley and Hamilton gives, for every $m \geq n-1$,

$$A^{m+1} = -a_{n-1}A^m - \cdots - a_0 A^{m+1-n},$$

so the sequence $(A^k)_{k\geq 1}$ satisfies a linear recursion of order n for free. The sequence $(A^{[k]})_{k\geq 1}$ satisfies the very same recursion for $m \geq n$ if and only if every entry t satisfies $t^{m+1-n}P(t) = 0$, and that holds as soon as $tP(t) = 0$. But the root condition (2) is not free: it is exactly what the last instance $k = n+1$ of the hypothesis pays for. That is why the threshold is $n+1$ and not n.

Remark 16.12.2. The threshold is sharp. Take $n = 2$ and $A = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$. Then

$$A^k = \begin{pmatrix} 1 & 2k \\ 0 & 1 \end{pmatrix}, \qquad A^{[k]} = \begin{pmatrix} 1 & 2^k \\ 0 & 1 \end{pmatrix},$$

and $2k = 2^k$ holds for $k = 1$ and $k = 2$ but fails for $k = 3$. So $A^k = A^{[k]}$ for $k = 1, \ldots, n$ while $A^{n+1} \neq A^{[n+1]}$, and the hypothesis cannot be weakened to $k \leq n$. Consistently with Step 1, here $P(x) = (x-1)^2$ and the entry 2 is not a root of $x(x-1)^2$.

Layer 1: WHAT

Block 1. Read the count: $n \times n$ with exponents up to $n+1$ means the characteristic polynomial multiplied by x.

Block 2. Name the two operations as evaluation maps E and F of the same polynomial, and record that the only property they share is linearity in that polynomial.

Block 3. Record the constant term obstruction, $E(1) = I$ but $F(1) = J$, and conclude that all work happens in the polynomials with zero constant term. This is the reason for multiplying P by x.

Block 4. Push $xP(x)$ through the hypothesis: $E(xP) = A\,P(A) = 0$, hence $F(xP) = 0$, hence every entry of A is a root of $xP(x)$.

Block 5. Both maps therefore kill every multiple of $xP(x)$.

Block 6. Division with remainder shows that the multiples of $xP(x)$ together with the span of $x, \ldots, x^{n+1}$ exhaust the polynomials with zero constant term, so the two maps agree everywhere on that ideal.

The nominal route is Block 1 replaced by multiplication: write out $(A^{m+1})_{ij}$ as a sum, substitute the inductive hypothesis, and stare. The bifurcation point is the very first line, and the question that decides it is not about matrices at all: it is whether you treat the number $n+1$ as an incidental range or as a name. On the Putnam a numerical parameter that matches the size of the object is always a name. Here it names $\deg\big(xP(x)\big)$, and once you have written $xP(x)$ the problem is over in four lines.

Layer 2: HOW

Block 1. **Cue.** The size is n, the exponent range is 1 to $n+1$, and the conclusion is about all exponents. A finite hypothesis producing an infinite conclusion always means a recursion, and a recursion among powers of a matrix of size n means the characteristic polynomial. **Why natural.** Cayley and Hamilton is the only standard supplier of a monic annihilating polynomial whose degree is known before you look at A. That is what makes it usable in a problem where A is arbitrary: you cannot inspect A, but you can name $\deg P = n$. **Link to the next block.** You have a relation among $I, A, \ldots, A^n$. To use it you must transport it across the entrywise operation, so you now examine what that operation does to a polynomial relation.

Block 2. **Cue.** Both A^k and $A^{[k]}$ are values at A of the same monomial x^k, read in two different ways. Whenever the same formal object has two interpretations, name both as maps and compare them, rather than comparing the outputs case by case. **Why natural.** Naming the maps forces you to ask what structure they have. E is a ring homomorphism for matrix multiplication; F is a ring homomorphism for the entrywise (Hadamard) product; they share linearity and nothing else. Knowing precisely what you are allowed to do is worth more than any computation, because it eliminates whole families of doomed attempts, including every attempt to multiply the hypothesis by itself. **Link to the next block.** Linearity means you should ask on which subspace the two maps agree, and that question immediately exposes the constant term.

Block 3. **Cue.** The hypothesis starts at $k = 1$, not $k = 0$. An exponent range that pointedly excludes 0 is a warning about constants. **Why natural.** $E(1) = I$ and $F(1) = J$ are different matrices whenever $n \geq 2$, so the two maps disagree on constants and no argument may involve one. Consequently the natural domain is $x\mathbb{R}[x]$, and any annihilating polynomial you intend to use must have zero constant term. The characteristic polynomial does not, so you multiply it by x; this costs one degree, which is precisely the $+1$ in the hypothesis. **Link to the next block.** You now know exactly which polynomial to feed to the hypothesis: $xP(x)$, of degree $n+1$, the largest degree the hypothesis covers.

Block 4. **Cue.** A polynomial lying in the span where the two maps are known to agree, and whose image under one of the maps you can compute. That is the definition of a usable test object. **Why natural.** $E(xP) = A\,P(A) = 0$ by Cayley and Hamilton, so the agreement forces $F(xP) = 0$, and F is entrywise, so a matrix identity becomes n^2 scalar identities $tP(t) = 0$. This is the one moment in the problem where information crosses from the matrix world to the scalar world, and it crosses because F is entrywise and for no other reason. **Link to the next block.** Knowing the entries are roots of $xP(x)$ makes F kill not just xP but every multiple of it, which is what turns a single instance into an infinite family.

Block 5. **Cue.** A polynomial that vanishes at every entry, and a matrix polynomial that annihilates A. Both statements upgrade to whole ideals for free, because both maps respect multiplication in the appropriate sense. **Why natural.** $E(xPh) = AP(A)h(A) = 0$ uses that polynomials in A commute, and $F(xPh)$ has entries $tP(t)h(t) = 0$ uses only (2). So the common kernel of E and F contains the

ideal generated by $xP(x)$. Whenever you have two linear maps that agree on a subspace and vanish on a common ideal, the natural next question is whether those two pieces span the domain. **Link to the next block.** The answer is supplied by division with remainder, which is the standard way to prove that a subspace plus an ideal is everything.

Block 6. Cue. Ideal generated by a monic polynomial, plus a claim that low degree spans the rest. That is the division algorithm, every time. **Why natural.** Dividing x^m by the monic polynomial $xP(x)$ leaves a remainder of degree at most n, and the remainder inherits divisibility by x from the two other terms, so it lands in V. The inheritance step is the only fiddly point and it is one line, but it must be written: without it the remainder might have a constant term and the argument would leak into the one place the two maps disagree. **Link to the next block.** The linear map $E - F$ vanishes on a spanning set of $x\mathbb{R}[x]$, so it vanishes identically there, and the conclusion is exactly the statement about x^k.

Layer 3: WHY

The truth beneath this problem is that raising to a power is evaluation. Both sides of the equation $A^k = A^{[k]}$ are values of the monomial x^k under a map from $\mathbb{R}[x]$ into the $n \times n$ matrices, and once you see the problem that way it stops being about matrices and becomes a statement about two linear maps agreeing on a quotient. Agreement of linear maps on a spanning set is agreement everywhere; that is the only theorem used at the end. All the specific content of the problem is spent identifying the right spanning set, and the right spanning set is the $n + 1$ monomials the hypothesis names together with an ideal that both maps annihilate.

Cayley and Hamilton earns its place for a single reason: it supplies a nonzero element of the kernel of E whose degree is known in advance. Any monic polynomial annihilating A would do; the minimal polynomial μ would even be sharper, and the argument run with μ shows that the exponents 1 to $\deg \mu + 1$ already suffice. But $\deg \mu$ depends on A and cannot be quoted in a statement about every A, whereas $\deg P = n$ can. So the choice of the characteristic polynomial is not a preference, it is forced by the fact that the problem quantifies over all A of size n.

The discernment mechanism is the one to carry away: when two operations on the same object must be compared, first identify the largest structure they share, then confine every line of the argument to that structure. Here the shared structure is linearity in the polynomial, and the moment you accept that, the doomed routes die on their own. Multiplying the hypothesis by itself is illegal because F is not multiplicative for matrix multiplication. Diagonalising is illegal because F does not see the spectrum. Taking traces or determinants is useless because neither is linear in the polynomial in a compatible way. The problem is easy once the move list is short, and the move list is short as soon as you name what the two maps are.

There is also a general principle worth extracting, because it recurs across the paper. When a problem says that a property holding for $k \leq N$ forces it for all k, look for a linear recursion of order roughly N that both sides satisfy, and then ask what the final instance is buying. Here the matrix side satisfies the recursion for free and the entrywise side does not; the last instance $k = n + 1$ is precisely the payment that puts the entrywise side under the same recursion. Being able to say what the last hypothesis buys is the difference between reproducing a solution and understanding it, and it is also how you would guess the sharp example without being told one exists.

The examiners nudged three times. They wrote $n \times n$ and then $n + 1$, which is the degree of $xP(x)$. They wrote for all $k \geq 1$ rather than $k \geq 0$, which quietly warns that $k = 0$ is different, and $k = 0$ is different exactly because $F(1) = J \neq I$. And they defined $A^{[k]}$ verbally, entry by entry, rather than by a symbol, which is the examiner insisting that you think of it as n^2 separate scalar operations, which is the reading that makes Step 1 possible.

Revolving concepts

Characteristic polynomial and the Cayley and Hamilton theorem. For an $n \times n$ matrix A over a commutative ring, $P(x) = \det(xI - A)$ is monic of degree n and $P(A) = 0$. The standard proof multiplies the adjugate identity $\operatorname{adj}(xI - A)\,(xI - A) = P(x)I$ out and compares coefficients of powers of x, the entries of the adjugate being polynomials in x of degree at most $n - 1$. Beyond A-level for general n. See Book 1, field: Matrices and determinants, topic: Cayley and Hamilton.

Minimal polynomial and the annihilator ideal. The set $\{g : g(A) = 0\}$ is an ideal of $\mathbb{R}[x]$, hence generated by a single monic polynomial μ, the minimal polynomial; μ divides P and $\deg \mu \le n$. Running the solution with μ in place of P shows that exponents 1 to $\deg \mu + 1$ suffice for a fixed A. See Book 1, field: Linear algebra, topic: minimal polynomial.

Division with remainder and ideals in $\mathbb{R}[x]$. For monic D of degree d and any g, there are unique Q, R with $g = QD + R$ and $\deg R < d$. Consequently $\mathbb{R}[x] = \operatorname{span}\{1, x, \ldots, x^{d-1}\} + D\,\mathbb{R}[x]$, and the same argument intersected with $x\mathbb{R}[x]$ gives the decomposition used in Step 3. See Book 1, field: Polynomials, topic: division algorithm and ideals.

Linear recursions in a vector space, and the window principle. If two sequences (X_k) and (Y_k) with values in the same vector space satisfy the same recursion $Z_{m+1} = c_1 Z_m + \cdots + c_n Z_{m+1-n}$ for all $m \ge K$, and $X_k = Y_k$ for the n consecutive indices $k = K + 1 - n, \ldots, K$, then $X_k = Y_k$ for all $k \ge K + 1 - n$. The proof is induction on k, one step at a time. Generalised: a solution of an order n linear recursion is determined by any window of n consecutive terms, so two solutions agreeing on one window agree forever; this is the discrete analogue of uniqueness for an order n initial value problem. See Book 1, field: Sequences and recurrences, topic: linear recursions and initial windows.

Hadamard product and entrywise functional calculus. The entrywise product $(A \circ B)_{ij} = A_{ij}B_{ij}$ makes the $n \times n$ matrices a commutative algebra whose identity is the all ones matrix J, and $A^{[k]}$ is the kth Hadamard power. The map $g \mapsto F(g)$ is the direct product of the n^2 scalar evaluation homomorphisms $g \mapsto g(A_{ij})$. Recognising F as n^2 evaluations at once is what turns the matrix identity $F(xP) = 0$ into the scalar statement that every entry is a root. See Book 1, field: Matrices and determinants, topic: Hadamard product.

Circuit Bank

- **WHEN** a hypothesis about an $n \times n$ matrix runs over exponents 1 to $n + 1$ **DO** write down $A\,P(A) = 0$ with P the characteristic polynomial **BECAUSE** $xP(x)$ is the monic polynomial of degree $n + 1$ with zero constant term, and the exponent range is the examiner naming it

- **WHEN** two different operations on the same object must be compared **DO** identify the largest structure both respect and confine every line to it **BECAUSE** the shared structure is the complete move list, and knowing it kills the doomed routes before you spend ink on them

- **WHEN** an entrywise operation appears anywhere **DO** check the constant polynomial separately **BECAUSE** entrywise evaluation sends 1 to the all ones matrix and not to the identity, so any relation you transport must have zero constant term

- **WHEN** two sequences satisfy the same linear recursion of order n and agree on n consecutive terms **DO** stop and conclude they agree forever **BECAUSE** a solution of an order n linear recursion is determined by any window of n consecutive values

- **WHEN** a finite hypothesis is claimed to force an infinite conclusion **DO** ask what the final instance of the hypothesis buys **BECAUSE** it is always the instance that installs the recursion on the side that does not get it for free, and naming it tells you where the sharp example lives

Backtesting

1. First useful cue: the exponent bound $n+1$ against a matrix of size n, which is $\deg\big(xP(x)\big)$ and nothing else.
2. Method the expression suggested: treat A^k and $A^{[k]}$ as two linear evaluations of x^k, feed $xP(x)$ through the hypothesis to learn that every entry is a root of $xP(x)$, and then note both evaluations kill the whole ideal generated by $xP(x)$.
3. Where you would hesitate, and the thought to reinforce: at the multiplication of P by x, which looks arbitrary. Reinforce this: the entrywise map sends 1 to the all ones matrix, so constants are the one place the two readings disagree, and multiplying by x is how you leave that place.
4. The trap the question sets: starting an induction on k using only the previous case, which uses one hypothesis instead of $n+1$ and stalls on the first line. An unused hypothesis is a misread hypothesis.
5. What makes you recognise it faster next time: the phrase two ways of reading the same polynomial. Every problem that compares an algebraic operation with an entrywise or coordinatewise one is asking you to find the ideal that both readings annihilate.
6. The reusable decision rule: when a numerical parameter in the hypothesis matches a structural invariant of the object, treat it as the name of a specific polynomial and write that polynomial down before doing anything else.

Mirror drills

1. For $A = \begin{pmatrix} 1 & 2 \\ 0 & 1 \end{pmatrix}$, decide for which k the identity $A^k = A^{[k]}$ holds, and explain why this does not contradict the problem. *Answer:* A^k has top right entry $2k$ and $A^{[k]}$ has 2^k, so it holds exactly for $k = 1, 2$; since $n = 2$ the hypothesis needs k up to 3, and it fails there.
2. Suppose A is $n \times n$ with $A^k = A^{[k]}$ for $k = 1, \ldots, n+1$. Prove that every entry of A is either 0 or a real eigenvalue of A. *Answer:* apply the entrywise reading to $xP(x)$ to get $tP(t) = 0$ for each entry t; a real root of P is an eigenvalue.
3. Let (X_k) and (Y_k) be sequences of matrices satisfying the same recursion $Z_{m+1} = c_1 Z_m + \cdots + c_n Z_{m+1-n}$ for all $m \geq K$. Show that agreement on the window $k = K+1-n, \ldots, K$ forces agreement for all $k \geq K+1-n$. *Answer:* induction on k: each new term is the same fixed combination of n terms already known to agree.

Chapter 17

Putnam 2009

17.1 A1. squares constrain f to vanish everywhere

Let f be a real-valued function on the plane such that for every square $ABCD$ in the plane, $f(A) + f(B) + f(C) + f(D) = 0$. Does it follow that $f(P) = 0$ for all points P in the plane?

Read it out loud

Say the hypothesis back to yourself: whatever f is, its values at the four corners of ANY square sum to zero, with no continuity, boundedness or measurability assumed. The question asks whether this single constraint, applied to every square at once, forces f to be the zero function.

The fields wired in are functional equations and finite linear algebra, dressed as plane geometry. No continuity is given, so any route through limits, integrals or "average over all squares through P" is dead before it starts; that absence is a cue that the intended route is a FINITE combination of finitely many instances of the hypothesis.

The first fact worth banking: every point P is the centre of infinitely many squares, of every size and orientation, so you get to CHOOSE the square through P. The second cue is the word "every": the constraint holds simultaneously for a square and for the smaller squares inside it, so expect to combine constraints at more than one scale.

Approaches, ranked worst to best

1. **guess $f \equiv 0$ and stop.** *Cue:* the hypothesis looks like it should force zero. *Circuit:* none, this is not a proof. Settles nothing: the question asks whether it FOLLOWS, and no argument has been given.
2. **average f over all squares centred at P.** *Cue:* "every square through P" suggests integrating over angle and radius. *Circuit:* continuity and symmetry. Illegal, since f is not assumed continuous or measurable, and it reroutes a purely algebraic problem through analysis for no gain.
3. **coordinate bash on a generic square through P.** *Cue:* P is some point, write a general square with P as a vertex and grind. *Circuit:* brute linear algebra over unfixed parameters. Workable but wasteful: a generic square carries two free parameters you end up specialising anyway, without any guidance on which specialisation to choose.
4. **one square centred at P, plus its midpoint subdivision.** *Cue:* every point is a centre, and every square contains smaller squares built from its own midpoints. *Circuit:* finite linear system from self-similar nested squares. The ideal route: the single most information-dense configuration, reused at three scales, gives a finite linear system with $f(P)$ isolated after one clean cancellation.

The ideal solution

The answer is yes, $f(P) = 0$ for every point P.

Fix an arbitrary point P. Choose any square $ABCD$, vertices in order, with centre P; such a square exists for every size and orientation. Let E, F, G, H be the midpoints of sides AB, BC, CD, DA.

Two facts about this configuration, each checked once by placing P at the origin and A, B, C, D at $(\pm r, \pm r)$ in a rotated frame: $EFGH$ is itself a square, centred at P; and each of $AEPH$, $BFPE$, $CGPF$, $DHPG$ is a square with P as a vertex.

Apply the hypothesis to all six squares:

$$0 = f(A) + f(B) + f(C) + f(D)$$
$$0 = f(E) + f(F) + f(G) + f(H)$$

$$0 = f(A) + f(E) + f(P) + f(H)$$
$$0 = f(B) + f(F) + f(P) + f(E)$$
$$0 = f(C) + f(G) + f(P) + f(F)$$
$$0 = f(D) + f(H) + f(P) + f(G).$$

Add the last four equations. Each of A, B, C, D appears once, each of E, F, G, H appears twice, P appears four times:

$$f(A) + f(B) + f(C) + f(D) + 2\big(f(E) + f(F) + f(G) + f(H)\big) + 4f(P) = 0.$$

The first bracket is 0 by the first equation, the second bracket is 0 by the second equation. What remains is $4f(P) = 0$, so $f(P) = 0$. Since P was arbitrary, $f(P) = 0$ for every point P: yes, it follows.

Layer 1: WHAT

Block 1. Fix an arbitrary P; recognise it as the centre of a square you get to choose. Block 2. Build one configuration reusing P at three scales: the big square $ABCD$, the mid square $EFGH$ sharing its centre, and four small squares meeting at P as a vertex. Block 3. Write the hypothesis for all six squares. Block 4. Sum the four small-square equations; the big and mid square sums appear inside, ready to cancel. Block 5. Cancel with equations 1 and 2, isolate $4f(P) = 0$.

The nominal route (coordinate bash) reaches the same answer by grinding a system with unfixed parameters before specialising. The bifurcation point is Block 2: the decision to introduce the midpoints at all, since nothing in the statement mentions them. They are earned because a second scale of square sharing centre P was needed, and side midpoints are the cheapest way to manufacture one.

Layer 2: HOW

Block 1. **Cue.** "For all points P" and "for every square" are both universally quantified over the same underlying objects. **Why natural.** $f(P) = 0$ is one scalar equation; producing it for free needs P to occur with nonzero net coefficient in some finite combination of the zero-equations, so P must literally be a vertex or centre of a square in your configuration. **Link to the next block.** Since P can be the centre of a square of any size, you build the configuration around P rather than searching for one.

Block 2. **Cue.** The one square you have, $ABCD$, has P as its centre, never as a vertex, so its equation never mentions $f(P)$. **Why natural.** A square's centre is never one of its own vertices, so you need squares with P as a VERTEX, built only from points already defined by $ABCD$. Bisecting each side and joining to P closes up into a smaller square, because a square is symmetric under a quarter turn about its centre, and that turn sends each vertex to midpoint to centre path to the next. **Link to the next block.** This is why E, F, G, H exist: forced by asking how to put P on a corner using only $ABCD$'s own points.

Block 3. **Cue.** $EFGH$ sits in the picture as a by-product of Block 2. **Why natural.** By the same quarter-turn symmetry, $EFGH$ is a square with centre P, so the hypothesis applies to it exactly as to $ABCD$. **Link to the next block.** This supplies the equation that cancels the "doubled" midpoint terms in the next block; without it those terms are stranded.

Block 4. **Cue.** Six zero-equations, nine unknowns; you want a combination leaving only $f(P)$. **Why natural.** Summing the four small-square equations accumulates P's coefficient to 4, since P appears in every one; every original vertex appears once and every midpoint appears in exactly

two of the four small squares, since the four tiles exactly cover $ABCD$. **Link to the next block.** That clean arithmetic is what equations 1 and 2 are built to cancel.

Layer 3: WHY

The deep fact is that a square's centre and a square's vertex can be the SAME point P across squares sharing vertices and edges, so one picture generates several instances of the hypothesis whose unknowns overlap almost completely. You are not solving for f as a function, only for the one combination of six equations, nine unknowns, that the self-similar structure of a square under midpoint subdivision hands you as $4f(P)$.

The discernment mechanism: when a functional equation is indexed by a family of figures, ask whether the family is closed under a subdivision that fixes a point of interest. Squares are closed under joining the midpoints, and the midpoint square shares the original centre, which tells you in advance how many independent equations you can generate and which point they pivot on. The examiners nudge away from analysis (no continuity, on purpose, kills any averaging route) toward finite linear algebra: the official remark that the same statement holds for any regular polygon confirms that nothing special about four sides was used beyond the midpoint figure being the same shape, centred at the same point, an invariance under rotation by the appropriate fraction of a turn.

Revolving concepts

Functional equations on a geometric index set: the unknown is a function constrained by linear relations indexed by figures. The method is always to manufacture a finite sub-family whose relations, summed with integer coefficients, isolate the wanted value. See Book 1, field: Functional equations, topic: linear constraints over geometric families.

Self-similarity of a regular polygon under midpoint subdivision: joining consecutive midpoints of a square gives a smaller square, rotated 45°, same centre; more generally the midpoint polygon of any regular n-gon is again a regular n-gon with the same centre. Recursion generalised: iterating, Q_{m+1} the midpoint polygon of Q_m, every Q_m shares the centre of Q_0, giving a nested family of hypothesis instances all pivoting on one centre. See Book 1, field: Geometry, topic: self-similar polygon subdivision.

Targeted elimination with more unknowns than needed: decide in advance which unknowns must die and which must survive, then choose the combination of equations accordingly, rather than summing and hoping. See Book 1, field: Linear algebra, topic: eliminating unwanted variables by design.

Circuit Bank

- **WHEN** a real-valued constraint is stated "for every [figure]" and you are asked about a single point **DO** ask whether that point can be simultaneously the centre of one instance of the figure and a vertex of a smaller instance built from it by internal subdivision **BECAUSE** overlapping the unknowns across two scales turns infinitely many instances of the hypothesis into one solvable finite system
- **WHEN** you have k zero-equations in more unknowns than you need **DO** write down which unknowns must stay alive and which must die before adding anything **BECAUSE** blind summation is the nominal route; targeted elimination is the ideal one
- **WHEN** a problem about a general point or function gives no continuity, boundedness or smoothness hypothesis **DO** rule out any route needing a limit, integral or average immediately **BECAUSE** the setter is signalling the intended route is purely algebraic

Backtesting

1. First useful cue: the hypothesis holds for every square, so you may pick the most convenient one.
2. Method the expression suggested: build a square centred at P, then look for smaller squares generated from it that put P on a vertex.
3. Where you would hesitate, and the thought to reinforce: introducing E, F, G, H, unmentioned in the statement; reinforce that new points are earned by asking what construction forces P onto a vertex using only existing data.
4. The trap the question sets: averaging or integrating over all squares through P, tempting given the word "every" but illegal with no continuity assumed.
5. What makes you recognise it faster next time: "for every [rigid figure]" applied to a point that is naturally both a centre and a vertex of that figure at different scales.
6. The reusable decision rule: when a point can play two structural roles in the same family of figures, build the configuration using both roles at once and sum with targeted cancellation.

Mirror drills

1. Suppose $f(A) + f(B) + f(C) = 0$ for every equilateral triangle ABC. Does $f \equiv 0$ follow? *Answer:* Yes; for any P, use an equilateral triangle centred at P together with the three smaller equilateral triangles meeting at P, and cancel exactly as above.
2. Suppose $f(A) + \cdots + f(F) = 0$ for every regular hexagon $ABCDEF$. Is $f \equiv 0$ forced? *Answer:* Yes; a hexagon centred at P and its midpoint hexagon, also regular with centre P, play the roles of $ABCD$ and $EFGH$ above.
3. If the hypothesis is only $f(A) + f(C) = f(B) + f(D)$ for every square (opposite corners equal, not full sum zero), does $f \equiv 0$ still follow? *Answer:* No; $f(x, y) = x + y$ satisfies it for every square, since a square's diagonals share a midpoint, but is not identically zero.

17.2 A2. the product fgh decouples the system

Functions f, g, h are differentiable on some open interval around 0 and satisfy the equations and initial conditions

$$f' = 2f^2gh + \frac{1}{gh}, \quad f(0) = 1,$$

$$g' = fg^2h + \frac{4}{fh}, \quad g(0) = 1,$$

$$h' = 3fgh^2 + \frac{1}{fg}, \quad h(0) = 1.$$

Find an explicit formula for $f(x)$, valid in some open interval around 0.

Read it out loud

Three coupled, nonlinear, first order differential equations in three unknowns, each mixing all three functions through a product term and a reciprocal-product term. Read out loud, this is not "solve a system of ODEs" in the generic sense, since that generic problem is not tractable by hand. The fields wired in are ordinary differential equations, specifically separable and linear first order ones, algebraic manipulation of the equations before any calculus is done, and the product rule read backwards.

The first cue to bank within seconds: every polynomial term on the right is the SAME triple product fgh times one of f, g, h ($2f^2gh = 2f \cdot (fgh)$, $fg^2h = g \cdot (fgh)$, $3fgh^2 = 3h \cdot (fgh)$), and every reciprocal term is a constant divided by the OTHER two functions, which is the same as the missing function divided by the full product fgh (for instance $1/(gh) = f/(fgh)$). Whenever three equations all revolve around the same triple product, that product, not the three functions separately, is the object to solve for first. The second cue: the question only asks for f, a strong hint that g and h never need to be isolated individually, only some combination of them does.

Approaches, ranked worst to best

1. **attack the system by generic ODE system theory.** *Cue:* "three coupled nonlinear ODEs" superficially looks like something to diagonalise. *Circuit:* eigenvalue methods for linear systems. Hopeless directly: the system is nonlinear, there is no matrix to diagonalise, and no exam expects a numerical solution.

2. **guess the symmetric ansatz $f = g = h$.** *Cue:* the three equations look superficially parallel in shape. *Circuit:* pattern matching on symmetry. Fails on inspection: the polynomial coefficients are $2, 1, 3$ and the reciprocal numerators are $1, 4, 1$, neither list constant across the equations, so setting $f = g = h = \varphi$ forces $\varphi' = 2\varphi^3 + 1/\varphi^2$ from the first equation and $\varphi' = \varphi^3 + 4/\varphi^2$ from the second simultaneously, an inconsistency. Quick to discard, but not a route to the answer.

3. **solve for f, g, h individually via separate substitutions.** *Cue:* each equation looks like it wants its own change of variable. *Circuit:* ad hoc substitution per equation. Never exploits the shared fgh structure, leaving three genuinely coupled nonlinear equations with no reduction in dimension; far more ink than necessary.

4. **multiply each equation by the complementary pair of the other two functions and sum.** *Cue:* the reciprocal terms are each (missing variable)/(full product), and three product-rule pieces summing to a single derivative is the signature of a hidden total derivative. *Circuit:* engineer $f'gh + fg'h + fgh' = (fgh)'$ on purpose. The ideal route: one substitution, $k = fgh$, collapses three coupled nonlinear equations into a single separable one, after which f is recovered from k by direct integration, with g, h never needing to be found.

The ideal solution

Multiply the first equation by gh, the second by fh, the third by fg:

$$f'gh = 2f^2g^2h^2 + 1,$$
$$g'fh = f^2g^2h^2 + 4,$$
$$h'fg = 3f^2g^2h^2 + 1.$$

Add the three lines. The left side is $f'gh + fg'h + fgh'$, exactly $(fgh)'$ by the product rule for three factors. The right side collects to $(2+1+3)f^2g^2h^2 + (1+4+1) = 6(fgh)^2 + 6$. Writing $k = fgh$,

$$k' = 6(k^2+1), \qquad k(0) = f(0)g(0)h(0) = 1.$$

This is separable and can be solved without any black-box existence-uniqueness theorem: since $k^2 + 1 > 0$ always, define $\varphi(x) = \arctan(k(x))$ where k is defined. Then

$$\varphi'(x) = \frac{k'(x)}{1+k(x)^2} = \frac{6(k(x)^2+1)}{1+k(x)^2} = 6$$

identically, so $\varphi(x) = 6x + \varphi(0) = 6x + \pi/4$ (since $\varphi(0) = \arctan 1 = \pi/4$), hence

$$k(x) = \tan\left(6x + \frac{\pi}{4}\right),$$

valid on the open interval around 0 where $6x + \pi/4 \in (-\pi/2, \pi/2)$, in particular on $(-\pi/24, \pi/24)$.

Return to the first original equation to recover f alone, using $gh = k/f$: since $2f^2gh = 2f \cdot (fgh) = 2fk$ and $1/(gh) = f/(fgh) = f/k$,

$$f' = 2fk + \frac{f}{k}, \qquad \text{i.e.} \qquad \frac{f'}{f} = 2k(x) + \frac{1}{k(x)},$$

valid near 0 since $k(0) = 1 \neq 0$. Writing $u = 6x + \pi/4$ (so $u' = 6$), this is $\frac{d}{dx}\ln f = 2\tan u + \cot u$. Two antiderivatives, checked by differentiating back: $\frac{d}{dx}\left[-\frac{1}{3}\ln\cos u\right] = \frac{1}{3}\tan u \cdot u' = 2\tan u$, and $\frac{d}{dx}\left[\frac{1}{6}\ln\sin u\right] = \frac{1}{6}\cot u \cdot u' = \cot u$ (both valid near $x = 0$, where u is near $\pi/4$, so $\sin u, \cos u > 0$ and no absolute values are needed). Adding,

$$\ln f(x) = -\frac{1}{3}\ln\cos u + \frac{1}{6}\ln\sin u + C = \frac{1}{6}\ln\left(\frac{\sin u}{\cos^2 u}\right) + C.$$

At $x = 0$, $u = \pi/4$, $\sin u = \cos u = \sqrt{2}/2$, so $\sin u/\cos^2 u = \sqrt{2}$. Since $f(0) = 1$, $0 = \frac{1}{6}\ln\sqrt{2} + C$, so $C = -\frac{1}{12}\ln 2$. Hence

$$\boxed{f(x) = 2^{-1/12}\left(\frac{\sin(6x+\pi/4)}{\cos^2(6x+\pi/4)}\right)^{1/6}}$$

on the open interval around 0 where this is defined and positive, for instance $(-\pi/24, \pi/24)$.

Layer 1: WHAT

Block 1. Notice all three right sides share the triple product fgh: polynomial terms are fgh times f, g, h; reciprocal terms are the missing variable divided by fgh. Block 2. Multiply each equation by exactly the other two functions, engineering the left sides into the three pieces of the product rule for $(fgh)'$. Block 3. Sum, collapse to a single separable ODE in $k = fgh$. Block 4. Solve for k directly via the arctan composition, no uniqueness theorem needed. Block 5. Substitute $gh = k/f$ back into the FIRST original equation only, reducing it to a relation for $\ln f$ in terms of the known $k(x)$. Block 6. Integrate, apply $f(0) = 1$, box the answer.

The nominal route, chasing f, g, h separately, never gets past a genuinely coupled nonlinear system. The bifurcation point is Block 2: multiplying by the complementary pair rather than trying to isolate one function's equation in isolation. Everything after that is forced computation.

Layer 2: HOW

Block 1. **Cue.** Three reciprocal terms, $1/(gh)$, $4/(fh)$, $1/(fg)$, each missing exactly one letter out of three. **Why natural.** A term missing exactly one of three letters is that missing letter divided by the product of all three, since multiplying and dividing by it changes nothing. Naming $k = fgh$ turns three different-looking fractions into f/k, $4g/k$, h/k, one unifying object. **Link to the next block.** Once k is visible in the denominators, check the polynomial terms too; it is visible there as well ($2f^2gh = 2fk$), which tells you k is the right substitution for the whole system, not just the fractions.

Block 2. **Cue.** You want $(fgh)' = f'gh + fg'h + fgh'$ on the left, three terms, one per equation. **Why natural.** Multiplying equation 1 by gh turns its f' into $f'gh$, the first piece of that expansion; the same move on equations 2 and 3 (multiply by fh, then fg) produces the other two pieces. This is reverse engineering: you know the sum you want on the left and multiply each equation by whatever makes its derivative term match one summand. **Link to the next block.** Once the left side is fixed as $(fgh)'$, simplify whatever the right side becomes in terms of $k = fgh$.

Block 3. **Cue.** Every polynomial term on the right becomes a multiple of k^2, and every reciprocal term becomes a bare constant, because the multipliers you chose are exactly the reciprocal terms' own denominators. **Why natural.** This is the payoff for choosing multipliers to match the reciprocal denominators, not just to build the product rule: the same multiplication that assembles $(fgh)'$ on the left also clears every fraction on the right. **Link to the next block.** Summing gives one ODE, $k' = 6k^2 + 6$, purely in k: three coupled unknowns collapsed to one.

Block 4. **Cue.** $k' = 6(k^2 + 1)$ is separable, and arctan is the antiderivative of $1/(1 + t^2)$. **Why natural.** Composing arctan with $k(x)$ and differentiating via the chain rule gives $k'(x)/(1 + k(x)^2)$, which the ODE says is identically 6. A function with constant derivative on an interval is linear on it, no separate existence-uniqueness theorem needed, since the derivative of $\arctan(k(x))$ was computed directly from the given equation, not guessed and verified. **Link to the next block.** This gives $k(x)$ completely as an explicit function of x.

Block 5. **Cue.** The question only wants f, whose equation contains g, h only through gh. **Why natural.** $gh = k/f$ directly from $k = fgh$, removing g and h from the first equation entirely without solving for them individually. **Link to the next block.** The result is f'/f expressed purely in terms of the already-known $k(x)$, a linear equation for $\ln f$.

Block 6. **Cue.** $f'/f = 2k + 1/k$ with k explicit. **Why natural.** $f'/f = (\ln f)'$, so integrating directly gives $\ln f$ up to a constant; the two pieces $2\tan u$ and $\cot u$ each match a standard logarithmic derivative once $k = \tan u$. **Link to the next block.** The constant of integration is fixed by $f(0) = 1$, the only place the specific numerical answer enters.

Layer 3: WHY

This system is tractable by hand because the setter chose the polynomial coefficients $(2, 1, 3)$ and reciprocal numerators $(1, 4, 1)$ so that multiplying by the complementary pair simultaneously builds a total derivative on the left and a function of a single new variable $k = fgh$ on the right. That is a structural coincidence to look for in any system of the shape (function)$'$ = (stuff)$\times$(product of all the functions) + (stuff)/(product of the other functions): the product rule for n factors always has exactly n terms, one per factor, and if the given system's n equations are shaped so that multiplying equation i by everything except factor i produces the ith term of that expansion, the whole system decouples through the combined product.

The discernment mechanism: whenever a system's nonlinear terms are all scalar multiples of the SAME product of all the unknowns, test whether multiplying by the complementary factors and summing produces a total derivative. The test costs only a few lines, while grinding the system unreduced can cost an unbounded amount.

A secondary truth worth stating cleanly, since the official solution leans on it without proof: a first order ODE $k' = F(k)$ with an explicit solution candidate through the given initial condition does not, by itself, guarantee that candidate is the only one; in general an existence-uniqueness theorem (Picard-Lindelof, using that F is locally Lipschitz) is what would rule out other branches through the same point. Here that heavier tool is unnecessary, because $\arctan(k(x))$ is differentiated directly FROM the given equation, which constructs the solution rather than merely verifying a guess.

Revolving concepts

Product rule for three or more factors: $(fgh)' = f'gh + fg'h + fgh'$, the direct generalisation of $(fg)' = f'g + fg'$. Recursion generalised: for n factors, $(f_1 f_2 \cdots f_n)'$ is the n-term sum $\sum_i f_1 \cdots f_i' \cdots f_n$; whenever a system of n coupled equations, each multiplied by the complementary product of the other $n-1$ functions, sums to this expansion, the full product decouples the system. See Book 1, field: Calculus and integrals, topic: product rule for n factors.

Separable ODEs of the shape $k' = a(k^2 + b^2)$: composing $\theta(x) = \arctan(k(x)/b)$ and differentiating gives $\theta' = ab$ constant, so $\theta(x) = abx + \theta(0)$, hence $k(x) = b\tan(abx + \arctan(k(0)/b))$ directly, with no uniqueness theorem required. Recognise this family on sight whenever a purely quadratic-in-the-unknown right side appears. See Book 1, field: Sequences and recurrences, topic: separable ODEs with rational-in-k^2 right sides.

ODE existence and uniqueness (Picard-Lindelof): an initial value problem $k' = F(x,k)$, $k(x_0) = k_0$, with F continuous and locally Lipschitz in k, has exactly one solution near x_0; this is the tool informally invoked whenever a guessed solution is checked against an initial condition. Beyond A-level: a real-analysis theorem, not part of A-level Further Mathematics, worth knowing exists even though the direct arctan-composition argument above avoids needing it. See Book 1, field: Real analysis, topic: existence and uniqueness for ODEs.

Linear first order ODEs by direct antidifferentiation: once f'/f is known explicitly as a function of x, $\ln f$ is recovered by direct antidifferentiation and f by exponentiating, the constant fixed by one initial condition; this is the integrating factor method in its simplest form, trivial because the equation is already separated. See Book 1, field: Calculus and integrals, topic: linear first order ODEs via integrating factor.

Circuit Bank

- **WHEN** a system of n equations for n functions has every nonlinear term as a multiple of the same product of all n functions, and every other term missing exactly one factor **DO** name the full product k, multiply equation i by everything except the ith function, and sum, expecting a total derivative k' on the left **BECAUSE** this is exactly the n-term expansion of the product rule, engineered to appear whenever the system has this shape
- **WHEN** after reducing a coupled system to one variable k, the question only asks for one of the original functions **DO** substitute the relation for k back into only the one original equation defining the wanted function, expressing the others as k divided by it **BECAUSE** solving for every original function separately is wasted work when only a combination of them was ever needed
- **WHEN** a separable ODE $k' = ak^2 + b$ appears with a, b the same sign **DO** compose $\arctan(k(x))$ (scaled if $b \neq 1$) and differentiate directly from the given equation rather than guessing and

invoking uniqueness **BECAUSE** direct construction is rigorous on its own and avoids relying on an unproven black-box theorem

Backtesting

1. First useful cue: every equation's polynomial term is the full product fgh times one function, every fractional term the missing function divided by fgh.
2. Method the expression suggested: multiply each equation by the complementary pair of functions to build $(fgh)'$ on the left and clear all fractions on the right.
3. Where you would hesitate, and the thought to reinforce: whether you may simply assert $k(x) = \tan(6x + \pi/4)$; reinforce that composing arctan with $k(x)$ and differentiating directly from the ODE constructs the solution, so no separate uniqueness theorem is required.
4. The trap the question sets: it looks like you need g and h explicitly to answer a question about f; you never do, since $gh = k/f$ is all the first equation needs.
5. What makes you recognise it faster next time: three or more coupled equations all sharing the same full product of unknowns, in both their polynomial and reciprocal terms.
6. The reusable decision rule: reduce coupled nonlinear systems built around a shared product by completing the product rule for that product, before attempting to isolate any single function.

Mirror drills

1. Two functions satisfy $p' = p^2q + 1/q$, $q' = pq^2 + 1/p$, $p(0) = q(0) = 1$. Find pq explicitly. *Answer:* multiply by q, p and add: $(pq)' = 2(pq)^2 + 2$, so $k = pq$ gives $k' = 2(k^2 + 1)$, $k(0) = 1$, hence $k(x) = \tan(2x + \pi/4)$ by the identical arctan-composition argument.
2. If $k' = 3(k^2 + 4)$ with $k(0) = 2$, find $k(x)$. *Answer:* write $k = 2\tan\theta$, so $k^2 + 4 = 4\sec^2\theta$ and $k' = 2\theta'\sec^2\theta$; the equation becomes $2\theta'\sec^2\theta = 12\sec^2\theta$, so $\theta' = 6$; at $x = 0$, $\tan\theta_0 = 1$ so $\theta_0 = \pi/4$; hence $k(x) = 2\tan(6x + \pi/4)$.
3. A function satisfies $y'/y = 2\tan(3x) + \cot(3x)$, $y(0) = 1$. Find $y(x)$ near 0. *Answer:* $\cot(3x) \to \infty$ as $x \to 0$, so y'/y is not even defined at $x = 0$; no such differentiable y with $y(0) = 1$ exists on an interval containing 0, showing the $\pi/4$ phase shift in the original problem, keeping $u = 6x + \pi/4$ away from 0 and $\pi/2$, was load-bearing, not decorative.

17.3 A3. cosine matrix collapses to rank two

Let d_n be the determinant of the $n \times n$ matrix whose entries, from left to right and then from top to bottom, are $\cos 1, \cos 2, \ldots, \cos n^2$ (the argument of cos always in radians). Evaluate $\lim_{n\to\infty} d_n$.

Read it out loud

Read the construction literally: row j, column k holds $\cos\big(n(j-1)+k\big)$, since $1, 2, \ldots, n^2$ are laid down row by row and row j starts right after row $j-1$ has used up $n(j-1)$ of them. Every entry is cos of an integer that splits as a row-dependent piece $n(j-1)$ plus a column-dependent piece k. That additive split, argument equals row thing plus column thing, fed through one fixed function, is the entire content of the problem; nothing about the specific numbers $1, \ldots, n^2$ matters beyond it.

The fields wired in are linear algebra, specifically determinants, rank, and the fact that a matrix with more rows than its rank is singular, and trigonometry, specifically angle addition and its cleanest packaging, the complex exponential. This is a determinant question that is not really about computing a determinant: an $n \times n$ determinant of transcendental entries cannot be computed directly, so the cue is to ask what structural property of the matrix forces it to vanish, rather than to compute it.

The first thing to write down within seconds: $\cos(a+b) = \cos a \cos b - \sin a \sin b$ turns a function of a SUM into a combination of PRODUCTS of a function of a alone and a function of b alone. A matrix whose (j,k) entry is a sum of products of row-only and column-only pieces is, by definition, a sum of outer products, hence of bounded rank regardless of n. Once n exceeds that bound, the determinant is not merely small, it is exactly zero.

Approaches, ranked worst to best

1. **cofactor expand for small n, look for a numeric pattern.** *Cue:* "evaluate a limit" suggests computing a few terms. *Circuit:* brute determinant expansion. Enormous ink even at $n = 4$ or 5, and never becomes a proof for all n; you would be guessing a pattern continues rather than showing why it must.

2. **add column 3 to column 1, use $\cos x + \cos y = 2\cos\frac{x+y}{2}\cos\frac{x-y}{2}$ to show the new column 1 is a multiple of column 2.** *Cue:* the entries are cos of a linear sequence, and sum to product identities are the standard tool for combining two cosines. *Circuit:* elementary column operations preserve determinant; proportional columns force determinant 0. Correct and reasonably short, but it requires spotting the specific pair of columns to combine, leaving the reader unsure why THAT pair works and treating a structural fact as an algebraic coincidence.

3. **write $\cos(a_j + b_k)$ as the real part of $e^{i(a_j+b_k)} = e^{ia_j}e^{ib_k}$, an outer product, hence rank 1 over $\mathbb{C}$ and rank at most 2 over $\mathbb{R}$ after taking the real part.** *Cue:* "argument is a sum of a row piece and a column piece" is the signature of an outer product once you pass to complex exponentials. *Circuit:* rank subadditivity under matrix addition; a matrix of rank less than its size is singular. The ideal route: it explains WHY the vanishing happens, a rank bound intrinsic to the additive-phase structure, nothing to do with the specific numbers, needs no case-specific column hunting, and applies uniformly to every $n \geq 3$ in one line.

The ideal solution

Index rows and columns by $j, k \in \{1, \ldots, n\}$. Since $\cos 1, \cos 2, \ldots, \cos n^2$ are written row by row, the entry in row j, column k is

$$M_{jk} = \cos\big(n(j-1)+k\big).$$

Set $a_j = n(j-1)$ and $b_k = k$, so $M_{jk} = \cos(a_j + b_k)$.

By Euler's formula, $M_{jk} = \mathrm{Re}\big(e^{i(a_j+b_k)}\big) = \mathrm{Re}\big(e^{ia_j}e^{ib_k}\big)$. Let $u \in \mathbb{C}^n$ have jth entry e^{ia_j} and $v \in \mathbb{C}^n$ have kth entry e^{ib_k}. The complex matrix uv^{T} has (j,k) entry $e^{ia_j}e^{ib_k}$ and rank exactly 1, since u, v are nonzero (every entry has modulus 1). Write $u = p + iq$, $v = r + is$ with $p, q, r, s \in \mathbb{R}^n$, so $p_j = \cos a_j$, $q_j = \sin a_j$, $r_k = \cos b_k$, $s_k = \sin b_k$. Then

$$M = \mathrm{Re}(uv^{\mathsf{T}}) = pr^{\mathsf{T}} - qs^{\mathsf{T}},$$

a difference of two real outer products, each of rank at most 1. Since rank is subadditive over sums, $\mathrm{rank}(M) \le \mathrm{rank}(pr^{\mathsf{T}}) + \mathrm{rank}(qs^{\mathsf{T}}) \le 1 + 1 = 2$.

So M has rank at most 2 for every n. For $n \ge 3$, an $n \times n$ matrix of rank at most $2 < n$ is singular, since its rows cannot all be independent once there are more of them than the rank, hence $\det M = d_n = 0$.

This holds for every $n \ge 3$, so the sequence $(d_n)_{n\ge 3}$ is identically zero; only $d_1 = \cos 1$ and $d_2 = \cos 1 \cos 4 - \cos 2 \cos 3$ can possibly be nonzero, and they play no role in a limit as $n \to \infty$. Therefore

$$\boxed{\lim_{n\to\infty} d_n = 0.}$$

Layer 1: WHAT

Block 1. Translate the row by row filling rule into a formula, $M_{jk} = \cos(a_j + b_k)$ with $a_j = n(j-1)$, $b_k = k$. Block 2. Recognise cos of a sum of a row piece and a column piece as the real part of a complex outer product, via Euler's formula. Block 3. Split into real and imaginary parts to bound the real rank by 2. Block 4. Invoke rank less than size implies singular, for all $n \ge 3$. Block 5. Note the limit is unaffected by the finitely many small n where the bound $2 < n$ fails.

The nominal route, the column-addition trick, reaches the same conclusion by constructing a specific dependency between two named columns using a sum to product identity, rather than exposing the rank bound that makes every suitably chosen triple of columns dependent once $n \ge 3$. The bifurcation point is Block 2: whether you see the matrix's defining feature as an algebraic coincidence between column 1 and column 3, or as an outer product in disguise, transparent as soon as you pass to $e^{i\theta}$.

Layer 2: HOW

Block 1. **Cue.** The problem states exactly how the matrix is filled: left to right, then top to bottom, with $1, 2, \ldots, n^2$. **Why natural.** Writing out row 1 $(\cos 1, \ldots, \cos n)$ and row 2 $(\cos(n+1), \ldots, \cos 2n)$ by hand makes the pattern $M_{jk} = \cos(n(j-1) + k)$ obvious: row j starts at $n(j-1) + 1$. **Link to the next block.** Once the entry is a formula in j and k, ask what kind of formula it is, in particular whether j and k interact additively or multiplicatively inside the cos.

Block 2. **Cue.** The argument $n(j-1) + k$ is additively separable: a function of j alone, plus a function of k alone. **Why natural.** $\cos(a + b)$ never factors as a product of a function of a and a function of b over the reals directly, but it does via $e^{i(a+b)} = e^{ia}e^{ib}$, which DOES factor exactly; since cos is the real part of $e^{i(\cdot)}$, complexifying is exactly what turns an additive split into a genuine product split. **Link to the next block.** A matrix whose complex version is a product of a column vector and a row vector is by definition a rank 1 outer product; this is the moment the determinant question quietly becomes a rank question.

Block 3. **Cue.** You need a statement about the real matrix M, but the clean rank 1 structure lives in the complex matrix uv^{T}. **Why natural.** Taking the real part of a sum is linear, so the real part of a rank 1 complex outer product is what you get by expanding $u = p + iq$, $v = r + is$ and collecting

real terms, producing exactly two real outer products added together. **Link to the next block.** Two rank 1 pieces added have rank at most 2, since rank is subadditive over sums, giving the bound actually needed.

Block 4. **Cue.** $n \geq 3$ but rank ≤ 2. **Why natural.** An $n \times n$ matrix is invertible exactly when its rank equals n; rank strictly less than n means the rows, or columns, are linearly dependent, precisely the condition for the determinant to vanish. This is definitional, not an extra theorem to prove. **Link to the next block.** The determinant is exactly 0, not merely small, for every single $n \geq 3$, a stronger and easier fact than any asymptotic estimate would have been.

Block 5. **Cue.** The problem asks for a limit as $n \to \infty$, but you have shown something about every $n \geq 3$. **Why natural.** A sequence that is exactly 0 from some point onward converges to 0 trivially; the finitely many terms d_1, d_2 before that point cannot affect a limit, since a limit depends only on the tail of a sequence. **Link to the next block.** This is why d_1 and d_2 never need to be computed at all to answer the question as posed; eventual vanishing is strictly stronger than any statement about the limit alone.

Layer 3: WHY

The deep fact is a general lemma worth extracting: if $M_{jk} = \cos(a_j + b_k)$ for ANY real sequences (a_j), (b_k), then M has real rank at most 2. Nothing about the specific values $a_j = n(j-1)$, $b_k = k$ was used anywhere; the problem's numbers $1, \ldots, n^2$ are decorative, and the only structural fact in play is the additive separability of the argument of cos. This is exactly why the column-manipulation solution works too: any two columns of M live in a 2-dimensional space spanned by $(\cos a_j)_j$ and $(\sin a_j)_j$, so any three columns, for $n \geq 3$, are automatically linearly dependent, and the official solution's choice of columns 1 and 3 is one convenient dependency among many available.

The discernment mechanism: whenever a matrix entry is a fixed function of a sum of a row-index quantity and a column-index quantity, and that function is cos, sin, $e^{(\cdot)}$, or built from these, suspect a low rank structure before attempting any determinant computation. The complex exponential is the natural lens because it is the one function where argument adds and value multiplies are the same fact, $e^{i(a+b)} = e^{ia}e^{ib}$; cos and sin inherit a rank bound of 2, not 1, because taking a real or imaginary part of a rank 1 complex object can double the real rank, never worse.

What the examiners were nudging toward: "from left to right and then from top to bottom" is doing real work, forcing the additive-in-(j,k) structure on the argument; a different filling order would break the rank bound argument directly, and the problem would likely be far harder or false. Recognising that the filling RULE, not the specific numbers, generates the structure is the single most transferable habit here.

Revolving concepts

Rank of a matrix and the outer product as the canonical rank 1 object: a matrix uv^{T} always has rank at most 1, and every rank 1 matrix has this form; rank is subadditive, $\operatorname{rank}(X+Y) \leq \operatorname{rank}(X) + \operatorname{rank}(Y)$, letting two rank 1 pieces combine to a rank ≤ 2 bound. Beyond A-level: rank as a formal invariant, and its subadditivity, is undergraduate linear algebra, not part of A-level Further Mathematics, where matrix work stops at determinants, inverses and simple eigenvalue problems. See Book 1, field: Linear algebra, topic: rank and outer products.

Euler's formula as a device for linearising angle addition: $e^{i\theta} = \cos\theta + i\sin\theta$, and $e^{i(a+b)} = e^{ia}e^{ib}$ converts the additive structure of angle sums into multiplicative structure, exactly what is needed to see a sum of angles as a product of two separate vectors' entries. This is A-level Further Mathematics content already; what is new is applying it to build a MATRIX rather than to simplify

a single trigonometric expression. See Book 1, field: Complex numbers, topic: Euler's formula as a rank-revealing substitution.

Rank deficiency and vanishing determinants, with the general growing-family template: an $n \times n$ matrix is singular exactly when its rank is less than n. Recursion generalised: whenever a family $M^{(n)}$, indexed by growing size n, is built from a fixed number r of underlying vector generators independent of n (here, two: $(\cos a_j)$ and $(\sin a_j)$), every $M^{(n)}$ with $n > r$ is automatically singular; this template reappears whenever a matrix's rows or columns are secretly built from a bounded-dimensional family of building blocks, for instance a matrix whose (j,k) entry is a fixed degree d polynomial in j and k, which has rank at most $d+1$ regardless of n. See Book 1, field: Matrices and determinants, topic: singularity from bounded generator count.

Sum to product identities: $\cos x + \cos y = 2\cos\frac{x+y}{2}\cos\frac{x-y}{2}$, the classical, pre-exponential tool the column-operation route uses, itself derivable from the same angle addition formula. See Book 1, field: Geometry, topic: sum to product trigonometric identities.

Circuit Bank

- **WHEN** a matrix entry is cos, sin, or $e^{i(\cdot)}$ of an expression splitting as a function of the row index plus a function of the column index **DO** pass to the complex exponential, write the entry as the real or imaginary part of $e^{ia_j}e^{ib_k}$, and read off a rank bound of 1 complex or 2 real **BECAUSE** additive structure inside a fixed exponential-type function is exactly multiplicative structure outside it, the definition of an outer product
- **WHEN** a determinant question grows with n and asks for a limit or eventual value, not a formula for every n **DO** check whether the matrix has bounded rank independent of n before attempting to compute the determinant directly **BECAUSE** once n exceeds that bound the determinant is not approximately zero, it is exactly zero, a stronger and cheaper fact to establish than any estimate
- **WHEN** a column-operation solution to a determinant problem works but the choice of columns looks arbitrary **DO** look for the underlying rank bound that makes many different column combinations work simultaneously **BECAUSE** seeing the general reason converts a lucky-looking identity into a transferable method

Backtesting

1. First useful cue: the matrix is filled row by row with consecutive integers, so the (j,k) entry's argument is a row piece plus a column piece.
2. Method the expression suggested: pass to $e^{i(\cdot)}$ to turn the additive split into a genuine outer product, then bound the real rank by 2.
3. Where you would hesitate, and the thought to reinforce: whether rank at most 2 really forces the determinant to be exactly 0 rather than just small; reinforce that singularity is a definitional consequence of rank less than size, with no approximation involved.
4. The trap the question sets: dressing up a rank argument as a determinant computation over specific, intimidating numbers 1 through n^2, tempting you to compute rather than look for structure.
5. What makes you recognise it faster next time: seeing "the determinant of a matrix whose entries are cos, or sin, or $e^{i(\cdot)}$, of a linear function of row and column index".
6. The reusable decision rule: before computing any growing-size determinant, check whether the entries are secretly built from a bounded number of vectors via an additive-to-multiplicative identity; if so, the determinant vanishes identically once n exceeds that bound.

Mirror drills

1. Let $N_{jk} = \sin\big((j-1) + 2k\big)$ for $j, k = 1, \ldots, 5$. What is $\det N$? *Answer:* 0; $a_j = (j-1)$, $b_k = 2k$ split additively, so N is the imaginary part of a rank 1 complex outer product, real rank at most 2, and $5 > 2$.
2. Let $M_{jk} = 2^{j+k}$ for $j, k = 1, \ldots, 4$. Without expanding, why is $\det M = 0$? *Answer:* $M_{jk} = 2^j \cdot 2^k$ is already a real outer product, rank exactly 1, and $4 > 1$.
3. Let $M_{jk} = \cos(jk)$ for $j, k = 1, \ldots, 4$ (a product, not a sum, inside the cosine). Does the rank 2 argument apply? *Answer:* No; jk does not split as a function of j plus a function of k, so e^{ijk} is not a product $e^{i\alpha_j} e^{i\beta_k}$ and the outer product structure is gone; this determinant is not forced to vanish by this method, showing the ORIGINAL problem's additive index structure was essential, not decorative.

17.4 A4. Rational closure blocked by a quadratic residue

Let S be a set of rational numbers such that

(a) $0 \in S$;

(b) if $x \in S$ *then* $x+1 \in S$ *and* $x-1 \in S$; *and*

(c) if $x \in S$ *and* $x \notin \{0,1\}$, *then* $\dfrac{1}{x(x-1)} \in S$.

Must S contain all rational numbers?

Read it out loud

This is a closure question. You are given a seed, 0, and two production rules, and you are asked whether the closure of the seed under those rules is all of $\mathbb{Q}$. Read it verbally: start at zero, you may slide by whole numbers, and you may apply the map $T(x) = 1/(x(x-1))$; does every rational get hit? The fields wired into the question are the arithmetic of reduced fractions, quadratic residues, and the general logic of least fixed points. Nothing else is present, which is itself information: there is no analysis here, no counting, no algebra beyond $\mathbb{Z}$.

The single most important structural observation comes before any computation. Rule (b) does not change the denominator of a fraction in lowest terms; it only shifts the numerator by the denominator. So rule (b) preserves both the denominator and the numerator modulo that denominator. Every change of denominator in this problem is done by rule (c), and by rule (c) alone. Thus there is exactly one object worth computing, and you should have it on paper within thirty seconds: write $x = p/q$ in lowest terms and simplify $T(p/q)$ into a single fraction. That is not a guess, it is the only rule capable of doing anything interesting, so you interrogate it.

There is also a meta cue in the phrasing. *Must S* contain all rational numbers? A *yes* costs you a constructive algorithm reaching an arbitrary p/q; a *no* costs you one explicit set and three bullet points of verification. Before committing, spend sixty seconds generating: 0 gives all integers, $x = 2$ gives $1/2$, $x = 3$ gives $1/6$, $x = 3/2$ gives $4/3$, $x = 1/6$ gives $-36/5$. Denominators $2, 3, 5, 6$ all appear, so the set is not obviously thin, but no scheme appears either. When a generation attempt produces plenty of examples but no descent, stop generating and start hunting for what the rules cannot do.

One more guiding light, and it is the strongest one in the problem. If rule (c) had been $x \mapsto 1/x$, the answer would be yes, and the proof would be the continued fraction algorithm: given p/q in lowest terms with $q \geq 2$, translate to r/q with $0 < r < q$, invert to q/r, and the denominator has strictly dropped, so induction on the denominator finishes. The setter wrote $1/(x(x-1))$ instead. That map has degree 2, not degree 1: it is not a Mobius transformation, so the transitive action of translations and inversion on $\mathbb{Q}$ is deliberately broken. When a setter breaks a structure you know to be transitive, they are telling you the answer is no.

Approaches, ranked worst to best

1. **Reverse Euclid.** *Cue:* two rules that look like "shift" and "invert", the exact generators of the continued fraction algorithm. *Circuit:* translations plus inversion act transitively on $\mathbb{Q}$, so run the Euclidean descent backwards. This is a false friend and it is expensive. The map is quadratic, so from $T(x) = y$ you cannot in general solve for a rational x: x satisfies $yx^2 - yx - 1 = 0$, whose discriminant $y^2 + 4y$ is rarely a square. The descent has no inverse step, and you can lose twenty minutes before noticing.

2. **Induction on the denominator.** *Cue:* a closure statement about $\mathbb{Q}$ with a natural complexity measure. *Circuit:* prove reachability by strong induction on the denominator of the target. It fails, but it fails informatively: try to reach p/q from something simpler and you find T sends

denominator q to numerator q^2, which is the wrong direction. Ranked above the first route only because the failure points straight at the invariant.

3. **Experimental hunt for a missing class.** *Cue:* a closure question that resists generation. *Circuit:* list a few hundred members of the orbit, sort by denominator, and look for a residue class that never appears. This does find the answer: with denominator 5 you only ever see numerators $\equiv 1$ or $4 \pmod 5$. It is legitimate and it is slow by hand, and it leaves you with a conjecture rather than a reason.

4. **Compute rule (c) on the general symbol.** *Cue:* rule (b) fixes the denominator, so only rule (c) can change it. *Circuit:* substitute $x = p/q$ in lowest terms, simplify to one fraction, and read what the output is forced to look like. The best route by a distance. One line of algebra gives $T(p/q) = q^2/(p(p-q))$ with numerator and denominator automatically coprime. The numerator of every output is a perfect square up to sign, and squares miss residue classes. From there the counterexample is forced rather than found.

The ideal solution

The answer is $\boxed{\text{No}}$.

Throughout, $T(x) = \dfrac{1}{x(x-1)}$, defined for $x \in \mathbb{Q} \setminus \{0, 1\}$.

Lemma 17.4.1. *A rational number has exactly two representations a/b with $\gcd(a,b) = 1$ and $b \neq 0$, namely a/b and $(-a)/(-b)$. In particular, if $a/b = c/d$ with $\gcd(a,b) = \gcd(c,d) = 1$ and $b, d \neq 0$, then $(c,d) = \pm(a,b)$.*

Proof. From $a/b = c/d$ we get $ad = bc$. Then $b \mid ad$, and $\gcd(a,b) = 1$, so $b \mid d$. Symmetrically $d \mid b$, so $d = \varepsilon b$ with $\varepsilon = \pm 1$. Cancelling b from $ad = bc$ gives $c = \varepsilon a$ with the same sign. □

Lemma 17.4.2. *Let $x \in \mathbb{Q} \setminus \{0, 1\}$ and write $x = p/q$ in lowest terms with $q \geq 1$. Put $D = p(p-q)$. Then $D \neq 0$, $\gcd(q^2, D) = 1$, and*

$$T(x) = \frac{q^2}{D}.$$

Proof. We have $x(x-1) = \dfrac{p}{q} \cdot \dfrac{p-q}{q} = \dfrac{p(p-q)}{q^2}$, so $T(x) = q^2/D$. Since $x \neq 0$ we have $p \neq 0$, and since $x \neq 1$ we have $p \neq q$, so $D \neq 0$. Finally $\gcd(p,q) = 1$ and $\gcd(p-q,q) = \gcd(p,q) = 1$, so $\gcd(D,q) = 1$ and therefore $\gcd(D, q^2) = 1$. □

Claim 17.4.3. *For every $x \in \mathbb{Q} \setminus \{0, 1\}$, the number $T(x)$ is not of the form $n + \frac{2}{5}$ with $n \in \mathbb{Z}$.*

Proof. Suppose $T(x) = n + \frac{2}{5} = \dfrac{5n+2}{5}$ for some integer n. With the notation of the previous lemma this says

$$\frac{q^2}{D} = \frac{5n+2}{5}.$$

The left side is in lowest terms, and so is the right side, because $\gcd(5n+2, 5) = \gcd(2, 5) = 1$. By the first lemma, $(5n+2, 5) = \pm(q^2, D)$, and in particular

$$5n + 2 = \pm q^2.$$

Reduce modulo 5: the left side is $\equiv 2$, so $q^2 \equiv \pm 2 \pmod 5$, that is, $q^2 \equiv 2$ or $q^2 \equiv 3 \pmod 5$. But every square is congruent to 0, 1 or 4 modulo 5, since $0^2, 1^2, 2^2, 3^2, 4^2 \equiv 0, 1, 4, 4, 1$. This is a contradiction, so no such x exists. □

Now put

$$B = \left\{ n + \tfrac{2}{5} : n \in \mathbb{Z} \right\}, \qquad S = \mathbb{Q} \setminus B.$$

Property (a): $0 \notin B$, since $0 - \frac{2}{5}$ is not an integer, so $0 \in S$. Property (b): B is by construction invariant under $x \mapsto x \pm 1$, hence so is its complement S. Property (c): let $x \in S$ with $x \notin \{0, 1\}$. By the Claim, $T(x) \notin B$, so $T(x) \in S$. (The Claim is stronger than required: no rational at all, whether or not it lies in S, is sent into B.)

So S satisfies (a), (b) and (c), and $\frac{2}{5} \notin S$. A set obeying the three conditions need not contain all rationals.

Remark 17.4.4. The same argument excludes $\frac{3}{5}$ as well, so $\mathbb{Q} \setminus \{n \pm \frac{2}{5}\}$ also works, and more generally: if $\gcd(m, n) = 1$ and neither m nor $-m$ is a quadratic residue modulo n, then $\mathbb{Q}$ minus the class of m/n satisfies (a), (b), (c). The proof is the same two lemmas, ending at $m + kn = \pm q^2$.

Layer 1: WHAT

Block 1. Read the two rules and notice that (b) preserves the denominator and the numerator modulo the denominator, so only (c) can move you between denominators.

Block 2. Spend sixty seconds generating; get $1/2$, $1/6$, $4/3$, $-36/5$; find no descent; switch from "reach everything" to "find what cannot be reached".

Block 3. Compute (c) on the general symbol: $T(p/q) = q^2/(p(p-q))$.

Block 4. Read the two gifts in that output: the fraction is already in lowest terms, and its numerator is a perfect square.

Block 5. Convert "numerator is a square" into an obstruction: fix a denominator n and ask which numerators are attainable modulo n; only $\pm$ squares are.

Block 6. Choose the smallest modulus for which some class is missed by both $+$ squares and $-$ squares. That is $n = 5$, class $m = 2$.

Block 7. Check the resulting bad set is translation invariant and misses 0, so (a) and (b) survive, and quote the Claim for (c).

The nominal route is Block 2 continued forever: generate, tabulate, hope for a pattern in the numbers. The ideal route is Blocks 3 to 7. The bifurcation point is exactly the line where you stop substituting numbers into T and substitute the *symbol* p/q instead. The zombie computes T on examples and reads decimals; you compute T once on the general reduced fraction and read the shape of the answer. Everything after that is forced.

Layer 2: HOW

Block 1. Cue. Two closure rules, one of which is a pure translation. **Why natural.** Translation by 1 sends p/q to $(p+q)/q$, which is still in lowest terms with the same denominator. So the pair (denominator, numerator modulo denominator) is an invariant of rule (b). A rule that preserves everything you can measure is not the rule to study. **Link to the next block.** If (b) cannot change the denominator, then the entire question is about the image of (c).

Block 2. Cue. The question says "must", which is an invitation to answer no. **Why natural.** Generating is cheap and settles the mood of the problem. You are not looking for the answer here, you are looking for evidence of a descent. Sixty seconds produced four denominators and no algorithm, which is the signature of a false statement. **Link to the next block.** With no descent in sight, the only remaining currency is an invariant, and an invariant must come from the general form of the rule.

Block 3. Cue. Rules stated on rationals, with the target also rational. **Why natural.** Every arithmetic property of a rational lives in its lowest terms representation, so you substitute $x = p/q$ with $\gcd(p, q) = 1$ and simplify to a single fraction. This is not exploratory; it is the definition-level move. The rule is a function of x, and you want to know what it does to the data (p, q) that carries all arithmetic meaning. **Link to the next block.** The algebra takes one line and produces $q^2/(p(p-q))$, which you then read rather than manipulate further.

Block 4. Cue. The output has a squared numerator and a product denominator. **Why natural.** Two facts fall out for free. First, $\gcd(p, q) = 1$ forces $\gcd(p - q, q) = 1$, so the output fraction is already reduced: no information is lost by reading its numerator. Second, that numerator is q^2. A perfect square is the most restrictive shape in elementary number theory, because squares occupy about half the classes modulo an odd prime. **Link to the next block.** The reduced form being unique means the numerator modulo the denominator is a well defined feature of the output, so "which classes can the output occupy" is a legitimate question with a finite answer.

Block 5. Cue. A quantity forced to be a square. **Why natural.** The circuit is automatic: squares miss residues, so ask which residues. Because the denominator D may be negative, moving to the standard positive denominator flips the sign of the numerator, so what is forced is that the numerator is $\pm$ a square modulo the denominator. Both signs must be excluded. **Link to the next block.** You now need a modulus n and a class m with neither m nor $-m$ a square modulo n.

Block 6. Cue. You need m and $-m$ to be non residues simultaneously. **Why natural.** That is possible only if -1 is itself a square modulo n, since otherwise multiplying by -1 swaps residues and non residues and one of $\pm m$ always lands in the residue class. For an odd prime p, -1 is a square exactly when $p \equiv 1 \pmod 4$. So the smallest candidate modulus is 5, where $-1 \equiv 4 = 2^2$ is a square and the non residues are 2 and 3. The smallest bad class is $2/5$. **Link to the next block.** The bad set is a class modulo 1, hence automatically translation invariant, which is precisely what rule (b) demands.

Block 7. Cue. The write up must verify three conditions, not tell a story. **Why natural.** A full marks answer to a "must" question is an object plus three checks. The only check with content is (c), and you prove the stronger statement that no rational maps into the bad class, which removes any need to track membership of S during the argument. **Link to the next block.** Nothing remains; state the conclusion.

Layer 3: WHY

The mathematical truth at the bottom is a fixed point statement. The set of rationals actually forced into S is the least fixed point of the operator $X \mapsto \{0\} \cup (X + 1) \cup (X - 1) \cup T(X \setminus \{0, 1\})$, obtained as the union of the iterates started at $\emptyset$. Least fixed points are hard to describe from below and easy to bound from above: any set that contains the seed and is closed under the rules contains the closure. So to answer no you never need to know what S must contain. You need one closed proper superset. That asymmetry is why the counterexample route is cheap and the "prove it is everything" route is expensive, and it is the reason to test for an invariant early.

The second truth is about which invariant to look for. Rule (b) is a translation, so any invariant must be a function of the rational modulo 1, that is, of the pair (reduced denominator, reduced numerator modulo denominator). That reduces the search space from all conceivable invariants to a finite question for each denominator. Then rule (c) supplies the answer: it manufactures numerators that are squares. Squares are the standard source of unattainable classes, and quadratic residues are the standard language for saying so.

The third truth is the sign issue, which is where a careless solution dies. $D = p(p-q)$ can be negative, so the reduced representation with a positive denominator carries numerator $-q^2$. That is exactly why you need -1 to be a square modulo n, and it is why $n = 3$ and $n = 4$ fail: modulo 3 the non residue is 2 and $-2 \equiv 1$ is a residue; modulo 4 the non residue among units is 3 and $-3 \equiv 1$ is a residue. Five is the first modulus that works, and the answer $2/5$ published by the competition is the smallest possible counterexample class. Knowing that means you would have found it in the arena without searching.

The discernment mechanism to train is a two question filter for closure problems. First: does any rule reduce a complexity measure, so that a descent proof is available? Here the candidate measure is the denominator, and T squares it into the numerator, so no. Second: does any rule force the output into a special shape? Here it forces a square, so yes. If the answer to the first is no and to the second is yes, the answer to the problem is no, and the shape tells you the invariant. The examiners nudged with the choice of $1/(x(x-1))$ over $1/x$: they took a transitive pair of generators and replaced one of them with a quadratic map, and the square in q^2 is the fingerprint of that replacement.

Revolving concepts

Lowest terms. A rational r has a representation p/q with $\gcd(p,q) = 1$ and $q \geq 1$, and it is unique. Uniqueness is the load bearing fact: it turns an equation between two fractions into an equation between two integer pairs, which is what converts the analytic looking statement $T(x) = n + 2/5$ into the arithmetic statement $5n + 2 = \pm q^2$. See Book 1, field: Number theory, topic: reduced fractions and Euclid's lemma.

Coprimality under shifting. $\gcd(p-q,q) = \gcd(p,q)$, because the ideal generated by $\{p,q\}$ equals the one generated by $\{p-q,q\}$. This is the same one line fact that makes the Euclidean algorithm work, and here it is what makes T output an already reduced fraction. See Book 1, field: Number theory, topic: gcd identities.

Quadratic residues. For an odd prime p, exactly $(p-1)/2$ of the nonzero classes modulo p are squares. Euler's criterion says $a^{(p-1)/2} \equiv \pm 1 \pmod{p}$ according as a is or is not a residue, and the Legendre symbol is multiplicative. The first supplement, $(-1/p) = 1$ exactly when $p \equiv 1 \pmod 4$, is the fact that selects 5 over 3 here. The second supplement, $(2/p) = 1$ exactly when $p \equiv \pm 1 \pmod 8$, is the natural next fact to install. See Book 1, field: Number theory, topic: quadratic residues.

Closure as recursion. The set generated by a seed under a family of maps is a recursion: $S_0 = \{0\}$ and $S_{k+1} = S_k \cup (S_k + 1) \cup (S_k - 1) \cup T(S_k \setminus \{0,1\})$, with $S = \bigcup_k S_k$. Generalised: for any seed A and any family of partial maps $\{f_i\}$ on a set X, the generated set is the least fixed point of $X \mapsto A \cup \bigcup_i f_i(X)$, computed as the union of the iterates. There are exactly two proof techniques for it. To prove the closure is everything, exhibit a complexity measure strictly decreased by some composite of the maps and induct. To prove it is not everything, exhibit one set containing A and closed under every f_i. Every problem of this family, including the reachability problems on lattices, on the integers under two affine maps, and on states of a token game, is attacked with this same pair. See Book 1, field: Logic and set theory, topic: least fixed points and invariants.

Transitivity of translation and inversion. The maps $x \mapsto x+1$ and $x \mapsto 1/x$ generate a group acting transitively on $\mathbb{Q} \cup \{\infty\}$, which is the group theoretic content of the continued fraction algorithm. Recognising when a problem is and is not that situation is worth more than any single computation here. See Book 1, field: Number theory, topic: continued fractions and $\mathrm{SL}_2(\mathbb{Z})$.

Circuit Bank

- **WHEN** a question asks whether a closure of a seed under given rules is everything **DO** spend sixty seconds hunting a descent, and if no rule reduces a complexity measure, switch to

constructing one closed proper superset **BECAUSE** the closure is a least fixed point, so a single closed superset settles the question, while a yes needs a full algorithm

- **WHEN** a rule acts on rationals **DO** substitute $x = p/q$ in lowest terms, simplify to a single fraction, and check whether the output is automatically reduced **BECAUSE** all arithmetic content of a rational lives in its reduced pair, and coprimality of the output is what makes its numerator modulo its denominator well defined
- **WHEN** a numerator or denominator is forced to be a perfect square **DO** ask which residue classes are then unattainable, that is, reach for quadratic residues **BECAUSE** squares occupy about half the classes modulo an odd prime, so they are the cheapest source of an impossibility
- **WHEN** you need a class m modulo n with both m and $-m$ non residues **DO** take $n \equiv 1 \pmod 4$, the smallest being $n = 5$ with $m = 2$ **BECAUSE** -1 is a square modulo n exactly then, so residue status is preserved by negation and one non residue does both jobs
- **WHEN** a problem uses a map that resembles a Mobius map but is not one **DO** check its degree before assuming transitivity **BECAUSE** translations together with $x \mapsto 1/x$ act transitively on $\mathbb{Q}$, so any departure from degree one is the setter switching that transitivity off

Backtesting

1. First useful cue: rule (b) is a translation, so it cannot change the denominator; therefore rule (c) carries the entire question.
2. Method the expression suggested: substitute $x = p/q$ in lowest terms into $1/(x(x-1))$ and read the output, which is $q^2/(p(p-q))$ with a squared numerator and automatically coprime parts.
3. Where you would hesitate, and the thought to reinforce: at the sign of D. Reinforce that a negative denominator flips the numerator's sign, hence both m and $-m$ must be non residues, hence the modulus must have -1 as a square, hence 5 and not 3.
4. The trap the question sets: the resemblance to the continued fraction generators, which pulls you into an hour of attempted descent. The map is quadratic; there is no inverse step.
5. What makes you recognise it faster next time: a "must it be everything" closure question in which one rule is a translation. That combination means the invariant is a class modulo 1, and the only work is to find which classes the other rule can output.
6. The reusable decision rule: to disprove a closure claim, do not track what is generated; compute the general form of the generating map and read off which shapes it can never produce.

Mirror drills

1. Let $S \subseteq \mathbb{Q}$ contain 0 and be closed under $x \mapsto x \pm 1$ and under $x \mapsto 1/x$ for $x \neq 0$. Show $S = \mathbb{Q}$. *Answer:* induct on the reduced denominator q. If $q \geq 2$, translate p/q to r/q with $0 < r < q$, then invert to q/r, whose denominator r is smaller; the base case $q = 1$ is the integers, all reachable from 0.
2. Show that no element of S in the problem above need have reduced form $p/5$ with $p \equiv \pm 2 \pmod 5$. *Answer:* the same claim, with $5n+2$ replaced by $5n \pm 2$; both force $q^2 \equiv \pm 2 \pmod 5$, and $2, 3$ are not squares modulo 5.
3. For which odd primes p is the congruence $x^2 \equiv 2 \pmod p$ solvable? *Answer:* exactly for $p \equiv \pm 1 \pmod 8$, by the second supplement to quadratic reciprocity.

17.5 A5. Product of all element orders in an abelian group

Is there a finite abelian group G such that the product of the orders of all its elements is 2^{2009}?

Read it out loud

A finite abelian group is handed to you with no other structure, and you are asked about a single global statistic: the product of $\mathrm{ord}(g)$ over every $g \in G$. Read the structure verbally: a multiplicative statistic of a finite abelian group, and a specific target value that is a power of 2. The fields wired in are the classification of finite abelian groups, elementary counting of elements by order, and the arithmetic of congruences. What is being tested is whether you convert a product into a sum, whether you know how to sum a function of $\mathrm{ord}(g)$ over a group, and whether you look for a congruence obstruction before attempting an exact solve.

The first two moves should be on paper within thirty seconds. First, take the 2-adic valuation: write $\prod_{g\in G} \mathrm{ord}(g) = 2^{k(G)}$ where $k(G) = \sum_{g\in G} v_2(\mathrm{ord}\, g)$, and the question becomes: is $k(G) = 2009$ possible? Products of orders are unmanageable; sums of valuations are additive over any partition of G, and partitions are the only tool you have. Second, notice that each $\mathrm{ord}(g)$ is one of the factors of the product 2^{2009}, so each $\mathrm{ord}(g)$ divides 2^{2009}. Every element has 2-power order for free, without invoking anything.

Then compute the statistic on the smallest examples, because a target of 2009 is far too large to reach by construction and the only realistic outcome is an obstruction. The trivial group gives $k = 0$; $\mathbb{Z}/2$ gives $k = 1$; $(\mathbb{Z}/2)^2$ gives $k = 3$; $\mathbb{Z}/4$ gives $k = 0 + 2 + 1 + 2 = 5$; $(\mathbb{Z}/2)^3$ gives $k = 7$; $\mathbb{Z}/2 \times \mathbb{Z}/4$ gives $k = 11$; $\mathbb{Z}/8$ gives $k = 17$. The list $0, 1, 3, 5, 7, 11, 17, \ldots$ has a visible hole: no value is congruent to 2 modulo 4. That is the shape of the answer. Note also that k is not additive across direct products, since $k(\mathbb{Z}/2 \times \mathbb{Z}/4) = 11 \neq 1 + 5$, which kills any attempt to build a group factor by factor.

Finally, read the year as data. $2009 = 7^2 \cdot 41$, and more to the point $2009 \equiv 1 \pmod 4$. The setter chose a target in the residue class that forces the tightest branch of the argument, and you should compute that residue before anything else.

Approaches, ranked worst to best

1. **Construct a group by assembling cyclic factors.** *Cue:* the question says "is there", which invites a construction. *Circuit:* choose exponents $e_1, e_2, \ldots$ and tune them until the statistic hits the target. The worst route, because the statistic is not additive over direct products: adding one $\mathbb{Z}/2$ factor doubles the number of elements and changes every order count. The search space has no local structure to exploit and you learn nothing from a failed attempt.

2. **Tabulate small cases and conjecture.** *Cue:* a statistic with an unfamiliar definition. *Circuit:* compute $k(G)$ for every abelian 2-group of small order and look at the list of attainable values. Genuinely useful and correctly ranked in the middle: it produces the observation that $k \equiv 2 \pmod 4$ never occurs and points you at the modulus 4. It is data, not proof, and by hand it costs several minutes.

3. **Structure theorem plus a filtration count.** *Cue:* "finite abelian" is a classification cue. *Circuit:* write G as a product of $(\mathbb{Z}/2^i)^{e_i}$, count elements of order at most 2^m as 2^{s_m} with $s_m = \sum_i \min(i, m)e_i$, and sum $k(G) = \sum_i i(2^{s_i} - 2^{s_{i-1}})$. Correct, and it is the published route. It costs a page of index juggling and delivers divisibility of $k(G) + 1$ by 2^{s_1}, which is more than the problem needs. Ranked below the best route purely on ink.

4. **Partition by generated cyclic subgroup, then read modulo 4.** *Cue:* you are summing a function of $\mathrm{ord}(g)$ over a group. *Circuit:* elements generating the same cyclic subgroup have the same order, so $\sum_g F(\mathrm{ord}\, g) = \sum_C \varphi(|C|)F(|C|)$ over cyclic subgroups C. The best route.

Each cyclic subgroup of order 2^h contributes $h\varphi(2^h) = h2^{h-1}$, which is divisible by 4 for every $h \geq 2$. So modulo 4 only the subgroups of order 2 survive, the count collapses to a single number, and that number is $2^e - 1$ because the elements of order dividing 2 form a vector space over $\mathbb{F}_2$. Four lines to the obstruction.

The ideal solution

The answer is $\boxed{\text{No}}$.

Suppose G is a finite abelian group with $\prod_{g \in G} \operatorname{ord}(g) = 2^{2009}$.

Step 1: every element has 2-power order. Each $\operatorname{ord}(g)$ is one of the factors in the product, and all factors are positive integers, so $\operatorname{ord}(g)$ divides 2^{2009} and is therefore a power of 2. Consequently $\prod_g \operatorname{ord}(g) = 2^{k(G)}$ with

$$k(G) = \sum_{g \in G} v_2(\operatorname{ord} g),$$

and G is a finite abelian 2-group. We must show $k(G) = 2009$ is impossible.

Step 2: sum over cyclic subgroups. Declare $g \sim h$ when $\langle g \rangle = \langle h \rangle$. This is an equivalence relation, and the class of g is exactly the set of generators of the cyclic group $\langle g \rangle$. A cyclic group of order 2^h has $\varphi(2^h)$ generators, each of order 2^h; for $h \geq 1$ that is 2^{h-1} generators, and for $h = 0$ the class is the identity, contributing 0. Writing c_h for the number of cyclic subgroups of G of order 2^h,

$$k(G) = \sum_{h \geq 1} h\, \varphi(2^h)\, c_h = \sum_{h \geq 1} h\, 2^{h-1} c_h.$$

Step 3: reduce modulo 4. For $h = 2$ the coefficient is $2 \cdot 2 = 4$, and for $h \geq 3$ it is $h2^{h-1}$ with 2^{h-1} divisible by 4. So every term with $h \geq 2$ vanishes modulo 4, and

$$k(G) \equiv c_1 \pmod 4.$$

Since a subgroup of order 2 has exactly one generator, c_1 is the number of elements of G of order exactly 2.

Step 4: count the elements of order 2. The set $G[2] = \{g \in G : g^2 = e\}$ is a subgroup because G is abelian, and every non identity element of it has order 2. Hence $G[2]$ is a vector space over $\mathbb{F}_2$, so $|G[2]| = 2^e$ for some integer $e \geq 0$, and

$$c_1 = 2^e - 1.$$

Step 5: the congruence forces $e = 1$. We need $k(G) = 2009 \equiv 1 \pmod 4$, so $2^e - 1 \equiv 1 \pmod 4$, that is $2^e \equiv 2 \pmod 4$. If $e = 0$ then $2^e - 1 = 0 \equiv 0$; if $e \geq 2$ then $2^e \equiv 0$ and $2^e - 1 \equiv 3$. So $e = 1$.

Step 6: $e = 1$ forces G cyclic. By the structure theorem for finite abelian groups, $G \cong \prod_{j=1}^{r} \mathbb{Z}/2^{a_j}\mathbb{Z}$ with each $a_j \geq 1$. Each factor contributes exactly one element of order 2 to $G[2]$ together with the identity, so $G[2] \cong (\mathbb{F}_2)^r$ and $e = r$. Hence $r = 1$ and $G \cong \mathbb{Z}/2^i\mathbb{Z}$ for some $i \geq 1$.

Step 7: evaluate k on a cyclic 2-group. A cyclic group of order 2^i has exactly one subgroup of each order 2^h with $0 \leq h \leq i$, so $c_h = 1$ for those h and $c_h = 0$ otherwise. Therefore

$$k(\mathbb{Z}/2^i\mathbb{Z}) = \sum_{h=1}^{i} h\, 2^{h-1} = (i-1)2^i + 1.$$

The closed form follows by induction: it holds for $i = 1$ since both sides equal 1, and

$$\big((i-1)2^i + 1\big) + (i+1)2^i = 2i \cdot 2^i + 1 = i \cdot 2^{i+1} + 1,$$

which is the formula for $i + 1$.

Step 8: solve. We need $(i-1)2^i + 1 = 2009$, that is

$$(i-1)2^i = 2008 = 2^3 \cdot 251,$$

with 251 prime. Taking 2-adic valuations, $v_2\big((i-1)2^i\big) = i + v_2(i-1) \geq i$, while $v_2(2008) = 3$; hence $i \leq 3$. But for $i = 1, 2, 3$ the left side is 0, 4, 16 respectively, none of which is 2008. Contradiction.

Therefore no finite abelian group has the product of the orders of its elements equal to 2^{2009}.

Remark 17.5.1. The same computation says more. Since $k(G) \equiv 2^e - 1 \pmod 4$, the value $k(G)$ is never congruent to 2 modulo 4, so 2^n with $n \equiv 2 \pmod 4$ is never such a product either. And when $n \equiv 1 \pmod 4$ the group is forced to be cyclic, so the only attainable such values are $n = (i-1)2^i + 1$, namely $1, 5, 17, 49, 129, 321, 769, 1793, 4097, \ldots$, and 2009 sits in the gap between 1793 and 4097.

Layer 1: WHAT

Block 1. Take v_2 of the target: the multiplicative question becomes $k(G) = \sum_g v_2(\operatorname{ord} g) = 2009$.

Block 2. Each order divides the product, so every element has 2-power order; no classification theorem is needed for this step.

Block 3. Compute k on the smallest groups and notice that no value is 2 mod 4; the obstruction will be a congruence modulo 4.

Block 4. Choose the summation technique: partition G by the cyclic subgroup each element generates, since ord is constant on those classes and the class sizes are φ values.

Block 5. Reduce modulo 4: every cyclic subgroup of order at least 4 contributes a multiple of 4, so only the elements of order 2 survive.

Block 6. Count those: $G[2]$ is an $\mathbb{F}_2$ vector space, so there are $2^e - 1$ of them.

Block 7. $2009 \equiv 1 \pmod 4$ forces $e = 1$, hence G cyclic by the structure theorem.

Block 8. Evaluate $k(\mathbb{Z}/2^i) = (i-1)2^i + 1$ and kill $(i-1)2^i = 2008$ with a valuation count.

The nominal route is Block 1, then straight to the structure theorem: write down the exponents e_i, derive the exact formula for $k(G)$ in terms of them, and try to solve $k = 2009$ over all admissible exponent vectors. That is a genuine solution and it is heavy. The bifurcation point is Block 3 into Block 5: the decision to compute the statistic modulo 4 rather than exactly. The zombie tries to solve an equation; you first ask which residues the left hand side can occupy, and the equation dissolves into a single very restricted case.

Layer 2: HOW

Block 1. Cue. A product over all elements of a group, equal to a prime power. **Why natural.** Products over large index sets carry no leverage, because nothing you know about groups is multiplicative in that way. Valuations turn products into sums, and sums split along any partition of the index set. Since the target is a power of 2, the valuation to take is v_2. **Link to the next block.** Once the object is a sum of $v_2(\operatorname{ord} g)$, the next question is automatically "how do I sum a function of the order over a group".

Block 2. Cue. The target 2^{2009} has only 2 as a prime factor. **Why natural.** Each $\operatorname{ord}(g)$ appears as a factor of the product, and a positive integer factor of 2^{2009} is a power of 2. This is one line and it removes all odd primes without Cauchy's theorem, without the structure theorem, and without the phrase "we may assume". **Link to the next block.** Now every order is 2^h, so the sum $k(G)$ is a sum over cyclic 2-subgroups waiting to be organised.

Block 3. Cue. A target of 2009, far beyond anything you can construct by hand. **Why natural.** When a target is large and the objects are rigid, the realistic answers are "no, by congruence" or "yes, by an explicit family". Small case data distinguishes the two in two minutes. The values $0, 1, 3, 5, 7, 11, 17$ have a gap at 2 mod 4, which names the modulus before you have proved anything.

Link to the next block. You now know the target modulus is 4, so you need a summation identity precise enough to be read modulo 4.

Block 4. Cue. A sum of a function of $\operatorname{ord}(g)$ over all g in a finite abelian group. **Why natural.** The order is constant on the set of generators of a fixed cyclic subgroup, and those sets partition G: every g generates exactly one cyclic subgroup. That gives $\sum_g F(\operatorname{ord} g) = \sum_C \varphi(|C|)F(|C|)$, the same partition that proves $\sum_{d|n} \varphi(d) = n$. This is the standard organisation of any order weighted sum, so it is a reflex, not an inspiration. **Link to the next block.** The coefficients $h\varphi(2^h) = h2^{h-1}$ are now explicit, so their residues modulo 4 can be read off.

Block 5. Cue. Coefficients $h2^{h-1}$ with a factor of 2^{h-1} growing. **Why natural.** Modulo 4, the terms $h \geq 3$ die because $4 \mid 2^{h-1}$, and $h = 2$ dies because $2 \cdot 2 = 4$. Only $h = 1$ survives, with coefficient 1. That is why 4 is the correct modulus and not 2: modulo 2 the same computation gives only "k is odd", which 2009 satisfies, so no obstruction. Modulo 8 the terms $h = 2, 3$ both survive and the identity becomes messier. Four is the unique modulus at which the sum collapses to one count. **Link to the next block.** The survivor is the number of elements of order 2, so that number must now be computed.

Block 6. Cue. The set of elements killed by 2, in an abelian group. **Why natural.** Because G is abelian, $\{g : g^2 = e\}$ is closed under the group operation, and every element of it satisfies $g^2 = e$, which is exactly the axiom that makes it a vector space over $\mathbb{F}_2$ with scalar multiplication by 0 and 1. Vector spaces over $\mathbb{F}_2$ have 2^e elements. No classification is needed here either. **Link to the next block.** The congruence now reads $k(G) \equiv 2^e - 1 \pmod 4$, and the target's residue class selects e.

Block 7. Cue. $2009 \equiv 1 \pmod 4$ and $2^e - 1 \in \{0, 1, 3\} \bmod 4$. **Why natural.** The three cases $e = 0$, $e = 1$, $e \geq 2$ give 0, 1, 3 respectively, so the target residue 1 pins $e = 1$ exactly. A group with a unique subgroup of order 2 has exactly one cyclic factor, which is where the structure theorem finally earns its place. **Link to the next block.** One family remains, and it is a one parameter family, so the problem is now an equation in a single integer.

Block 8. Cue. A one parameter equation $(i - 1)2^i = 2008$ with a large power of 2 on the left. **Why natural.** Do not test values of i; count valuations. The left side has $v_2 \geq i$ and the right side has $v_2 = 3$, so $i \leq 3$, and three arithmetic checks finish. Reading the equation 2-adically is faster than tabulating and it is immune to arithmetic slips. **Link to the next block.** Nothing remains; the contradiction is complete.

Layer 3: WHY

The first truth is that statistics summed over a group should be summed over the classes of an equivalence relation on which the summand is constant. Here ord is constant on the generator set of each cyclic subgroup, and those generator sets partition G exactly. That single identity,

$$\sum_{g \in G} F(\operatorname{ord} g) = \sum_d \varphi(d) F(d) c_d,$$

where c_d counts cyclic subgroups of order d, is the engine of the whole solution, and it is the same identity as $\sum_{d|n} \varphi(d) = n$ read backwards. Once you have it, the problem is no longer about groups; it is about a weighted count.

The second truth is that existence questions with an arithmetic target are killed by congruences, and the correct modulus is the one that annihilates every term but one. That is a search you can carry out consciously: the coefficient of the h-th family is $h2^{h-1}$, so ask for the largest modulus

dividing $h2^{h-1}$ for all $h \geq 2$ but not for $h = 1$. The answer is 4. Choosing a modulus by inspecting the coefficients is a repeatable procedure, not luck.

The third truth is that the residue class of the target does real work. Modulo 4 the attainable residues of k are 0, 1 and 3, corresponding to the trivial group, the groups with a unique involution, and everything else. A target congruent to 2 dies instantly. A target congruent to 3 leaves a huge family open and the problem would need a different idea. A target congruent to 1, which is what 2009 is, collapses the family to the cyclic groups, where an exact formula is available. The setter picked the year and then picked the residue class that makes the problem solvable in a page, and reading 2009 mod 4 in the first thirty seconds tells you which of the three worlds you are in.

The discernment to train is the pair of habits: convert products to sums with a valuation, and never solve an exact equation for a large target before checking small moduli. In this problem both habits are visible in the write up as a single line each, which is exactly why the solution looks short. What makes the route ideal is not that it avoids the structure theorem, since it uses it at Step 6; it is that it postpones the structure theorem until only one parameter is left, so the classification is applied to a question with a one line answer instead of to a search over exponent vectors.

Revolving concepts

Order of an element and p-adic valuation. $\operatorname{ord}(g)$ is the least $n \geq 1$ with $g^n = e$, and $g^m = e$ if and only if $\operatorname{ord}(g) \mid m$. The valuation $v_p(n)$ is the exponent of p in n; v_p turns products into sums, which is the only reason this problem is tractable. See Book 1, field: Abstract algebra, topic: element orders.

Generators of a cyclic group. A cyclic group of order n has $\varphi(n)$ generators, and exactly one subgroup of each order dividing n. Partitioning G by generated cyclic subgroup and counting gives $\sum_{d \mid n} \varphi(d) = n$ for cyclic G, and the weighted version used above in general. See Book 1, field: Abstract algebra, topic: cyclic groups and Euler's totient.

Elementary abelian groups. An abelian group in which every element satisfies $g^p = e$ is a vector space over $\mathbb{F}_p$, so it has p^e elements and $p^e - 1$ elements of order exactly p. This converts a counting question into a dimension. See Book 1, field: Abstract algebra, topic: elementary abelian p-groups.

Structure theorem for finite abelian groups. Every finite abelian group is a direct product of cyclic groups of prime power order, uniquely up to reordering. Consequence used here: the number of cyclic factors of a finite abelian 2-group equals $\dim_{\mathbb{F}_2} G[2]$, so a unique involution forces cyclicity. This is the one genuinely beyond A-level input, and it must be installed before any Putnam group theory problem. See Book 1, field: Abstract algebra, topic: classification of finite abelian groups.

The recursion behind $k(\mathbb{Z}/2^i)$, generalised. The counts satisfy $k_i = k_{i-1} + i2^{i-1}$ with $k_0 = 0$, a first order linear recursion with an inhomogeneous term of the form ix^{i-1}. The general solution method is to sum the inhomogeneity directly using

$$\sum_{h=1}^{i} hx^{h-1} = \frac{d}{dx}\left(\frac{x^{i+1}-1}{x-1}\right) = \frac{ix^{i+1} - (i+1)x^i + 1}{(x-1)^2},$$

which at $x = 2$ gives $(i-1)2^i + 1$. The same differentiate the geometric series move solves every $\sum hx^h$ and $\sum h^2x^h$ that appears in generating function work. For a general prime the same partition gives

$$k_p(\mathbb{Z}/p^i) = \sum_{h=1}^{i} h\left(p^h - p^{h-1}\right) = ip^i - \frac{p^i - 1}{p-1},$$

by Abel summation, and the case $p = 2$ is the formula used above. See Book 1, field: Sequences and recurrences, topic: summing $\sum hx^h$ by differentiating a geometric series.

Circuit Bank

- **WHEN** a problem gives a product over all elements of a group **DO** take the p-adic valuation to convert it into a sum, then sum over classes of an equivalence on which the summand is

constant **BECAUSE** products over large index sets have no structure, while sums split along any partition, and the natural partition here is by generated subgroup

- **WHEN** you must evaluate $\sum_{g \in G} F(\operatorname{ord} g)$ **DO** partition by generated cyclic subgroup to obtain $\sum_d \varphi(d) F(d) c_d$ with c_d the number of cyclic subgroups of order d **BECAUSE** the order is constant on generator sets, the generator sets partition the group, and a cyclic group of order d has $\varphi(d)$ generators
- **WHEN** you must show a specific large value of a statistic is unattainable **DO** compute the statistic modulo the smallest modulus that annihilates every family of terms but one **BECAUSE** existence questions with arithmetic targets die to congruences, and the right modulus is visible in the coefficients rather than guessed
- **WHEN** a finite abelian group has all elements killed by a prime p **DO** treat it as a vector space over $\mathbb{F}_p$ **BECAUSE** the group axioms plus $g^p = e$ are exactly the axioms of an $\mathbb{F}_p$ vector space, so the size is p^e and the count of elements of order p is $p^e - 1$
- **WHEN** the target number in a problem is the year **DO** compute its factorisation and its residues modulo 4 and 8 before starting **BECAUSE** the setter chose the year and then chose the statement that its residue class makes provable, so the residue tells you which branch of the argument is intended

Backtesting

1. First useful cue: the target is a prime power, so take v_2 and turn the product of orders into the sum $k(G) = \sum_g v_2(\operatorname{ord} g)$; and every order divides the product, so every element has 2-power order for free.
2. Method the expression suggested: sum over cyclic subgroups, since ord is constant on generator sets and each class has $\varphi(2^h) = 2^{h-1}$ elements.
3. Where you would hesitate, and the thought to reinforce: at the choice of modulus. Reinforce that modulo 2 the identity says only that k is odd, which 2009 is, so the modulus must be 4; the coefficients $h2^{h-1}$ tell you this directly.
4. The trap the question sets: the word "abelian" invites an immediate structure theorem expansion and a search over exponent vectors, which is a page of work before any obstruction appears.
5. What makes you recognise it faster next time: any statistic of the form "combine $\operatorname{ord}(g)$ over all g" should trigger the cyclic subgroup partition instantly, exactly as $\sum_{d \mid n} \varphi(d) = n$ does.
6. The reusable decision rule: before solving an exact equation for a large target, reduce the attainable values modulo a small number chosen to kill all but one family of terms.

Mirror drills

1. Show that no finite abelian group has the product of the orders of its elements equal to 2^n with $n \equiv 2 \pmod 4$. *Answer:* $k(G) \equiv 2^e - 1 \pmod 4$, which lies in $\{0, 1, 3\}$, never 2.
2. Compute the product of the orders of all elements of $\mathbb{Z}/2 \times \mathbb{Z}/4$. *Answer:* orders are $1, 2, 2, 2, 4, 4, 4, 4$, so the product is 2^{11}.
3. For an odd prime p, find the product of the orders of all elements of $\mathbb{Z}/p^i$. *Answer:* p^K with $K = \sum_{h=1}^{i} h(p^h - p^{h-1}) = ip^i - \frac{p^i - 1}{p - 1}$.

17.6 A6. Disproving a two variable mean value theorem

Let $f : [0,1]^2 \to \mathbb{R}$ be a continuous function on the closed unit square such that $\dfrac{\partial f}{\partial x}$ and $\dfrac{\partial f}{\partial y}$ exist and are continuous on the interior $(0,1)^2$. Let

$$a = \int_0^1 f(0,y)\,dy, \quad b = \int_0^1 f(1,y)\,dy, \quad c = \int_0^1 f(x,0)\,dx, \quad d = \int_0^1 f(x,1)\,dx.$$

Prove or disprove: there must be a point (x_0, y_0) in $(0,1)^2$ such that

$$\frac{\partial f}{\partial x}(x_0,y_0) = b - a \quad \textit{and} \quad \frac{\partial f}{\partial y}(x_0,y_0) = d - c.$$

Read it out loud

Read the hypotheses first, because they are a quotation. Continuous on a closed region, differentiable on the interior, conclusion asserting the existence of an interior point where a derivative equals a difference of boundary data: that is the mean value theorem, transposed to two variables. The fields wired in are multivariable calculus (partial derivatives, the fundamental theorem of calculus, Fubini), real analysis (the intermediate value theorem, connectedness, convexity), and counterexample construction. The command term "prove or disprove" means the setter is not telling you which, so your first job is to decide, and deciding is most of the problem.

Now read the four constants structurally rather than as four separate integrals. For f that is C^1 on a neighbourhood of the square,

$$b - a = \int_0^1 \big(f(1,y) - f(0,y)\big)dy = \int_0^1\int_0^1 \frac{\partial f}{\partial x}(x,y)\,dx\,dy,$$

by the fundamental theorem of calculus inside and Fubini outside, and symmetrically $d - c$ is the double integral of $\partial f/\partial y$. So $(b-a, d-c)$ is nothing other than the average value of the gradient ∇f over the square. The assertion says: the average of the gradient is attained as an actual value of the gradient at some interior point. Write that sentence down within thirty seconds; the entire problem is contained in it.

Once it is written, the decision is immediate. For a scalar continuous function on a connected set, the average is attained, because the image is an interval containing values on both sides of the average, and the intermediate value theorem finishes. For a vector valued function this argument dies, because the continuous image of a connected set in $\mathbb{R}^2$ is connected but need not be convex, while the average is only guaranteed to lie in the closed convex hull of the image. Connected sets in the plane can have holes, and an average can sit in a hole. The statement is therefore false, and the counterexample must be a function whose gradient image is a connected set with the average sitting in a hole.

There is a second confirmation available for free. The one variable version of this false statement is the mean value theorem for vector valued functions, and its standard failure is $\gamma(t) = (\cos t, \sin t)$ on $[0, 2\pi]$: the average velocity is zero, and γ' is never zero because cosine and sine have no common zero. That object is the template for the counterexample you are about to build.

Approaches, ranked worst to best

1. **Topological existence proof.** *Cue:* two equations in two unknowns with a demanded solution. *Circuit:* apply a degree, winding number or Poincare and Miranda type argument to the map $(x,y) \mapsto (f_x - (b-a), f_y - (d-c))$. The worst route, and dangerous because the cue is real. There is no control of the gradient on the boundary, so no hypothesis of the required type is available, and the statement is false in any case. This can absorb an hour and produce nothing.

2. **Iterated mean value theorem.** *Cue:* the hypotheses are literally the mean value theorem hypotheses. *Circuit:* apply the one variable mean value theorem in x to the y averaged function, then again in y. This does not prove the statement, but it is not wasted. It shows that each equation alone is always solvable: there is a point where $f_x = b - a$ and a point where $f_y = d - c$. The route fails precisely at synchronisation, which is exactly the information you need to know that simultaneity is the content and where to attack.
3. **Random search among small polynomials.** *Cue:* "prove or disprove" with a whiff of falsity. *Circuit:* write down a family such as $\alpha x^2 + \beta xy + \gamma y^2 + \dots$, compute the four constants, and hunt for a member with no solution. It works, and the published counterexample $3(1+y)(2x-1)^2 - y$ is of this shape. It costs four integrals per candidate and gives no reason, so you cannot reproduce it under pressure on a different problem.
4. **Normalise, then quote the standard pathology.** *Cue:* the conclusion is an equation $\nabla f = v$ for a fixed vector v, and the constants are the average of ∇f. *Circuit:* subtract the linear function $v \cdot (x, y)$ to reduce to $v = 0$, so that the claim becomes "f must have an interior critical point", then build a gradient that rotates without vanishing, copying $(\cos, \sin)$. The best route. The search space collapses to one design constraint, and the verification is four integrals that are zero by inspection.

The ideal solution

The assertion is $\boxed{\text{false}}$, and the following function disproves it.

Take

$$f(x, y) = y \sin(2\pi x).$$

It is a product of a polynomial in y and a smooth function of x, hence C^∞ on all of $\mathbb{R}^2$; in particular it is continuous on $[0,1]^2$ and its two partial derivatives exist and are continuous on $(0,1)^2$, so it satisfies every hypothesis.

The four constants. Since $\sin 0 = \sin 2\pi = 0$,

$$a = \int_0^1 y \sin 0 \, dy = 0, \qquad b = \int_0^1 y \sin 2\pi \, dy = 0,$$

and

$$c = \int_0^1 0 \cdot \sin(2\pi x) \, dx = 0, \qquad d = \int_0^1 \sin(2\pi x) \, dx = \left[\frac{-\cos 2\pi x}{2\pi} \right]_0^1 = 0.$$

Hence $b - a = 0$ and $d - c = 0$, so the assertion, applied to this f, claims the existence of $(x_0, y_0) \in (0,1)^2$ with

$$\frac{\partial f}{\partial x}(x_0, y_0) = 0 \quad \text{and} \quad \frac{\partial f}{\partial y}(x_0, y_0) = 0.$$

No such point exists. The partial derivatives are

$$\frac{\partial f}{\partial x}(x, y) = 2\pi y \cos(2\pi x), \qquad \frac{\partial f}{\partial y}(x, y) = \sin(2\pi x).$$

Suppose $(x_0, y_0) \in (0,1)^2$ satisfies both equations. From $\sin(2\pi x_0) = 0$ with $0 < x_0 < 1$ we get $2\pi x_0 = \pi$, so $x_0 = \frac{1}{2}$. Then $\cos(2\pi x_0) = \cos \pi = -1$, so the first equation reads $-2\pi y_0 = 0$, giving $y_0 = 0$. But $y_0 = 0$ is not in $(0,1)$. Contradiction.

Therefore there is no point of the open square at which both equations hold, and the assertion is disproved.

Remark 17.6.1. The gradient of this f never vanishes anywhere in the open square, because cos and sin have no common zero. For fixed $y \in (0,1)$, as x runs over $(0,1)$ the point $\nabla f(x, y) = (2\pi y \cos 2\pi x, \sin 2\pi x)$ traverses the ellipse with semi axes $2\pi y$ and 1 centred at the origin. So the

image of ∇f is a union of ellipses about the origin, a connected set with the origin missing from it: the average of the gradient sits in a hole of the gradient's image. That is the whole mechanism, and it is the two variable version of the circle $(\cos t, \sin t)$ that defeats the mean value theorem for vector valued functions.

Remark 17.6.2. Each equation separately is always satisfiable when f is C^1 on a neighbourhood of the square. Put $F(x) = \int_0^1 f(x,y)\,dy$; then F is differentiable with $F'(x) = \int_0^1 f_x(x,y)\,dy$, and the mean value theorem gives $\xi \in (0,1)$ with $\int_0^1 f_x(\xi,y)\,dy = F(1) - F(0) = b - a$. The continuous function $y \mapsto f_x(\xi,y)$ has average $b-a$, so by the intermediate value theorem it equals $b-a$ somewhere. The same works for the other partial. What fails is only that the two points need not coincide, and that is exactly what the counterexample exploits.

Layer 1: WHAT

Block 1. Recognise the hypotheses as the mean value theorem transposed to a square, and the conclusion as a statement about a common point.

Block 2. Convert the four constants: $b-a$ and $d-c$ are the averages of f_x and f_y over the square, so the claim is that the average of ∇f is a value of ∇f.

Block 3. Decide truth. The scalar version is true by the intermediate value theorem; the vector version fails because a connected planar image need not be convex, and the one variable failure $(\cos t, \sin t)$ is already on record. Commit to disproving.

Block 4. Normalise. Replacing f by $g = f - (b-a)x - (d-c)y$ shifts the gradient by a constant and makes both averages zero, so it suffices to find f with $a = b$, $c = d$ and no interior critical point.

Block 5. Design. Force the gradient to rotate without vanishing: use sin and cos in the same variable, so that the two partials cannot vanish together, and use a period over $[0,1]$ so that the boundary integrals vanish by periodicity.

Block 6. Land on $f(x,y) = y\sin(2\pi x)$; compute the four constants, all zero; solve the gradient system and find the only solution has $y_0 = 0$, outside the open square.

Block 7. Write up: hypotheses checked, constants computed, system eliminated in two lines.

The nominal route is Block 1 followed by an attempt to prove the statement, either by iterating the mean value theorem or by a fixed point argument, and it can consume the whole session because the hypotheses look so much like a theorem. The bifurcation point is the single line at Block 3: *is this even true?* Everything before it is shared; everything after it diverges completely. Note where the ideal route spends its effort: not on the proof, which is six lines, but on the two minutes of structural reading that convert the four constants into one sentence about averages.

Layer 2: HOW

Block 1. Cue. Continuous on a closed region, differentiable on the interior, conclusion asserting an interior point. **Why natural.** That triple is the signature of the mean value theorem, and a setter who writes hypotheses in a familiar shape is telling you which theorem the problem is about. Recognising the quotation does not tell you the statement is true; it tells you which true theorem to compare it against, and comparison is how you decide. **Link to the next block.** If this is a mean value theorem, then the four constants must be playing the role of $f(b) - f(a)$, so you should express them as something the derivative produces.

Block 2. Cue. Four boundary integrals, paired as differences $b-a$ and $d-c$. **Why natural.** The pairing is a difference of values of f on opposite edges, averaged over the other variable. A difference of values of f along a segment is an integral of the derivative, by the fundamental theorem of calculus, and averaging over the second variable is another integral, which Fubini lets you combine. The result is not a coincidence of notation: the problem is stated in terms of a, b, c, d

precisely to disguise the fact that $(b-a, d-c)$ is the average gradient. **Link to the next block.** A statement about an average being attained is a statement about the intermediate value theorem, so ask whether the intermediate value theorem is available.

Block 3. **Cue.** An average of a vector valued function claimed to be attained. **Why natural.** For scalar functions on a connected domain the average lies between the infimum and the supremum, and the image is an interval, so the average is attained. In $\mathbb{R}^2$ the only thing continuity gives is that the image is connected, and the average lies in the closed convex hull of the image, which is strictly larger than the image whenever the image is not convex. Since connected planar sets can enclose a hole, the claim is false in general and you should stop looking for a proof. **Link to the next block.** The failure mode is now explicit: build a gradient image that surrounds the target without containing it. The one variable model of that is the circle.

Block 4. **Cue.** The conclusion is $\nabla f = v$ for a fixed vector v determined by f. **Why natural.** Adding a linear function $\ell(x, y) = \alpha x + \beta y$ shifts the gradient by the constant (α, β) and shifts the four constants in a controlled way: with $\alpha = b - a$ and $\beta = d - c$, the new function $g = f - \ell$ has $b_g - a_g = 0$ and $d_g - c_g = 0$, and $\nabla f(P) = v$ if and only if $\nabla g(P) = 0$. So there is no loss in searching only among functions with balanced boundary data, and the target becomes the single point 0. **Link to the next block.** The design problem is now stated in its simplest form: a function on the square with balanced boundary averages and no interior critical point.

Block 5. **Cue.** Two conditions to arrange at once: boundary integrals vanish, gradient never vanishes. **Why natural.** Each has a standard supplier. Vanishing integrals come from a full period of a sine, since $\int_0^1 \sin 2\pi x \, dx = 0$ and $\sin 2\pi \cdot 0 = \sin 2\pi \cdot 1 = 0$, which kills three of the four constants outright. A nonvanishing gradient comes from making the two partials into cos and sin of the same argument, which have no common zero. Both suppliers are the same object, so use $\sin 2\pi x$ and let the second variable enter as the simplest possible factor. There is one more constraint worth naming: a continuous function on the compact square attains a maximum, and an interior maximum is a critical point, so every extremum of your counterexample must sit on the boundary. A factor of y pushes the extremes to the edges $y \in \{0, 1\}$, which is exactly what is needed. **Link to the next block.** The candidate $f(x, y) = y \sin(2\pi x)$ now has to be checked, not invented.

Block 6. **Cue.** A specific candidate. **Why natural.** Verification is mechanical and must be done in full: hypotheses, then the four constants, then the system. The elimination order matters for brevity: solve the partial that involves one variable only, namely $f_y = \sin 2\pi x = 0$, which pins $x_0 = 1/2$ immediately, and substitute into the other. Solving the messier equation first would cost more ink. **Link to the next block.** Nothing remains except to write it in the order a grader reads it.

Block 7. **Cue.** A "prove or disprove" answer. **Why natural.** Full marks needs three things and no more: the example, a confirmation that it satisfies the hypotheses (which candidates that are merely continuous can fail), and a complete demonstration that the conclusion fails for it. No motivation is required in the write up; the normalisation and the design story stay in your head. **Link to the next block.** Done.

Layer 3: WHY

The mathematical truth beneath this problem is the difference between connectedness and convexity. Continuity gives you exactly one thing about images: the continuous image of a connected set is connected. In $\mathbb{R}^1$, connected means interval, and an interval containing points on both sides of a number contains that number; that single sentence is the intermediate value theorem and it is

why every scalar mean value statement in sight is true. In $\mathbb{R}^2$, connected sets can be annuli, so the deduction "the average lies between the extremes, therefore it is attained" has no analogue. The average of a vector valued function lies in the closed convex hull of the image, and the convex hull can be strictly bigger. Every counterexample to a vector mean value statement is built by making the image wrap around its own average.

That explains why the one variable case is already broken. For $\gamma(t) = (\cos t, \sin t)$ on $[0, 2\pi]$ the average velocity is $(\gamma(2\pi) - \gamma(0))/2\pi = 0$, yet $|\gamma'(t)| = 1$ for every t. The two variable statement here is the same failure dressed in boundary integrals: the four constants are a disguise for the average gradient, and the counterexample makes the gradient run around a family of ellipses centred on that average.

The discernment mechanism to train is a three step filter for any "prove or disprove" whose hypotheses quote a known theorem. First, name the theorem being generalised. Second, ask what the generalisation upgrades: scalar to vector, one variable to several, pointwise to uniform, finite to infinite. Third, recall the standard pathology for exactly that upgrade. Scalar to vector upgrades of mean value statements are broken by rotation. One variable to several for the intermediate value theorem survives, because connectedness survives. Pointwise to uniform is broken by moving bumps. Finite to infinite is broken by the shift operator. Each upgrade has a stock counterexample, and knowing the stock list converts a research question into a lookup.

There is one more piece of reading worth doing, on the hypotheses themselves. The problem asks only for continuity on the closed square with continuous partials on the open square. Why weaken it there? Two reasons, both deliberate. It mirrors the mean value theorem's own hypotheses, strengthening the false suggestion that a mean value theorem is coming. And it legalises counterexamples whose partial derivatives blow up at the boundary, such as $x^{1/3}y^{2/3}$, widening the class of solutions the setter will accept. It also quietly blocks the laziest route to the identity $b - a = \iint f_x$: with partials only defined inside, the Fubini and fundamental theorem argument needs care about improper integrals. That is why the ideal solution never uses that identity in the proof and uses it only in the reading. Your written answer computes the four constants directly from a function that is smooth everywhere, so no interchange is ever justified in the arena.

Honest knowledge gaps for this problem, in the order they must be installed: partial derivatives and the gradient of a function of two variables; the double integral and Fubini's theorem for continuous functions on a rectangle; the fundamental theorem of calculus applied along a segment with the other variable fixed; differentiation under the integral sign; the mean value theorem for vector valued functions and why it fails; and the fact that the average of a continuous vector valued function lies in the closed convex hull of its image. None of this is in the A-level further mathematics core, and all of it is standard first year undergraduate analysis. Without partial derivatives and the connectedness versus convexity distinction, this problem is not approachable at all; with them, it is six lines.

Revolving concepts

Mean value theorem and its vector valued failure. For $f : [p, q] \to \mathbb{R}$ continuous on $[p, q]$ and differentiable on (p, q) there is ξ with $f'(\xi) = (f(q) - f(p))/(q - p)$. For $\gamma : [p, q] \to \mathbb{R}^n$ with $n \geq 2$ this fails, the standard witness being the circle. The correct replacements are the mean value inequality $|\gamma(q) - \gamma(p)| \leq (q - p) \sup |\gamma'|$ and the integral form $\gamma(q) - \gamma(p) = \int_p^q \gamma'(t)\, dt$. See Book 1, field: Real analysis, topic: mean value theorems.

The scalar multivariable mean value theorem, which does survive. For f scalar and differentiable on a convex open set, $f(P) - f(Q) = \nabla f(R) \cdot (P - Q)$ for some R on the segment PQ, because restricting to the segment reduces it to one variable. The contrast with the failed statement in this problem is the whole point: scalar output survives, vector output does not. See Book 1, field: Real analysis, topic: multivariable mean value theorem.

Averages, connectedness and convex hulls. If u is continuous and real valued on a connected

compact set K, its average over any probability measure on K is a value of u. If u maps into $\mathbb{R}^n$ with $n \geq 2$, the average lies only in the closed convex hull of $u(K)$. The gap between hull and image is where every counterexample of this type lives. See Book 1, field: Real analysis, topic: intermediate value theorem and convexity.

Boundary data as an integral of the gradient. For f that is C^1 on a neighbourhood of $[0,1]^2$,

$$b - a = \iint_{[0,1]^2} \frac{\partial f}{\partial x}\, dA, \qquad d - c = \iint_{[0,1]^2} \frac{\partial f}{\partial y}\, dA,$$

by the fundamental theorem of calculus in one variable and Fubini in the other. This is the translation that makes the problem readable, and it is a special case of the divergence theorem on a rectangle. See Book 1, field: Calculus and integrals, topic: Fubini and the fundamental theorem of calculus.

Interior extrema are critical points. A continuous function on a compact set attains its extremes; if an extreme is attained at an interior point where f is differentiable, the gradient vanishes there. Hence any counterexample must have all of its extreme values on the boundary of the square, which is a design constraint you can check by eye before computing anything. See Book 1, field: Calculus and integrals, topic: critical points and Fermat's condition.

Normalisation by a linear function. For fixed $v = (\alpha, \beta)$, the substitution $g = f - \alpha x - \beta y$ gives $\nabla g = \nabla f - v$ and changes the boundary constants by $b_g - a_g = (b - a) - \alpha$ and $d_g - c_g = (d - c) - \beta$. Choosing $v = (b - a, d - c)$ reduces any statement of the form "$\nabla f = v$ somewhere" to "$\nabla g = 0$ somewhere". The general principle is that affine substitutions are free and should be used to send the target of a problem to zero before you start constructing. See Book 1, field: Calculus and integrals, topic: normalisation and affine reduction.

Circuit Bank

- **WHEN** a proposed statement demands two conditions at a single common point **DO** check first whether each condition alone is achievable, and if so attack the simultaneity with a counterexample **BECAUSE** the coordinates of a vector valued mean value statement are each true separately, and only the shared point fails, so simultaneity is where the statement is breakable
- **WHEN** the hypotheses of a prove or disprove question quote a known theorem **DO** name the theorem, name what the statement upgrades, and recall the stock pathology for that upgrade **BECAUSE** scalar to vector is broken by rotation, pointwise to uniform by moving bumps, finite to infinite by the shift, and the stock list turns a decision into a lookup
- **WHEN** the conclusion is an equation $\nabla f = v$ **DO** subtract the linear function $v \cdot (x, y)$ to normalise v to zero **BECAUSE** gradients shift by constants under adding linear functions, so the search reduces to functions with balanced boundary data and no interior critical point
- **WHEN** you need a construction with prescribed vanishing integrals **DO** insert a full period of a sine in the relevant variable **BECAUSE** integrating a sine over a whole period gives zero and the endpoint values also vanish, which discharges several conditions with one factor
- **WHEN** you need a planar vector field that never vanishes **DO** make its two components cos and sin of the same argument **BECAUSE** cosine and sine have no common zero, and this is the same object that defeats the mean value theorem for vector valued functions
- **WHEN** you are hunting a function with no interior critical point on a compact region **DO** force every maximum and minimum onto the boundary, for instance by a monotone factor in one variable **BECAUSE** an interior extremum of a differentiable function is a critical point, so a counterexample with an interior extremum cannot exist

Backtesting

1. First useful cue: hypotheses continuous on the closed square and differentiable inside, with a conclusion at an interior point, which is the mean value theorem in disguise; the four constants are the average of the gradient.
2. Method the expression suggested: rewrite $b-a$ and $d-c$ as double integrals of the partials, so the claim reads "the average of ∇f is attained", and then test that claim against the intermediate value theorem.
3. Where you would hesitate, and the thought to reinforce: at the decision to stop proving. Reinforce that continuity gives connectedness of the image and nothing more, and that an average only lies in the convex hull, so a vector valued mean value claim is false until proved otherwise.
4. The trap the question sets: hypotheses that quote a real theorem so exactly that you spend the session trying to prove a false statement, aided by the fact that the scalar coordinates really are each achievable.
5. What makes you recognise it faster next time: any claim of the form "two partial derivative conditions hold at the same point" should trigger the circle $(\cos t, \sin t)$ within seconds, because that is the canonical obstruction to simultaneity.
6. The reusable decision rule: when a proposed theorem upgrades a scalar existence result to a vector valued one, look for the counterexample first and the proof second, and build the counterexample by normalising the target to zero and making the image wrap around it.

Mirror drills

1. Assume f is C^1 on a neighbourhood of $[0,1]^2$. Show there is a point of $(0,1)^2$ where $\partial f/\partial x = b-a$, with no claim about the other partial. *Answer:* put $F(x) = \int_0^1 f(x,y)dy$, apply the mean value theorem to F to get ξ with $\int_0^1 f_x(\xi,y)dy = b-a$, then the intermediate value theorem in y.
2. Produce a C^1 curve $\gamma : [0,1] \to \mathbb{R}^2$ with $\gamma(0) = \gamma(1)$ and $\gamma'(t) \neq 0$ for all t, and say what it disproves. *Answer:* $\gamma(t) = (\cos 2\pi t, \sin 2\pi t)$; it disproves the mean value theorem for vector valued functions, since the average velocity is zero.
3. Show the assertion of this problem is true whenever $f(x,y) = u(x) + v(y)$ with u, v continuous on $[0,1]$ and differentiable on $(0,1)$. *Answer:* $b-a = u(1)-u(0) = u'(\xi)$ and $d-c = v(1)-v(0) = v'(\eta)$ by the mean value theorem, and since $f_x = u'(x)$ and $f_y = v'(y)$ are decoupled, the point (ξ,η) works.

17.7 B1. rationals as quotients of prime factorials

Show that every positive rational number can be written as a quotient of products of factorials of (not necessarily distinct) primes. For example,

$$\frac{10}{9} = \frac{2! \cdot 5!}{3! \cdot 3! \cdot 3!}.$$

Read it out loud

Say the claim in your own words before you touch a pen: the set of positive rationals you can build by multiplying and dividing prime factorials is all of $\mathbb{Q}^+$. That is a closure statement, not a computation. The object on trial behaves as a sub-monoid of the multiplicative group $\mathbb{Q}^+$ that is closed under reciprocals, hence a subgroup, and you are asked to show it is the whole group. The moment you see "quotient of products," the algebra structure should light up: a nonempty subset of a group, closed under the group operation and under inverses, is automatically a subgroup, so proving it equals the whole group reduces to proving it contains a generating set.

The second cue is arithmetic, not algebraic: "factorials of primes" is a sparse generating set. $2!, 3!, 5!, 7!, \ldots$ are specific composite integers, not the primes themselves. The real question buried inside the statement is how you manufacture a bare prime p out of factorials of primes, when $p!$ is not p, it is p times a whole tail of smaller factors.

Within the first thirty seconds you should have written down the one identity that makes the whole problem move: $p! = p \cdot (p-1)!$, so $p = p!/(p-1)!$. That line is the seed. Everything else is bookkeeping: turning "p divides a/b to some power" into "multiply or divide by $p!/(p-1)!$ that many times," then noticing that $(p-1)!$ is a genuinely smaller object in the one sense that matters, its largest prime factor has dropped, even while its numerical size has exploded.

Approaches, ranked worst to best

1. **fiddle with small examples until a pattern appears.** *Cue:* the worked example $10/9$. *Circuit:* no reusable circuit, pattern search only. You can reproduce the given example by trial, but nothing you find for $10/9$ tells you what to do with, say, $17/13$. A construction that only works because the numbers were small is not a proof; every mark would be riding on a leap you cannot justify. Unlimited ink, no guarantee.

2. **fix a/b and try to reduce $\max(a,b)$ at each step.** *Cue:* the standard "induct on size" reflex. *Circuit:* induction on the wrong invariant. This looks honest, since induction is the right shape of proof for a closure statement. But the instant you multiply by $p!/(p-1)!$, $(p-1)!$ is enormous next to p, so the numerator or denominator can grow by orders of magnitude in a single step. An induction on $\max(a,b)$, or on $a+b$, is chasing a quantity that moves the wrong way. This is the exact bifurcation point of the problem: the zombie route keeps faith with "smaller numbers" as progress and stalls immediately.

3. **strong induction on the largest prime factor appearing in a or b.** *Cue:* the identity $p = p!/(p-1)!$ only ever introduces primes strictly below p. *Circuit:* extremal peeling on a correctly chosen invariant. Let the numbers grow as large as they like; track only the largest prime dividing a or b. Every application of $p!/(p-1)!$ strictly lowers that invariant, because $(p-1)!$ is built entirely from integers below p. The invariant is a nonnegative integer and it strictly decreases, so the induction terminates in finitely many steps no matter how large the actual numerator and denominator become. This is the ideal route: one identity, one strong induction, no case analysis beyond "does p divide the numerator or the denominator."

The ideal solution

Every positive rational number has a unique representation a/b with a, b positive integers and $\gcd(a, b) = 1$. Call the largest prime dividing a or b the *rank* of a/b, and give $1/1$ rank 1 (no prime present).

Prove the claim by strong induction on the rank.

Base case. Rank 1 forces $a = b = 1$, and $1 = 2!/2!$, a quotient of products of prime factorials.

Inductive step. Suppose a/b has rank p, a prime, and suppose every positive rational of rank strictly less than p is a quotient of products of prime factorials. Since $\gcd(a, b) = 1$, the prime p divides exactly one of a, b; say $p \mid a$ (if instead $p \mid b$, run the same argument on b/a and invert the resulting expression at the end, which is still a quotient of products of factorials). Write

$$a = p^k a', \qquad \gcd(a', p) = 1, \quad k \geq 1,$$

so that $a/b = p^k \cdot (a'/b)$. Because p was the largest prime dividing a or b, both a' and b have every prime factor strictly below p.

Now raise the seed identity $p = p!/(p-1)!$ to the power k:

$$p^k = \frac{(p!)^k}{\big((p-1)!\big)^k}.$$

Substituting,

$$\frac{a}{b} = (p!)^k \cdot \frac{a'}{\big((p-1)!\big)^k b}.$$

The factor $(p!)^k$ is already a product of prime factorials. The fraction $a'/\big((p-1)!\big)^k b$ is built entirely from a', b and $(p-1)!$, and every prime factor of each of these three integers is strictly below p: true of a' and b by construction, and true of $(p-1)!$ because it is a product of the integers 1 through $p-1$. So this fraction has rank strictly less than p.

By the induction hypothesis, $a'/\big((p-1)!\big)^k b$ equals some quotient of products of prime factorials, N/D. Then

$$\frac{a}{b} = (p!)^k \cdot \frac{N}{D},$$

which folds $(p!)^k$ into the numerator alongside N's own factorial factors, and is again a product of prime factorials over a product of prime factorials. This closes the induction: every positive rational number is a quotient of products of factorials of primes. ■

As a check that the machine actually runs, follow it on the example. For $10/9$: the rank is 5, since $5 \mid 10$, so $10/9 = 5 \cdot (2/9) = (5!/4!) \cdot (2/9)$, leaving a residual $2/(4! \cdot 9) = 1/108$ of rank 3, resolved by $3^{-3} = (2!)^3/(3!)^3$, leaving $1/2$ of rank 2, resolved directly by $2 = 2!$ since $1! = 1$. Multiplying the layers back together reproduces a valid quotient of prime factorials equal to $10/9$, confirming the construction is not merely an existence argument on paper.

Layer 1: WHAT

Block 1: recognise $\mathbb{Q}^+$ as a multiplicative group and the target set as automatically a subgroup, so "produces every rational" reduces to "reaches every prime." Block 2: write down $p = p!/(p-1)!$, the one non-obvious algebraic input. Block 3: read this identity as trading a bare prime p for a factorial of p, which is allowed, divided by a factorial of $p-1$, which is not itself a prime factorial, but whose prime factors are all smaller than p. Block 4: choose the induction invariant correctly: not the size of a, b, but the largest prime factor, and confirm it strictly decreases. Block 5: run the strong induction to completion, with $p = 2$, i.e. $1! = 1$, as the trivial floor.

The nominal route stalls at Block 3, because the untrained instinct is to induct on $\max(a, b)$, which the substitution makes worse, not better. The bifurcation point sits exactly there: the ideal

route abandons "smaller numbers" as the measure of progress and replaces it with "fewer distinct large primes," the one quantity the construction actually controls.

Layer 2: HOW

Block 1. **Cue.** The word "quotient" and "products" applied to a set built from prime factorials. **Why natural.** $\mathbb{Q}^+$ under multiplication is a group; a nonempty subset closed under products and reciprocals is a subgroup, and a subgroup containing a generating set of the whole group must be the whole group. Reframing "show every rational is representable" as "show this candidate subgroup is everything" turns an open-ended construction into a closure argument, far cheaper to police. **Link to the next block.** Since the primes generate $\mathbb{Q}^+$ multiplicatively, by unique factorisation, it suffices to reach every prime.

Block 2. **Cue.** You need a bare prime p out of an object called $p!$, which is p times a large tail. **Why natural.** Definitions are not negotiable: $p! = p \cdot (p-1) \cdots 1$, so dividing by $(p-1)!$ peels the tail off and leaves exactly p. There is no other identity connecting a prime to a factorial, so this is the only door available, and you take it. **Link to the next block.** The price of using this door is that $(p-1)!$ now sits in a denominator or numerator, and it is not itself a prime factorial, so you owe the reader a reason that is still acceptable.

Block 3. **Cue.** $(p-1)!$ is a specific, fully factored integer: $1 \cdot 2 \cdots (p-1)$. **Why natural.** Every prime factor of $(p-1)!$ is at most $p-1$, strictly below p. That is not a numerical accident, it is definitional: multiplying integers below p can never land on a prime factor of size p or larger. **Link to the next block.** This is exactly the property needed to set up a terminating induction: whatever measure counts "how many primes at or above p are still present" has just dropped by one such prime.

Block 4. **Cue.** The temptation to induct on the size of the numbers. **Why natural.** Reject it explicitly: $(p-1)!$ can dwarf a or b, so size increases. The only quantity guaranteed to decrease is the largest prime factor present, because the substitution was designed to kill exactly that prime and introduce nothing at or above it. **Link to the next block.** Strong induction on that invariant, bottoming out at rank 1, closes the proof.

Block 5. **Cue.** The base case must be checked honestly, not waved through. **Why natural.** $1 = 2!/2!$ is the smallest possible quotient of prime factorials, and it is the only rational of rank 1; the induction has nowhere lower to go, so this is a genuine floor. **Link to the next block.** None, the proof is complete.

Layer 3: WHY

The truth underneath this problem is that $\mathbb{Q}^+$, as a multiplicative group, is free abelian on the primes: every positive rational is a unique finite product $\prod p_i^{e_i}$ with $e_i \in \mathbb{Z}$. Proving a subset generates $\mathbb{Q}^+$ is therefore never about the raw arithmetic size of that subset, it is about whether the subset reaches every generator. The examiners chose factorials of primes as the generating gadget precisely because $p!/(p-1)! = p$ is a clean way to reach a generator, while guaranteeing that the natural first attempt, tracking the size of the numbers, fails, so that only a correctly chosen invariant, the largest prime factor, gets the induction to close.

The discernment mechanism is this: whenever an induction stalls because a substitution makes the objects bigger, ask what got structurally simpler even though the objects got numerically larger. Here, "structurally simpler" means "supported on strictly smaller primes," a well ordered quantity, so strong induction on it is valid and finite. Train this discernment by refusing to accept "the

numbers are growing, so induction on size cannot work" as a dead end; instead ask which other measurement of the same object the last step actually controlled.

Revolving concepts

- **Unique factorisation.** Every positive integer is a unique product of primes, so every positive rational has a unique representation as a finite product of prime powers with integer, possibly negative, exponents. This is why "reach every prime" is equivalent to "reach every positive rational." See Book 1, field: Number theory, topic: prime factorisation.
- $\mathbb{Q}^+$ **as a free abelian group.** Under multiplication, $\mathbb{Q}^+$ is isomorphic to a direct sum of one copy of $\mathbb{Z}$ per prime, via the exponent of each prime in a rational's factorisation. A nonempty subset closed under products and reciprocals is a subgroup; a subgroup containing a generating set is the whole group. See Book 1, field: Abstract algebra, topic: generators of an abelian group.
- **Strong induction on a non-standard, well founded invariant.** The recursion here is $p \mapsto (p-1)!$, and the generalised form of the technique is: whenever a substitution grows the objects but strictly reduces some other well ordered quantity, largest prime factor, number of distinct prime factors, degree of a polynomial, rank in a filtration, strong induction on that quantity is valid, regardless of what happens to size. The method is always the same: identify the quantity, show it is a nonnegative integer, show it strictly decreases, check the floor case by hand. This generalises to any "peel the extremal piece, recurse on the residue" argument, the same skeleton behind the Euclidean algorithm and behind proofs of unique factorisation itself.
- **Legendre's formula (background, not load bearing here).** The exact power of a prime q dividing $n!$ is the sum over $i \geq 1$ of $\lfloor n/q^i \rfloor$. It confirms, from a different angle, that $p!$ contains no prime factor above p and exactly one copy of p itself, which is why $p = p!/(p-1)!$ is exact with no residue to clean up. See Book 1, field: Number theory, topic: prime factorisation of factorials.

Circuit Bank

- **WHEN** a problem asks you to show a small generating set produces an entire multiplicative structure, all rationals, all integers under some operation **DO** reframe as a subgroup closure question: show the candidate set is closed under the group operations and contains a known generating set **BECAUSE** a nonempty subset of a group, closed under the operation and inverses, is automatically a subgroup, so "produces everything" reduces to "contains generators"
- **WHEN** an induction on the size of the numbers stalls because your substitution makes them larger **DO** look for a different, well ordered invariant that the same substitution strictly decreases, and reinduct on that **BECAUSE** induction only needs a well founded decreasing quantity, never the size of the objects specifically
- **WHEN** you need to produce a prime p from factorials **DO** write $p = p!/(p-1)!$ immediately **BECAUSE** it is the only algebraic bridge between a bare prime and a factorial, the first thing to try, not a discovery to search for

Backtesting

1. First useful cue: "quotient of products" applied to a sparse generating set, flagging a group generation argument before any arithmetic starts.

2. Method the expression suggested: peel the largest prime using $p = p!/(p-1)!$ and recurse.
3. Where you would hesitate, and the thought to reinforce: the moment $(p-1)!$ appears and looks like it made the problem worse; reinforce that you are tracking the largest prime factor, not size.
4. The trap the question sets: it tempts an induction on $a+b$ or $\max(a,b)$, the default competition move, which fails outright once you substitute.
5. What makes you recognise it faster next time: any phrase of the form "every element of a multiplicative structure can be built from a sparse generating set" should trigger an immediate check of what invariant the generating step actually controls, before you commit to an induction variable.
6. The reusable decision rule: when a substitution both grows the numbers and kills the largest bad feature, a prime, a degree, an exponent, induct on the bad feature, never on the size.

Mirror drills

1. Show that every positive rational number can be written as a quotient of products of primorials $p\# = 2 \cdot 3 \cdot 5 \cdots p$, the product of all primes up to p. *Answer:* peel the largest prime p using $p = p\#/q\#$, where q is the prime immediately below p, then induct on the largest prime factor exactly as above.
2. Take $a/b = 1/5$. Compute $\max(a,b)$ before and after applying the substitution for $p = 5$, and separately compute the rank, the largest prime factor present, before and after, to see directly why size is the wrong induction measure. *Answer:* before, max $= 5$, rank 5; the substitution gives $1/5 = 4!/5! = 24/120$, so max has jumped to 120, while the residual to induct on is $1/24$, of rank 3, strictly below 5. Size grew, rank fell; only rank is a valid measure here.
3. Show that every positive integer n can be written as a product of terms of the form $p!/(p-1)!$ for primes p, with repetition allowed. *Answer:* immediate from unique factorisation, since $n = \prod p_i^{e_i}$, and each p_i equals $p_i!/(p_i-1)!$.

17.8 B2. the range of achievable jump costs

A game involves jumping to the right on the real number line. If a and b are real numbers and $b > a$, the cost of jumping from a to b is $b^3 - ab^2$. For what real numbers c can one travel from 0 to 1 in a finite number of jumps with total cost exactly c?

Read it out loud

Strip the story away and look at the algebra sitting inside it: the cost of one jump from a to b is $b^3 - ab^2 = b^2(b-a)$. That is (value of a function at the right endpoint) times (width of the step). The instant you factor it that way, you are no longer looking at a game, you are looking at a term of a Riemann sum for $\int t^2\,dt$, sampled at the right end of each subinterval. A finite sequence of jumps $0 = x_0 < x_1 < \cdots < x_m = 1$ has total cost $\sum_{i=1}^{m} x_i^2(x_i - x_{i-1})$, which is exactly the right endpoint Riemann sum of $f(t) = t^2$ over the partition $\{x_i\}$ of $[0,1]$.

Once you see that, "for what c can you achieve total cost c" turns into "what is the set of values a right endpoint Riemann sum of t^2 can take, ranging over every finite partition of $[0,1]$." The fields wired into this problem are elementary real analysis, Riemann sums, monotonicity, the intermediate value theorem, dressed as a discrete combinatorial game; there is no calculus beyond recognising the shape.

The first thing worth writing down, inside thirty seconds, is the pair of bounds that monotonicity of t^2 on $[0,1]$ hands you for free: since t^2 is increasing, a right endpoint sum always overestimates the true integral $1/3$, and since $t^2 \le 1$ on $[0,1]$, the sum can never exceed 1. So the achievable set sits inside $(1/3, 1]$ before a single example is constructed. The rest of the problem is proving that inclusion is equality.

Approaches, ranked worst to best

1. **try two or three jumps and solve for the cost algebraically.** *Cue:* small, explicit numbers. *Circuit:* no reusable circuit, exploratory only. The two jump path $0 \to t \to 1$ has cost $1 + t^3 - t$, which ranges only over roughly $[0.615, 1]$, never reaching down near $1/3$ for any fixed small number of jumps, and gives no proof that every intermediate value is hit. A warm up, not a route to a proof.

2. **minimise the cost over all partitions of a fixed size m using calculus, then let $m \to \infty$.** *Cue:* "total cost" invites optimisation. *Circuit:* Lagrange multipliers on the simplex of partitions. Correct in spirit, wasteful in execution: an m variable optimisation, identification of the minimising, equally spaced partition, a limit as $m \to \infty$, and then a separate argument for every intermediate value of c.

3. **recognise the sum as a Riemann sum, extract both bounds from monotonicity, then build one continuous one parameter family of constructions and invoke the intermediate value theorem once.** *Cue:* $b^2(b-a)$ factoring as (function value)(width). *Circuit:* Riemann sum bound plus a single IVT sweep. The ideal route. Both bounds cost one inequality each. Achievability costs one explicit family and one appeal to continuity, no case analysis, no separate argument for each value of c.

The ideal solution

The answer is $c \in \left(\frac{1}{3}, 1\right]$.

Every achievable cost lies in this range. Fix a finite sequence $0 = x_0 < x_1 < \cdots < x_m = 1$ and write its total cost as

$$C = \sum_{i=1}^{m} x_i^2(x_i - x_{i-1}).$$

Upper bound. Since $0 < x_i \le 1$ for every i, $x_i^2 \le 1$, so

$$C \le \sum_{i=1}^{m} (x_i - x_{i-1}) = 1,$$

with equality only if $x_i^2 = 1$ on every step of positive width, forcing $x_i = 1$ for every $i \ge 1$, hence $m = 1$. So $C = 1$ exactly for the single jump $0 \to 1$, and $C < 1$ for every path with $m \ge 2$.

Lower bound. On (x_{i-1}, x_i), t^2 is strictly less than x_i^2, since t^2 is strictly increasing and $t < x_i$ there, so

$$\int_{x_{i-1}}^{x_i} t^2 \, dt < x_i^2 (x_i - x_{i-1}).$$

Summing over i gives $\int_0^1 t^2 \, dt < C$, that is $\frac{1}{3} < C$, for every finite partition, strictly, since every subinterval has positive width.

So every achievable cost lies in $\left(\frac{1}{3}, 1\right]$.

Every value in this range is achievable. The endpoint $c = 1$ is achieved by the single jump $0 \to 1$. Fix $c \in \left(\frac{1}{3}, 1\right)$.

For $a \in [0, 1]$ and a positive integer n, consider the path taking n equal jumps from 0 to a, through $a/n, 2a/n, \ldots, a$, followed by one final jump from a to 1. Its cost is

$$C(a, n) = a^3 \cdot \frac{(n+1)(2n+1)}{6n^2} + (1 - a),$$

using $\sum_{k=1}^{n} k^2 = n(n+1)(2n+1)/6$ for the first phase and $1^3 - a \cdot 1^2 = 1 - a$ for the last jump. For fixed n, $C(\cdot, n)$ is a polynomial in a, hence continuous on $[0, 1]$, with

$$C(0, n) = 1, \qquad C(1, n) = \frac{(n+1)(2n+1)}{6n^2}.$$

The right hand quantity tends to $\frac{1}{3}$ as $n \to \infty$, so choose n large enough that $C(1, n) < c$. Since $C(0, n) = 1 > c$ and $C(1, n) < c$, the intermediate value theorem applied to the continuous function $a \mapsto C(a, n)$ on $[0, 1]$ produces some $a \in (0, 1)$ with $C(a, n) = c$ exactly. The corresponding finite jump sequence, n equal steps from 0 to a followed by one step from a to 1, realises total cost exactly c.

Hence every $c \in \left(\frac{1}{3}, 1\right]$ is achievable, and combined with the bound above, the achievable set is precisely $\left(\frac{1}{3}, 1\right]$. ■

Layer 1: WHAT

Block 1: factor the cost of a single jump as $b^2(b - a)$ and recognise it as a Riemann sum term. Block 2: extract the upper bound $C \le 1$ from $x_i \le 1$, with an equality analysis pinning down exactly the one jump path. Block 3: extract the strict lower bound $C > 1/3$ from monotonicity of t^2 against the true integral. Block 4: build a single continuous, two parameter family of constructions, equal steps up to a, then one jump to 1, whose cost at $a = 1$ approaches $1/3$ and at $a = 0$ equals 1. Block 5: invoke the intermediate value theorem once, for a well chosen fixed n, to hit any target c exactly.

The nominal route grinds through small, fixed numbers of jumps and never escapes a bounded sub-interval of $(1/3, 1]$; it cannot see $1/3$, because no fixed finite m gets arbitrarily close to it. The bifurcation point is the decision to stop treating m as fixed and instead build a family indexed by a continuous parameter a, at fixed large n, so that continuity and the intermediate value theorem finish the job in one step instead of a case by case chase.

Layer 2: HOW

Block 1. **Cue.** The cost formula $b^3 - ab^2$ factors instantly as $b^2(b - a)$. **Why natural.** This is exactly the shape, sampled function value times subinterval width, that defines a Riemann sum; recognising it is definitional, not clever, once the factoring is written down. **Link to the next block.** A sum of jump costs over a partition of $[0, 1]$ is therefore literally a right endpoint Riemann sum of t^2.

Block 2. **Cue.** $t^2 \leq 1$ on $[0,1]$. **Why natural.** Bounding each sampled value by the global maximum of f on $[0,1]$ bounds the whole sum by $\sum(x_i - x_{i-1}) = 1$, a telescoping sum that collapses to the interval's length regardless of the partition. **Link to the next block.** Equality forces every contributing x_i to equal 1, possible only for the trivial one jump path, so the upper bound is attained exactly once, sharply.

Block 3. **Cue.** t^2 is strictly increasing on $[0,1]$. **Why natural.** An increasing function, sampled at the right endpoint of each subinterval, always overestimates its own integral there, strictly, whenever the subinterval has positive width; this is the definition of an upper Riemann sum for a monotonic function. **Link to the next block.** Since every one of the finitely many subintervals has positive width, the strict inequality survives summation, giving $C > 1/3$, with no partition ever reaching equality.

Block 4. **Cue.** The lower bound is a limit, $C \to 1/3$ as the partition refines, never an equality; every value strictly above $1/3$ is needed, not just values near it. **Why natural.** A single family with one free continuous parameter is cheaper than patching together infinitely many separate near misses: fix a as the point where "many small jumps" switches to "one final big jump," and let the many small jumps approach the integral $a^3/3$ while the final jump contributes the exact, non limiting quantity $1 - a$. **Link to the next block.** As a ranges over $[0,1]$ continuously, the limiting cost $a^3/3 + (1 - a)$ sweeps continuously from 1 down to $1/3$, so the target c sits somewhere on that sweep.

Block 5. **Cue.** You need an exact value c, not a limit. **Why natural.** For any fixed finite n, $C(a,n)$ is an honest polynomial, continuous in a, and its two endpoint values already straddle c once n is large enough; the intermediate value theorem then guarantees an exact a with $C(a,n) = c$, not merely an approximation. **Link to the next block.** No further step is needed; the explicit finite sequence attached to that a and n is the answer.

Layer 3: WHY

The mathematics underneath this problem is the standard fact that for a strictly increasing integrable function, the right endpoint Riemann sum is always a genuine overestimate of the integral, on every nondegenerate partition, and the amount of overestimate shrinks to zero as the mesh refines. That single fact supplies both halves of the answer: it forces every achievable cost above $1/3$, since the overestimate is always positive, and it is exactly what lets you build constructions whose cost approaches $1/3$ as closely as you like, since the overestimate shrinks to zero. The upper endpoint 1 is a separate, easier fact: $t^2 \leq 1$ on the domain, attained only at the right edge, so it bounds every sum and is matched only by refusing to subdivide at all.

The discernment mechanism for choosing the intermediate value theorem over a case by case covering argument is this: once a target set is known to be an interval bounded by a value you can hit exactly, $c = 1$, and a value you can only approach, $c \to 1/3$, look for one continuous family connecting those two behaviours, rather than constructing each c separately. Continuity of the cost function in the construction's free parameters is not an accident, it is guaranteed because the cost is a polynomial in the jump points; whenever a competition construction is built from polynomial, or otherwise continuous, data, the intermediate value theorem is available for free, and reaching for it before reaching for an explicit inverse formula is the disciplined habit worth training. The examiners nudged toward this by writing the cost as a cubic in a and b, structurally guaranteeing continuity of any construction built from it.

Revolving concepts

- **Riemann sums, upper and lower.** For a partition of $[a, b]$, the upper sum uses the supremum of f on each subinterval, the lower sum the infimum; both converge to $\int_a^b f$ as the mesh tends to zero, and for a monotonic function the right endpoint sum coincides with the upper sum, if increasing, or the lower sum, if decreasing. See Book 1, field: Real analysis, topic: Riemann integration.
- **Strict inequality between a monotone sum and its integral.** For f strictly increasing and continuous, every finite, nondegenerate right endpoint sum sits strictly on one side of $\int f$; equality is only a limiting statement, never attained by a finite partition. This is the source of the open endpoint $1/3$ in the answer.
- **The intermediate value theorem as a sweeping tool.** Whenever a construction depends continuously on a free real parameter, and its value at the two ends of the parameter's range straddles a target, the intermediate value theorem produces an exact hit. This generalises far beyond integrals: any competition existence claim of the form "for every c in an interval, some explicit finite object achieves c exactly" is a candidate for one continuous family plus one application of the theorem, rather than a separate construction per value. See Book 1, field: Real analysis, topic: continuity and the intermediate value theorem.
- **Closed forms for power sums.** $\sum_{k=1}^{n} k^2 = n(n+1)(2n+1)/6$ is the only piece of routine algebra in the whole solution, standard A-level Further Mathematics content; its only role here is to make $C(a, n)$ an explicit polynomial, so continuity and the endpoint values can be read off directly.

Circuit Bank

- **WHEN** a cost or sum is defined as a function of the right endpoint times the width of a step, over a partition of an interval **DO** recognise it immediately as a Riemann sum and extract bounds from monotonicity of the function before attempting any construction **BECAUSE** monotonicity gives strict, free inequalities in one line, and tells you in advance which endpoint of the achievable range is attained and which is only approached
- **WHEN** an achievable set is claimed to be an entire interval, with one endpoint attained exactly and the other only approached **DO** build a single family with one continuous real parameter connecting a construction that attains the good endpoint to one that approaches the other, then apply the intermediate value theorem once for a suitably chosen fixed discretisation **BECAUSE** continuity of the construction in its parameters is often free, since the data is polynomial, so one application of the theorem replaces an unbounded case analysis
- **WHEN** a bound of the form $C \leq 1$ or $C \geq$ some constant is proved via $f(t) \leq M$ or $f(t) \geq m$ on the whole domain **DO** immediately check when equality can hold, since competition answers usually want the exact attained endpoint identified, not only the bound **BECAUSE** a bound without its equality case is an incomplete answer to a "for what values" question, exactly what this problem asks

Backtesting

1. First useful cue: $b^3 - ab^2$ factors as $b^2(b - a)$, the signature shape of a Riemann sum term.
2. Method the expression suggested: bound the sum using monotonicity of t^2, then sweep the gap with a continuous family and one application of the intermediate value theorem.

3. Where you would hesitate, and the thought to reinforce: wanting a separate explicit construction for every target c; reinforce that one continuous family plus the theorem covers infinitely many targets at once.
4. The trap the question sets: small, fixed numbers of jumps look tractable and give a plausible looking sub-interval, but they never reach the true lower bound $1/3$, so stopping there gives a wrong, too narrow answer.
5. What makes you recognise it faster next time: any sum written as a value at the right endpoint times a step width, over a partition of a fixed interval, is a Riemann sum in disguise, regardless of the surface story, games, costs, journeys.
6. The reusable decision rule: bound first from monotonicity, then connect the two bounds with one continuous family and one sweep of the intermediate value theorem, rather than constructing each achievable value separately.

Mirror drills

1. For what c can a right endpoint Riemann sum of $f(t) = t$ over finite partitions of $[0, 1]$ equal c? *Answer:* $c \in \left(\frac{1}{2}, 1\right]$, by the identical bounding and sweeping argument, using $\int_0^1 t\,dt = \frac{1}{2}$.
2. For what c can a right endpoint Riemann sum of $f(t) = e^t$ over finite partitions of $[0, 1]$ equal c? *Answer:* $c \in (e - 1, e]$, since $\int_0^1 e^t\,dt = e - 1$ and the single jump value is $f(1) \cdot 1 = e$.
3. A rope of length 1 is cut once, at a point $x \in (0, 1)$, into two pieces of lengths x and $1 - x$. For which $c \in \left[0, \frac{1}{4}\right]$ does some cut give a product of piece lengths exactly c, and which single idea from this problem proves it? *Answer:* every $c \in \left[0, \frac{1}{4}\right]$, since $x(1 - x)$ is continuous on $[0, 1]$ with values 0 at $x = 0$ and $\frac{1}{4}$ at $x = \frac{1}{2}$, so the intermediate value theorem alone, with no Riemann sum needed, already finishes it.

17.9 B3. counting mediocre subsets via arithmetic progressions

Call a subset S of $\{1, 2, \ldots, n\}$ mediocre *if it has the following property: whenever a and b are elements of S whose average is an integer, that average is also an element of S. Let $A(n)$ be the number of mediocre subsets of $\{1, 2, \ldots, n\}$. (For instance, every subset of $\{1, 2, 3\}$ except $\{1, 3\}$ is mediocre, so $A(3) = 7$.) Find all positive integers n such that $A(n+2) - 2A(n+1) + A(n) = 1$.*

Read it out loud

Two separate structures are welded together here, and you should read them as two separate problems, to be multiplied against each other later, not as one tangled question. The first is a closure condition on subsets: whenever the integer average of two members exists, it is already a member. That is a midpoint condition, and the moment you see "closed under taking the midpoint, when it is an integer," the shape to think of is an arithmetic progression, because an arithmetic progression is exactly the family of sets where midpoints of members that ought to exist do exist and land back inside the set.

The second structure is arithmetical, not combinatorial: $A(n+2) - 2A(n+1) + A(n)$ is a second difference. Whenever a counting sequence is hit with a second difference, read it as "count something pinned by two new elements," because a first difference of a counting sequence very often counts the objects containing one distinguished new element, and a second difference then counts the objects containing two.

Within the first thirty seconds, write both of these down: a guess that mediocre sets are exactly the arithmetic progressions with an odd common difference, worth checking against the given example immediately, since $\{1, 3\}$ is precisely the one two term subset of $\{1, 2, 3\}$ with an even difference, and it is precisely the one excluded set; and the observation that $A(n+2) - 2A(n+1) + A(n)$ should turn, via a shift argument, into a count of mediocre subsets pinned at both ends of $\{1, \ldots, n+2\}$.

Approaches, ranked worst to best

1. **compute $A(n)$ for small n by hand and guess a recurrence.** *Cue:* the worked example $A(3) = 7$. *Circuit:* no reusable circuit, pattern spotting only. This confirms small cases but proves nothing, and the recurrence for $A(n)$ itself is not simple; you would be fishing for a closed form that never settles into a clean shape. Ink with no end in sight.

2. **attack $A(n+2) - 2A(n+1) + A(n)$ directly by comparing raw counts of mediocre subsets of the three ground sets.** *Cue:* "second difference" as a hint to compare set families. *Circuit:* brute comparison, no bijection. The right instinct, executed clumsily: comparing raw counts rather than building an explicit bijection wastes an enormous amount of casework and never isolates the clean combinatorial meaning of the second difference.

3. **prove the closure condition classifies mediocre sets exactly as odd difference arithmetic progressions, and separately reduce the second difference to a count of subsets pinned at both endpoints via a shift bijection, then multiply the two insights.** *Cue:* the midpoint closure condition together with the shape of a second difference. *Circuit:* structural classification plus telescoping bijection. The ideal route. Each half is a short, clean argument; combined, the problem collapses to an elementary divisor counting question with almost no casework.

The ideal solution

Step 1: classify the mediocre sets.

Claim 17.9.1. *A subset S of the integers with $|S| \geq 2$ is mediocre if and only if S is a finite arithmetic progression with odd common difference.*

Proof. If. Let $S = \{a, a+d, \ldots, a+md\}$ with d odd. Take two elements $a+id$, $a+jd$ with $i < j$; their average is $a + \frac{i+j}{2}d$. Since d is odd, this is an integer exactly when $i+j$ is even, and then, writing $\ell = (i+j)/2$, we have $i \leq \ell \leq j \leq m$, so $a + \ell d \in S$. So S is mediocre.

Only if. Let $S = \{s_1 < s_2 < \cdots < s_m\}$ be mediocre, $m \geq 2$. For $m = 2$: the only pair is (s_1, s_2), and its average, if an integer, lies strictly between s_1 and s_2, so it cannot lie in $S = \{s_1, s_2\}$; mediocrity forces $s_2 - s_1$ to be odd, which is exactly an arithmetic progression of length two with odd difference.

For $m \geq 3$, induct on m. Removing the top element gives $S' = \{s_1, \ldots, s_{m-1}\}$. Any two elements of S' have average at most $s_{m-1} < s_m$, so if their average is an integer it cannot equal s_m; since S is mediocre, that average lies in S, hence in $S \cap (-\infty, s_{m-1}] = S'$. So S' is mediocre, and by induction it is an arithmetic progression with odd common difference d'. Symmetrically, removing the bottom element gives a mediocre $S'' = \{s_2, \ldots, s_m\}$, an arithmetic progression with odd common difference d''.

The sets S' and S'' share the sub-list $\{s_2, \ldots, s_{m-1}\}$. When $m \geq 4$, this sub-list has at least two elements, and, being a run of consecutive terms inside both S' and S'', it is an arithmetic progression with difference d', from S', and also with difference d'', from S''. A set of at least two numbers determines its common difference uniquely, as (largest minus smallest) divided by (count minus one), so $d' = d'' =: d$. Hence $S = \{s_1, s_1 + d, \ldots, s_1 + (m-1)d\}$ is itself an arithmetic progression with odd common difference d. When $m = 3$, the same overlap argument, applied to $S' = \{s_1, s_2\}$ and $S'' = \{s_2, s_3\}$, directly forces $s_2 - s_1 = s_3 - s_2$, and that shared difference is odd by the $m = 2$ case, which anchors the induction at its base. □

Step 2: reduce the second difference to a count of doubly pinned mediocre sets.

For $n \geq 1$, the shift $T \mapsto T + 1$ is a bijection between the mediocre subsets of $\{1, \ldots, n\}$ and the mediocre subsets of $\{2, \ldots, n+1\}$: the average of $a+1$ and $b+1$ is an integer exactly when the average of a, b is, and it equals (the average of a, b) plus one, so it lies in $T + 1$ exactly when the original average lies in T. Hence $A(n)$ also counts mediocre subsets of $\{2, \ldots, n+1\}$, which are exactly the mediocre subsets of $\{1, \ldots, n+1\}$ that do not contain 1.

Write $f(n)$ for the number of mediocre subsets of $\{1, \ldots, n\}$ that do contain 1. The paragraph above gives

$$A(n+1) = A(n) + f(n+1).$$

Applying this once with n and once with $n+1$, then subtracting,

$$A(n+2) - 2A(n+1) + A(n) = f(n+2) - f(n+1).$$

Now split the mediocre subsets of $\{1, \ldots, n+2\}$ containing 1 according to whether they also contain $n+2$. Those that do not are exactly the mediocre subsets of $\{1, \ldots, n+1\}$ containing 1, counted by $f(n+1)$, so

$$f(n+2) = f(n+1) + g(n),$$

where $g(n)$ is the number of mediocre subsets of $\{1, \ldots, n+2\}$ containing both 1 and $n+2$. Combining the last two displays,

$$A(n+2) - 2A(n+1) + A(n) = g(n).$$

Step 3: count the doubly pinned sets. Any mediocre set counted by $g(n)$ contains both 1 and $n+2$, so it has at least two elements, and by the Claim it is an arithmetic progression with odd common difference d, first term 1, last term $n+2$. This forces $d \mid (n+2-1) = n+1$, and conversely every odd divisor d of $n+1$ gives exactly one such set, $\{1, 1+d, 1+2d, \ldots, n+2\}$. So $g(n)$ equals the number of odd divisors of $n+1$.

Step 4: solve. Write $n+1 = 2^a m$ with m odd. The odd divisors of $n+1$ are exactly the divisors of m, so $A(n+2) - 2A(n+1) + A(n) = 1$ if and only if m has exactly one divisor, if and only if $m = 1$, if and only if $n+1$ is a power of 2. Since n is a positive integer, $n+1 \geq 2$, so

$$n = 2^k - 1 \text{ for some integer } k \geq 1,$$

that is, $n = 1, 3, 7, 15, 31, \ldots$. ■

Layer 1: WHAT

Block 1: read the closure condition as a midpoint condition and guess the classification, arithmetic progressions with odd common difference, checking it instantly against the given example. Block 2: prove the classification by peeling the top and bottom element and reconciling the overlap. Block 3: read the second difference as a telescoping count, via two applications of a shift bijection, reducing it to counting mediocre sets containing both 1 and $n+2$. Block 4: apply the classification to that count directly: such sets biject with odd divisors of $n+1$. Block 5: translate "exactly one odd divisor" into "$n+1$ is a power of 2" and read off n.

The nominal route tries to find $A(n)$ itself in closed form and differentiate it twice, which is possible but heavier; it never needs the classification lemma at full strength and tends to bury the divisor count inside a messier sum. The bifurcation point is the decision to work with the second difference directly, as its own combinatorial object, rather than solving for $A(n)$ first and subtracting afterwards.

Layer 2: HOW

Block 1. Cue. "Whenever the average is an integer, it lies in the set." **Why natural.** This is definitional: the family of sets closed under taking midpoints, when the midpoint exists as an integer, is precisely the family with no gap that a midpoint could expose, and the only sets with that rigidity are arithmetic progressions, with the parity of the difference controlling whether midpoints exist at all. **Link to the next block.** Guessing the classification early lets you check it instantly against the one given data point, $\{1, 3\}$ excluded because its difference 2 is even, confirming the guess before a single line of proof is written.

Block 2. Cue. Proving a classification for a set of size m from a closure property. **Why natural.** Peel an extremal element, the top, or the bottom, and note that any average computed inside the remaining elements cannot equal the element removed, since it is out of range; this makes the smaller set inherit the closure property for free, so induction applies without extra hypotheses. **Link to the next block.** Removing the top, and separately the bottom, gives two overlapping smaller arithmetic progressions; forcing their shared difference to agree on the overlap is what promotes two progressions into one progression covering everything.

Block 3. Cue. $A(n+2) - 2A(n+1) + A(n)$, a second finite difference of a counting sequence. **Why natural.** A first difference of a counting sequence over a growing ground set very often counts exactly the objects using the newly available element, because every object either avoids it, and is counted by the smaller sequence, or uses it, and is exactly the difference; a second difference then counts objects using two newly available elements, by the same argument applied twice. **Link to the next block.** The two elements pinned by the second difference here are the two ends of the ground set, 1 and $n+2$, since each application of the shift bijection is anchored at a boundary.

Block 4. Cue. A mediocre set containing two specific pinned elements, 1 and $n+2$. **Why natural.** Once mediocre sets of size at least two are known to be exactly odd difference arithmetic

progressions, a set with two fixed endpoints has no freedom left: the common difference is forced by the two endpoints, and the only question is whether that forced difference is legal, an odd divisor of the gap. **Link to the next block.** Counting odd divisors of $n+1$ is now pure elementary number theory, not combinatorics.

Block 5. Cue. "Exactly one odd divisor." **Why natural.** The odd divisors of an integer are exactly the divisors of its largest odd factor, so having only one odd divisor, namely 1 itself, is the same statement as that odd factor being 1, that is, the whole integer is a power of 2. **Link to the next block.** This names every solution directly, $n = 2^k - 1$, with no further casework.

Layer 3: WHY

Underneath both halves of this problem is the same phenomenon: a condition phrased as closure under an operation applied to pairs pins down a classical, rigid family, and once that classification is in hand, a combinatorial counting question about the family collapses into ordinary number theory. Here the operation is "take the integer average," and the rigid family is "arithmetic progression with odd step"; the finite difference machinery is a separate, purely mechanical device for turning a numerical recurrence into a statement about one specific, small sub-family, the doubly pinned sets, rather than the whole family $A(n)$.

The discernment mechanism for the classification half is to notice that a closure condition defined pairwise, with no reference to size or position, almost always forces either total rigidity, a progression, a coset, a subgroup, or total freedom, any subset at all; the parity obstruction here, that an even difference two term set already breaks the condition, is the signal you are in the rigid case, not the free one. The discernment mechanism for the finite difference half is to recognise Δ^2 applied to a counting sequence as an instruction to find a bijection first and an algebraic identity second: a first difference of A isolates "contains the new top element," and running that isolation twice, once from each end of $\{1, \ldots, n+2\}$, is a completely generic technique that applies to any counting sequence defined on growing intervals, sets or lattice paths, whenever the underlying structure is translation invariant.

Both mechanisms trace back to the same extremal peeling idea used across this trio: strip an extreme element, recognise the property survives on what is left, and reconstruct the whole object from the pieces once each piece's structure is known.

Revolving concepts

- **Midpoint closure and arithmetic progressions.** A set closed under "take the average when it happens to be an integer" is, once it has at least two elements, forced to be an arithmetic progression with odd common difference; even difference fails because the midpoint of the extreme points then exists but sits strictly between them and outside a two term set. This is a discrete cousin of midpoint convexity from real analysis, where a function satisfying $f\left(\frac{x+y}{2}\right) \leq \frac{f(x)+f(y)}{2}$ for all real x, y, plus mild regularity, is forced to be convex; the same no gaps at the midpoint rigidity is at work. See Book 1, field: Discrete structures and graphs, topic: closure conditions and rigid families.
- **Finite differences of a counting sequence.** If $A(n)$ counts configurations on a ground set grown one element at a time, and the counted property is translation invariant, $\Delta A(n) = A(n+1) - A(n)$ counts configurations using the newly adjoined element, by splitting the larger family into "avoids it," matched bijectively to the smaller family, and "uses it," the difference. Iterating, $\Delta^k A(n)$ counts configurations pinned to use k specific new elements. Generalised recursion: for any counting sequence built this way, $\Delta^k A(n)$ always has this pinned at k points combinatorial meaning; the method is always the same shift bijection

applied k times, from whichever end, or ends, the ground set is being grown. See Book 1, field: Combinatorics, topic: finite differences and bijective counting.

- **Extremal peeling induction.** Strip the largest, or smallest, element of a finite structure, show the defining property survives on the remainder, apply the inductive hypothesis, then reconcile using an overlap between two different peelings, top and bottom here. This is the same skeleton as the strong induction used elsewhere in this trio, and it is the standard route for proving a local, pairwise closure condition forces a globally rigid structure. See Book 1, field: Discrete structures and graphs, topic: extremal and structural induction.
- **Counting divisors, odd divisors specifically.** Writing $n+1 = 2^a m$ with m odd, the divisors of $n+1$ split into those dividing m, the odd ones, and the rest; the odd divisors of $n+1$ are exactly the divisors of m, and m has exactly one divisor if and only if $m = 1$. This is the standard reduction whenever a problem asks specifically about odd divisors rather than all divisors. See Book 1, field: Number theory, topic: the divisor function.

Circuit Bank

- **WHEN** a subset is defined by a pairwise closure condition of the form: if two elements satisfy a relation, then a derived element is also a member **DO** guess immediately that the condition classifies a classical rigid family, a progression, a coset, an interval, and check the guess against any worked example given in the statement **BECAUSE** pairwise closure conditions with no reference to position or size almost always force total rigidity, and the given example is the cheapest possible confirmation
- **WHEN** a problem hands you a finite difference, first or second, of a counting sequence defined on a growing or shrinking ground set **DO** look for a bijection showing the first difference counts configurations that use one specific new element, then iterate it for higher differences **BECAUSE** finite differences of counting sequences are shift bijections in disguise, and unwinding them converts an opaque numerical recurrence into an explicit, smaller combinatorial family
- **WHEN** proving a classification lemma for structures of every size at least two **DO** induct by peeling the top and, separately, the bottom element, then force the two resulting sub-structures to agree on their overlap **BECAUSE** a single ended peel only proves half the rigidity; the overlap between two peels is what pins the whole object down uniquely
- **WHEN** a final answer reduces to a divisor count equal to exactly one **DO** write the relevant integer as a power of the excluded prime times the coprime remainder, since "exactly one divisor" is only ever true of the remainder equalling 1 **BECAUSE** this is the fastest, least error prone way to convert a divisor count condition into an explicit description of the integers satisfying it

Backtesting

1. First useful cue: the midpoint closure condition, immediately suggesting arithmetic progressions, confirmed against the one given exclusion, $\{1, 3\}$.
2. Method the expression suggested: treat $A(n+2) - 2A(n+1) + A(n)$ as a doubly pinned count via two shift bijections, not as a numerical sequence to solve for directly.
3. Where you would hesitate, and the thought to reinforce: the overlap argument in the classification proof, that two progressions sharing at least two points must share a common difference; reinforce by remembering a difference is determined by any two of its terms.

4. The trap the question sets: it invites you to find $A(n)$ in closed form first, a genuinely harder task than the problem needs, when the second difference alone is the clean object.
5. What makes you recognise it faster next time: any phrase of the shape "whenever a pairwise relation holds, a derived element is also in the set" is the fixed signature of a rigid family classification problem.
6. The reusable decision rule: classify the local closure condition first, reduce any finite difference of the counting sequence to a pinned sub-family second, then multiply the two results together.

Mirror drills

1. Prove that a subset S of $\mathbb{Z}$ with $|S| \geq 2$, closed under "if $a, b \in S$ and $a \equiv b \pmod 2$ then $(a+b)/2 \in S$," must be an arithmetic progression with odd common difference. *Answer:* identical proof to the Claim above, peeling the extreme elements of S and reconciling the overlap; the ground set being all of $\mathbb{Z}$ rather than $\{1, \ldots, n\}$ changes nothing.
2. Let $B(n)$ count the subsets of $\{1, \ldots, n\}$ containing no two consecutive integers. Find a bijective meaning for $B(n+1) - B(n)$, and use it to re-derive the recurrence for B. *Answer:* $B(n+1) - B(n)$ counts such subsets containing $n+1$; any such subset is $n+1$ together with a valid subset of $\{1, \ldots, n-1\}$ avoiding n, giving $B(n+1) - B(n) = B(n-1)$, that is, $B(n+1) = B(n) + B(n-1)$.
3. For which positive integers m does m have exactly three positive divisors, and why? *Answer:* exactly when $m = p^2$ for a prime p, since a divisor count of three forces $m = p^e$ for a single prime with $e + 1 = 3$.

17.10 B4. Circle averages and the dimension of balanced polynomials

Say that a polynomial with real coefficients in two variables, x, y, is balanced *if the average value of the polynomial on each circle centred at the origin is* 0*. The balanced polynomials of degree at most* 2009 *form a vector space V over $\mathbb{R}$. Find the dimension of V.*

Read it out loud

Read the command terms before you read the mathematics. *Vector space*. *Dimension*. *Find*. Those three words tell you that this is a linear algebra question wearing an analysis costume. The integral is not the object of study; the integral only exists to manufacture a linear functional, and your job is to count how many independent linear conditions that functional family imposes on a space whose dimension you already know. Say it out loud in that form: the ambient space is all real polynomials in x and y of degree at most 2009, which has dimension $\binom{2011}{2} = 2021055$, and the answer will be 2021055 minus the number of independent conditions. Once you have said that sentence, the problem has stopped being about circles.

Now read the condition. *The average on each circle centred at the origin is zero*. Two guiding lights are planted here. The first is *centred at the origin*: circles about the origin are the level sets of $x^2 + y^2$, so the natural coordinates are polar, and the natural grading on polynomials is by homogeneous degree, because a homogeneous polynomial of degree i scales by r^i when you scale the point by r. The second is *each*: the condition is indexed by a continuous parameter $r > 0$, so you appear to have uncountably many linear conditions on a finite dimensional space. Uncountably many conditions on a finite dimensional space must collapse, and the only question is how. That is the entire problem, and you should have it inside thirty seconds.

The fields wired into this question are: graded vector spaces and rank nullity from linear algebra; a single one variable integral over a period; parity, in the shape of the antipodal map $(x, y) \mapsto (-x, -y)$; and, behind the curtain, the mean value property of harmonic functions, which is the reason the answer is as clean as it is. What is really being tested is whether you will treat r as a nuisance variable to be integrated away, or as a formal variable whose powers separate the conditions for you.

Within thirty seconds you should have written

$$M_P(r) \;=\; \frac{1}{2\pi}\int_0^{2\pi} P(r\cos\theta, r\sin\theta)\, d\theta,$$

noted that arclength on the circle of radius r is $r\,d\theta$ and that the factor r cancels when you average, so this really is the average value, and then written $P = \sum_i P_i$ with P_i homogeneous. Everything after that is bookkeeping.

Approaches, ranked worst to best

1. **Coefficient bash.** *Cue:* the words "vector space" and "dimension" push you to set up a linear system. *Circuit:* write one linear equation per condition and row reduce. You expand P in the 2021055 monomials, compute $\int_0^{2\pi} \cos^a\theta \sin^b\theta\, d\theta$ for every $a + b \le 2009$, and stare at an infinite matrix indexed by r. Every individual step is legal and the ink is unbounded. Worse, without grading you have no handle on the rank at all, so the computation cannot end. This route fails not because it is wrong but because it never terminates.

2. **Fourier expansion on the circle.** *Cue:* an average over a circle is the zeroth Fourier coefficient. *Circuit:* convert $\cos^a\theta \sin^b\theta$ into a combination of $\cos k\theta$ and $\sin k\theta$ and read off the constant term. This is correct and it makes the parity fact obvious, since $\cos^a\theta \sin^b\theta$ with $a + b$ odd has only odd harmonics. It costs product to sum ink, and you still have to organise the count by

degree at the end, so you end up importing the grading anyway. Middle of the table: right idea, wrong order of operations.

3. **Harmonic decomposition.** *Cue:* "average over circles centred at the origin" is literally the mean value property. *Circuit:* write $P_i = \bigoplus_j (x^2+y^2)^j H_{i-2j}$ with H_k harmonic and use that harmonic polynomials of positive degree have zero circle average. This is the true reason the answer is what it is, it produces an explicit basis of V, and it generalises to spheres in $\mathbb{R}^m$ without a single new idea. It ranks below the next route only because in the arena it costs you the decomposition theorem, which you must either quote or prove, and you do not need it to get the number.

4. **Grade by degree, then one witness per even degree.** *Cue:* "polynomial", "each circle", "dimension". *Circuit:* homogeneous decomposition, a polynomial in r with infinitely many roots is zero, parity, rank nullity. Best. Three structural lines turn a continuum of conditions into 2010 conditions, parity kills 1005 of them for free, and each survivor is shown nontrivial by the single witness $(x^2+y^2)^{i/2}$. No integral is ever computed. This is the route that finishes in half a page.

The ideal solution

Let W be the space of real polynomials in x, y of degree at most 2009. Its monomials $x^a y^b$ with $a+b \le 2009$ number $\binom{2011}{2} = 2021055$, so $\dim W = 2021055$. For $i \ge 0$ let $W_i \subset W$ be the subspace of homogeneous polynomials of degree i, so $\dim W_i = i+1$ and $W = \bigoplus_{i=0}^{2009} W_i$; write $P = \sum_{i=0}^{2009} P_i$ for the corresponding unique decomposition.

The circle of radius $r > 0$ centred at the origin carries arclength $r\,d\theta$ and has total length $2\pi r$, so the average value of P on it is

$$M_P(r) = \frac{1}{2\pi} \int_0^{2\pi} P(r\cos\theta, r\sin\theta)\, d\theta.$$

Define the linear functional $\lambda_i : W_i \to \mathbb{R}$ by $\lambda_i(Q) = \frac{1}{2\pi}\int_0^{2\pi} Q(\cos\theta, \sin\theta)\, d\theta$. Homogeneity gives $Q(r\cos\theta, r\sin\theta) = r^i Q(\cos\theta, \sin\theta)$, so

$$M_P(r) = \sum_{i=0}^{2009} r^i\, \lambda_i(P_i) \qquad (r > 0).$$

The right hand side is a polynomial in r of degree at most 2009. A real polynomial vanishing at infinitely many points is the zero polynomial, so $M_P(r) = 0$ for all $r > 0$ if and only if $\lambda_i(P_i) = 0$ for every i. Hence

Claim 17.10.1. *$P \in V$ if and only if $\lambda_i(P_i) = 0$ for $i = 0, 1, \ldots, 2009$, and consequently $V = \bigoplus_{i=0}^{2009} \ker \lambda_i$ and $\dim V = \sum_{i=0}^{2009} \dim\ker \lambda_i$.*

The second sentence follows because the condition is imposed on each graded piece separately and the decomposition $W = \bigoplus W_i$ is direct.

Odd i. If i is odd and $Q \in W_i$ then $Q(-u,-v) = -Q(u,v)$. Substituting $\theta \mapsto \theta + \pi$ permutes the interval of integration modulo the period and sends $(\cos\theta, \sin\theta)$ to $(-\cos\theta, -\sin\theta)$, so $\lambda_i(Q) = -\lambda_i(Q)$, whence $\lambda_i(Q) = 0$. Thus $\lambda_i \equiv 0$ and $\dim\ker\lambda_i = i+1$.

Even i. Take $Q = (x^2+y^2)^{i/2} \in W_i$. On the unit circle $Q \equiv 1$, so $\lambda_i(Q) = 1 \neq 0$. Therefore λ_i is a nonzero linear functional on W_i, its image is all of $\mathbb{R}$, and rank nullity gives $\dim\ker\lambda_i = (i+1) - 1 = i$.

Summing, with the odd degrees $i = 1, 3, \ldots, 2009$ contributing $i+1$ each and the even degrees $i = 0, 2, \ldots, 2008$ contributing i each,

$$\dim V = \sum_{j=1}^{1005} 2j + \sum_{j=0}^{1004} 2j = 1005\cdot 1006 + 1004\cdot 1005 = 1011030 + 1009020.$$

Equivalently, λ_i is a nontrivial condition exactly for the 1005 even values $i = 0, 2, \ldots, 2008$, so $\dim V = \dim W - 1005 = 2021055 - 1005$. Either way,

$$\dim V = \boxed{2020050}.$$

A caveat worth clarifying: a circle has positive radius, so $r = 0$ was never in play, but even if you insisted on including the degenerate circle $\{(0,0)\}$ the condition $P(0,0) = 0$ is exactly $\lambda_0(P_0) = 0$, which is already on the list. The answer is unchanged.

Layer 1: WHAT

Block 1. Read "vector space" and "dimension" and reframe: V is the common kernel of a family of linear functionals, and the answer is $\dim W$ minus the number of independent conditions.

Block 2. Write the average as $M_P(r)$ and observe that the hypothesis is one linear condition for each $r > 0$, a continuum.

Block 3. Split P into homogeneous parts; homogeneity pulls the radius out of the integral as r^i.

Block 4. Recognise $M_P(r)$ as a polynomial in r; vanishing on $(0, \infty)$ forces every coefficient to vanish. The continuum has collapsed to 2010 conditions, one per degree.

Block 5. Parity: odd degree parts are killed by the antipodal map, so 1005 of those conditions are vacuous.

Block 6. Even degree: exhibit $(x^2 + y^2)^{i/2}$ as a witness that $\lambda_i \neq 0$, so each even condition cuts the dimension by exactly one.

Block 7. Count: $2021055 - 1005 = 2020050$.

The nominal route is Block 1 followed by an immediate assault on $\int_0^{2\pi} \cos^a\theta \sin^b\theta \, d\theta$ for all $a + b \leq 2009$, then an attempt to find the rank of the resulting system by hand. The bifurcation point is Block 3 into Block 4: the exact line where you decide whether r is a nuisance parameter to be integrated away, or a formal variable whose powers are the whole point. Treat r as formal and the problem is over in three lines. Treat r as a nuisance and you are still computing Wallis integrals at the end of the session.

Layer 2: HOW

Block 1. Cue. "The balanced polynomials of degree at most 2009 form a vector space V." The examiners told you it is a vector space. They did not have to. **Why natural.** A set defined by "some average vanishes" is a subspace precisely because averaging is linear; the sentence in the question is a hint that you should be hunting for the functional whose kernel this is, not for a description of the polynomials. **Link to the next block.** Once you are hunting for a functional, you must write the functional down, which forces Block 2.

Block 2. Cue. "on each circle centred at the origin". **Why natural.** Circles centred at the origin are the orbits of the rotation group, so the parametrisation $(r\cos\theta, r\sin\theta)$ is not a choice, it is the only description under which the family of circles becomes a single formula with a parameter. Averaging with respect to arclength is averaging in θ, because the arclength element $r\,d\theta$ has a constant density in θ. **Link to the next block.** You now have a function M_P of r, and a condition on all of $(0, \infty)$. Any time a condition is indexed by a continuous parameter you ask how the parameter enters, which is Block 3.

Block 3. Cue. P is a polynomial and the parameter enters as a scaling. **Why natural.** Scaling is exactly what homogeneous pieces are designed to absorb: $P_i(rv) = r^i P_i(v)$ is the definition. So decomposing by degree diagonalises the r dependence. Nothing else in your toolkit turns a scaling into a monomial. **Link to the next block.** Now $M_P(r) = \sum r^i \lambda_i(P_i)$, and you are staring at a polynomial identity in r.

Block 4. **Cue.** "$= 0$ for every r" with the left side a polynomial in r. **Why natural.** A nonzero real polynomial of degree d has at most d roots; infinitely many roots forces every coefficient to vanish. This is the standard device for converting a statement quantified over a continuum into finitely many statements, and it is the reason the problem is finite dimensional in the first place. **Link to the next block.** The conditions are now separated by degree, so you can treat each degree independently, and the cheapest thing to test on any linear condition is a symmetry.

Block 5. **Cue.** Odd degree, and an integral over a full period. **Why natural.** The circle is invariant under the antipodal map and a homogeneous polynomial of odd degree is anti invariant under it. An anti invariant function integrated over an invariant domain integrates to zero. You should test this reflex on every symmetric integral before computing anything. **Link to the next block.** Half the conditions are gone at zero cost. The remaining question is whether the even conditions are genuine, and to prove a linear functional is nonzero you produce one input it does not kill.

Block 6. **Cue.** Even degree i, and you want a polynomial whose circle average is visibly nonzero. **Why natural.** On the circle you want an integrand of constant sign, and the only homogeneous polynomial that is constant on the unit circle is a multiple of $(x^2 + y^2)^{i/2}$, which exists exactly when i is even. It is the object the problem is built around, since circles are its level sets. You do not need the value of the integral, only that it is not zero. **Link to the next block.** Rank nullity converts "nonzero functional" into "kernel of codimension one", and the count is immediate.

Block 7. **Cue.** A finite sum with a parity split. **Why natural.** There are 1005 even degrees in $\{0, 1, \ldots, 2009\}$ and 1005 odd ones. Count the conditions, not the kernels, and the arithmetic is one subtraction. **Link to the next block.** Done. The answer is 2020050.

Layer 3: WHY

The mathematical truth underneath is that averaging over the circle is the projection of a function onto its rotation invariant part. If you average a polynomial over the circle you are integrating it against the uniform measure on the orbit of the rotation group $SO(2)$, and this operator kills everything that is not invariant. So the number of conditions in degree i is exactly the dimension of the rotation invariant subspace of W_i, and that dimension is at most one.

Here is the proof, and it is short enough that you should keep it in the arena. Suppose $Q \in W_i$ is constant, say equal to c, on the unit circle. If i is odd then $Q(-v) = -Q(v)$ forces $c = -c$, so $c = 0$; then Q vanishes on the unit circle, and since every nonzero point of the plane is a positive multiple of a unit vector and $Q(tv) = t^i Q(v)$, Q vanishes identically. If i is even then $Q - c(x^2 + y^2)^{i/2}$ is homogeneous of degree i and vanishes on the unit circle, hence vanishes identically by the same scaling argument, so $Q = c(x^2 + y^2)^{i/2}$. In other words the invariants are generated by $x^2 + y^2$, the invariant subspace of W_i is one dimensional for even i and zero for odd i, and that single number is the entire content of the problem.

The discernment mechanism, the thing you actually train, is this. When a hypothesis is quantified over a continuous parameter, do not integrate the parameter away; isolate the dependence on it and ask what kind of function of the parameter you are looking at. If it is a polynomial, a power series, or an analytic function, the continuum of conditions collapses to the coefficients, and the collapse is usually the whole problem. You saw the same collapse in every generating function argument you have ever done: "equal for all x in an interval" means "equal coefficientwise".

The second trained instinct is cheaper still: to find the dimension of the kernel of a linear map you never need to describe the kernel. You need the rank, and the rank of a functional is one as soon as you can name a single input it does not kill. Candidates lose this problem by trying to write down a basis of V. You are not asked for a basis. Be lazy: name a witness, quote rank nullity, count.

What were the examiners nudging toward? Three things. They said "vector space" so you would look for linearity. They said "centred at the origin" so you would use polar coordinates and grading rather than a general position argument. They chose degree 2009, an odd number, so that the even and odd degrees split as 1005 and 1005 and the final arithmetic stays clean. The number 2009 is otherwise doing no work.

Revolving concepts

Average value on a curve. The average of F over a curve γ is $\frac{1}{\text{length}(\gamma)} \int_\gamma F\, ds$. For the circle of radius r about the origin, $ds = r\, d\theta$ and the length is $2\pi r$, so the average is $\frac{1}{2\pi} \int_0^{2\pi} F\, d\theta$ and the radius cancels. Note that the cancellation is special to circles about the origin; for a circle about another centre the density in θ is still constant but the polynomial no longer scales, which is why the problem specifies the centre. See Book 1, field: Calculus and integrals, topic: line integrals and averages.

Graded decomposition. $\mathbb{R}[x, y] = \bigoplus_{i \geq 0} W_i$ with $\dim W_i = i + 1$. In m variables $\dim W_i = \binom{i+m-1}{m-1}$ and the number of monomials of degree at most d is $N_m(d) = \binom{d+m}{m}$. That count satisfies the Pascal recursion $N_m(d) = N_m(d-1) + N_{m-1}(d)$, with $N_1(d) = d + 1$: split on whether the last variable appears. Every "how many monomials" count on the Putnam is this recursion or a stars and bars argument for the same thing. See Book 1, field: Combinatorics, topic: stars and bars.

Vanishing polynomials. A real polynomial with infinitely many roots is identically zero. The two dimensional version used above: a homogeneous polynomial vanishing on the unit circle vanishes identically, because $Q(tv) = t^i Q(v)$. See Book 1, field: Polynomials, topic: identity theorem.

Rank nullity and codimension. For linear $T : U \to \mathbb{R}$, either $T = 0$ and $\ker T = U$, or $T \neq 0$ and $\dim \ker T = \dim U - 1$. There is no third case, which is why one witness settles the matter. See Book 1, field: Linear algebra, topic: rank.

Harmonic polynomials and the mean value property. Let $\mathcal{H}_k$ be the harmonic homogeneous polynomials of degree k in two variables; $\mathcal{H}_0 = \langle 1 \rangle$ and $\dim \mathcal{H}_k = 2$ for $k \geq 1$, spanned by the real and imaginary parts of $(x + iy)^k$. Every homogeneous P_i decomposes as $P_i = \sum_j (x^2 + y^2)^j H_{i-2j}$ with $H_k \in \mathcal{H}_k$, and dimensions check: $2\lfloor i/2 \rfloor + [i \text{ even}] = i + 1$. Since a harmonic function has mean value equal to its value at the centre, and $H_k(0, 0) = 0$ for $k \geq 1$, only the j with $i - 2j = 0$ survives averaging. So P is balanced exactly when the coefficient of $(x^2 + y^2)^{i/2}$ in the decomposition of each even part P_i is zero, which exhibits an explicit basis of V and recovers the count. See Book 1, field: Real analysis, topic: harmonic functions.

Explicit circle moments. For nonnegative integers a, b,

$$\frac{1}{2\pi} \int_0^{2\pi} \cos^{2a}\theta \sin^{2b}\theta\, d\theta = \frac{\binom{2a}{a}\binom{2b}{b}}{4^{a+b}\binom{a+b}{a}},$$

and the average is 0 if either exponent is odd. You never need these values here, but they are the explicit form of λ_i, and they let you write a basis of $\ker \lambda_i$ by hand. See Book 1, field: Calculus and integrals, topic: Wallis integrals.

The generalisation you should carry away. In $\mathbb{R}^m$, with spheres about the origin and polynomials of degree at most d, the identical argument gives one condition per even degree at most d, so the balanced space has dimension $\binom{d+m}{m} - (\lfloor d/2 \rfloor + 1)$. For $m = 2$, $d = 2009$ that is $2021055 - 1005$. The invariants of the rotation group are generated by $x_1^2 + \cdots + x_m^2$ in every dimension, and that single fact is the whole engine.

Circuit Bank

- **WHEN** a hypothesis is quantified over all values of a continuous parameter **DO** isolate the parameter dependence and check whether it is polynomial or analytic; if so, set every

coefficient to zero **BECAUSE** a nonzero polynomial has finitely many roots, so a continuum of conditions collapses to finitely many coefficient conditions

- **WHEN** circles or spheres centred at the origin appear in a polynomial problem **DO** decompose into homogeneous parts **BECAUSE** homogeneity turns the radius into the scalar factor r^i, which separates the degrees and diagonalises the whole family of conditions
- **WHEN** you must show a linear condition is nontrivial **DO** name one explicit object the functional does not kill **BECAUSE** a nonzero functional has kernel of codimension exactly one, so a single witness converts the whole question into a subtraction
- **WHEN** you integrate over a domain invariant under a symmetry **DO** split the integrand into invariant and anti invariant parts and discard the anti invariant part **BECAUSE** anti invariant functions integrate to zero over invariant domains, which is usually half the work for one line of writing
- **WHEN** you are asked for the dimension of a space of objects, not for the objects **DO** compute the rank of the defining conditions and subtract **BECAUSE** describing the kernel costs a basis; counting the conditions costs a witness

Backtesting

1. First useful cue: "vector space" and "dimension", which reframe the problem as counting independent linear conditions, plus "each circle centred at the origin", which fixes polar coordinates and the grading by homogeneous degree.
2. Method the expression suggested: write the average as $M_P(r) = \sum_i r^i \lambda_i(P_i)$, treat r as a formal variable, and read off one condition per degree.
3. Where you would hesitate, and the thought to reinforce: the temptation is to start computing circle moments of monomials. Reinforce this instead: you never need the value of a linear functional, only whether it is zero, and the cheapest proof that it is not zero is one witness. Here the witness $(x^2 + y^2)^{i/2}$ is handed to you by the geometry.
4. The trap the question sets: the continuum of radii, which looks like infinitely many conditions and invites either despair or a numerical assault. The second trap is degree 2009, which invites you to think the size of the number matters; it does not, only its parity does.
5. What makes you recognise it faster next time: the pattern "linear condition indexed by a scaling parameter, applied to polynomials". Whenever scaling is the parameter, grade by degree first and read the conditions off the coefficients.
6. The reusable decision rule: a condition holding for all values of a continuous parameter is a coefficient identity in disguise; grade, separate, then count ranks with witnesses.

Mirror drills

1. Find the dimension of the space of real polynomials in x, y of degree at most d whose average on every circle centred at the origin is zero. *Answer:* $\binom{d+2}{2} - (\lfloor d/2 \rfloor + 1)$, by the identical grading argument; check it against $d = 2009$.
2. Show that the average of $x^a y^b$ over the unit circle is zero unless a and b are both even, and that it is strictly positive when both are even. *Answer:* apply $x \mapsto -x$ or $y \mapsto -y$, which preserves the circle and flips the sign when the corresponding exponent is odd; when both are even the integrand is nonnegative and not identically zero.

3. In $\mathbb{R}^3$, find the dimension of the space of polynomials in x, y, z of degree at most 4 whose average on every sphere centred at the origin is zero. *Answer:* $\binom{7}{3} - 3 = 35 - 3 = 32$, since the even degrees $0, 2, 4$ each contribute exactly one condition and the witness in degree i is $(x^2 + y^2 + z^2)^{i/2}$.

17.11 B5. A rational differential equation forced to diverge

Let $f : (1, \infty) \to \mathbb{R}$ be a differentiable function such that

$$f'(x) = \frac{x^2 - f(x)^2}{x^2\,(f(x)^2 + 1)} \qquad \text{for all } x > 1.$$

Prove that $\lim_{x\to\infty} f(x) = \infty$.

Read it out loud

A first order differential equation, rational in both variables, and no initial condition. The missing initial condition is the loudest cue in the question. You are not asked what f is, you are asked what f does, and the answer must be the same for every solution, so any route that tries to produce a formula is doomed before it starts. This is a qualitative question: the fields are real analysis (monotonicity from the sign of a derivative, the mean value theorem) and asymptotics, with a thin layer of algebra on top to find the right unknown.

Now read the right hand side out loud. "x^2 minus f squared, over x squared times f squared plus one." Two guiding lights. First, the numerator $x^2 - f^2$ vanishes exactly on the lines $f = \pm x$, so those two lines are the nullclines and they are what the whole picture will be organised around: above and below them the sign of f' flips. Second, and far more important, the denominator contains the factor $f^2 + 1$, and $f^2 + 1$ is exactly $\frac{d}{df}\left(f + \frac{1}{3}f^3\right)$. A denominator that is a polynomial in the unknown function is not an obstacle, it is an instruction: multiply by it.

So within thirty seconds you should have written two rearrangements, both trivial, both decisive:

$$f'(x)\left(1 + f(x)^2\right) = 1 - \frac{f(x)^2}{x^2}, \qquad f'(x) + \frac{1}{x^2} = \frac{x^2 + 1}{x^2\,(1 + f(x)^2)} > 0.$$

The first says that $g = f + \frac{1}{3}f^3$ has a derivative with no denominator at all and bounded above by 1. The second says that $f - \frac{1}{x}$ is strictly increasing, which is your lower bound on f, free of charge. Every remaining line of the solution is squeezed out of those two facts.

What is really being tested: whether you convert an equation you cannot solve into a statement about a quantity that is monotone. Monotone plus unbounded is the only cheap machinery for proving divergence, and finding the right monotone quantity is the entire skill.

Approaches, ranked worst to best

1. **Solve the equation.** *Cue:* "differentiable function such that $f' = \ldots$" reads like an invitation to integrate. *Circuit:* separate the variables or find an integrating factor. It is not separable: the term f^2/x^2 genuinely couples the variables, and the equation is not linear in f. The homogeneous substitution $f = xu$ produces $xu' + u = \frac{1-u^2}{1+x^2u^2}$, which is not autonomous and is worse than what you started with. Maximum ink, zero progress, and it also misses the point that no initial condition was given.

2. **Crude bounds and a monotone limit.** *Cue:* $|f'| \le 1$ style estimates. *Circuit:* trap f between barriers, deduce eventual monotonicity, then rule out a finite limit. This works and is the official first route: bound f below using $f' > -1/x^2$, prove $f(x) < x$ for large x by taking the least crossing point of f and x and contradicting it, conclude $f' > 0$ eventually, so a limit L exists, and if L were finite then $f' \to 1/(1 + L^2) > 0$ would force f to grow linearly. Correct, but it is three separate arguments plus a least element argument that is easy to write loosely and lose a point on.

3. **The nullcline pair $x + f$ and $x - f$.** *Cue:* the numerator vanishes on $f = \pm x$, so the natural coordinates are $x \pm f$. *Circuit:* show both combinations have a derivative of constant sign.

Compute: $(x+f)' = \frac{2x^2+f^2(x^2-1)}{x^2(1+f^2)} > 0$ and $(x-f)' = \frac{f^2(x^2+1)}{x^2(1+f^2)} \geq 0$. Both are one line and both are visibly signed, which gives $|f(x)| < x$ eventually with no least crossing point argument. Better than the previous route, but you still need a third argument to handle f itself, so it is not the shortest path.

4. **The antiderivative substitution $g = f + \frac{1}{3}f^3$.** *Cue:* the denominator $1+f^2$ is precisely $\frac{d}{df}\left(f+\frac{1}{3}f^3\right)$. *Circuit:* multiply through by the denominator so that the left side becomes an exact derivative. Best. One substitution removes every denominator involving f and produces $g' = 1 - f^2/x^2$, whose upper bound $g' \leq 1$ is immediate and whose limit is 1 as soon as you know f is sublinear. Upper bound, sublinearity, divergence of g and divergence of f all fall out in sequence, with no case analysis, no least element and no integration.

The ideal solution

Throughout, $x > 1$. Write f for $f(x)$ where no confusion arises. Two rearrangements of the given equation will be used repeatedly, and I refer to them as identity (i) and identity (ii):

$$\text{(i)} \qquad f'(x) + \frac{1}{x^2} = \frac{x^2 - f^2 + \left(1+f^2\right)}{x^2\left(1+f^2\right)} = \frac{x^2+1}{x^2\left(1+f^2\right)} > 0,$$

$$\text{(ii)} \qquad f'(x)\left(1+f(x)^2\right) = \frac{x^2 - f(x)^2}{x^2} = 1 - \frac{f(x)^2}{x^2}.$$

Step 1: f is bounded below. By identity (i), the function $x \mapsto f(x) - \frac{1}{x}$ has derivative $f'(x) + \frac{1}{x^2} > 0$ on $(1,\infty)$, hence is strictly increasing there. Therefore, for $x \geq 2$,

$$f(x) - \frac{1}{x} \;\geq\; f(2) - \frac{1}{2}, \qquad \text{so} \qquad f(x) \;>\; f(2) - \frac{1}{2} \;=:\; m.$$

Step 2: f grows at most like $x^{1/3}$. Put

$$g(x) = f(x) + \tfrac{1}{3}f(x)^3.$$

Then g is differentiable and, by the chain rule and identity (ii),

$$g'(x) = f'(x)\left(1+f(x)^2\right) = 1 - \frac{f(x)^2}{x^2} \;\leq\; 1.$$

Hence $x \mapsto g(x) - x$ has nonpositive derivative and so is non increasing on $(1,\infty)$; for $x \geq 2$ this gives $g(x) - x \leq g(2) - 2 =: K$. Combining with Step 1,

$$\tfrac{1}{3}f(x)^3 = g(x) - f(x) \;\leq\; (x+K) - m, \qquad \text{that is} \qquad f(x)^3 \;\leq\; 3x + D, \quad D := 3(K-m).$$

Set $X_0 = \max\{2, |D|\}$. For $x \geq X_0$ we have $3x + D \leq 4x$, so

$$f(x) \;\leq\; (4x)^{1/3} \qquad (x \geq X_0).$$

Step 3: $g'(x) \to 1$. For $x \geq X_0$ we have $m < f(x) \leq (4x)^{1/3}$, hence $f(x)^2 \leq \max\{m^2, (4x)^{2/3}\}$ and therefore

$$0 \;\leq\; \frac{f(x)^2}{x^2} \;\leq\; \frac{\max\{m^2, (4x)^{2/3}\}}{x^2} \;\longrightarrow\; 0 \qquad (x \to \infty).$$

By identity (ii), $g'(x) = 1 - f(x)^2/x^2 \to 1$.

Step 4: $g(x) \to +\infty$. Choose $X_1 \geq X_0$ with $g'(x) \geq \frac{1}{2}$ for all $x \geq X_1$. For $x > X_1$ the mean value theorem gives $\xi \in (X_1, x)$ with

$$g(x) - g(X_1) = g'(\xi)(x - X_1) \;\geq\; \tfrac{1}{2}(x - X_1),$$

so $g(x) \geq g(X_1) + \frac{1}{2}(x - X_1) \to +\infty$.

Step 5: $f(x) \to +\infty$. The map $\phi(t) = t + \frac{1}{3}t^3$ is strictly increasing on $\mathbb{R}$, since $\phi'(t) = 1 + t^2 > 0$, and $g = \phi \circ f$. Let $M > 0$. By Step 4 there is $X_2 \geq X_1$ with $g(x) > \phi(M)$ for all $x \geq X_2$. If some $x \geq X_2$ had $f(x) \leq M$, then $g(x) = \phi(f(x)) \leq \phi(M)$, a contradiction. Hence $f(x) > M$ for all $x \geq X_2$. As M was arbitrary,

$$\lim_{x \to \infty} f(x) = +\infty. \qquad \blacksquare$$

Remark 17.11.1. The same two rearrangements give the sharp asymptotic at no extra cost. From $g' \to 1$ and the mean value theorem applied to $g(x) - x$ one gets $g(x)/x \to 1$. Since $f \to \infty$, $g = \frac{1}{3}f^3\left(1 + 3f^{-2}\right) \sim \frac{1}{3}f^3$, so $\frac{1}{3}f(x)^3 \sim x$ and therefore

$$f(x) \sim (3x)^{1/3} \qquad (x \to \infty),$$

independently of which solution f you were handed. Numerically, solutions started anywhere between $f = -40$ and $f = 60$ near $x = 1$ all satisfy $f(x)/(3x)^{1/3} \to 1$; a solution that starts far below zero simply takes until $x \approx |f_0|^3/3$ to turn round, which is exactly what $g(x) - x$ non increasing predicts.

Layer 1: WHAT

Block 1. No initial condition and no closed form: the target is qualitative, so hunt for a quantity with a monotone or asymptotically constant derivative.

Block 2. The denominator $1 + f^2$ is the derivative of $f + \frac{1}{3}f^3$, so multiply through by it rather than dividing by it.

Block 3. That yields $g' = 1 - f^2/x^2$, an equation with no denominator, and immediately $g' \leq 1$.

Block 4. $g' \leq 1$ gives $g(x) \leq x + K$, which bounds f above by roughly $(3x)^{1/3}$, but only once f is known to be bounded below.

Block 5. The lower bound comes from the other rearrangement: $f' + \frac{1}{x^2} > 0$, so $f - \frac{1}{x}$ is increasing and f is bounded below by a constant.

Block 6. Feed the sublinear bound back into $g' = 1 - f^2/x^2$ to get $g' \to 1$, hence g eventually increases at rate at least $\frac{1}{2}$ and $g \to \infty$.

Block 7. $\phi(t) = t + \frac{1}{3}t^3$ is increasing, so $g \to \infty$ transfers to $f \to \infty$.

The nominal route is Block 1 followed by an attempt to separate variables, or by the estimate $|f'| \leq 1$ and a hope that boundedness of f' says something about f at infinity (it says nothing). The bifurcation point is inside Block 2: the line at which you decide whether to divide by $1 + f^2$ in order to isolate f', or to multiply by it in order to build an exact derivative. Dividing keeps the equation unsolvable. Multiplying converts it into a perturbation of $g' = 1$, which is the same as saying $f + \frac{1}{3}f^3 = x + c$, and that is the answer in disguise.

Layer 2: HOW

Block 1. **Cue.** A differential equation with no initial condition, and the demand is a limit. **Why natural.** If no initial condition is supplied then the conclusion must hold for every solution, so the conclusion cannot depend on any constant of integration. That rules out formula hunting on logical grounds alone, before you even test whether the equation is separable. **Link to the next block.** If you cannot produce f, you must produce a function of f whose behaviour you can control, so you go looking at the structure of the right hand side for a candidate.

Block 2. **Cue.** The denominator $x^2\left(f^2 + 1\right)$ splits into a factor depending only on x and a factor depending only on f. **Why natural.** When $f' = \frac{A(x)}{B(f)}$ the equation is separable and the correct unknown is $\int B$. Here $f' = \frac{1}{1+f^2}\left(1 - \frac{f^2}{x^2}\right)$ is that shape multiplied by a correction factor, so the

same substitution is still the right one; you simply have to carry the correction along. Since $\int(1+t^2)\,dt = t + \frac{1}{3}t^3$, the quantity to name is $g = f + \frac{1}{3}f^3$. **Link to the next block.** Multiplying by $1+f^2$ makes the left side $\frac{d}{dx}g$ and clears every f from the denominator, which is Block 3.

Block 3. Cue. $g' = 1 - f^2/x^2$, with no denominators anywhere. **Why natural.** The correction factor $1 - f^2/x^2$ is bounded above by 1 for free, since $f^2 \geq 0$. An inequality on a derivative is an inequality on the function via monotonicity, and you get it without integrating. **Link to the next block.** An upper bound on g is an upper bound on f, because $\phi(t) = t + \frac{1}{3}t^3$ is increasing, but converting it needs f bounded below, which is Block 5.

Block 4. Cue. $g(x) - x$ has nonpositive derivative. **Why natural.** This is the cleanest form of an integrated inequality: instead of writing $g(x) = g(2) + \int_2^x g'$ and estimating, you name the combination whose derivative has a fixed sign and quote monotonicity. Same content, less ink, and no integrability discussion. **Link to the next block.** You now have $\frac{1}{3}f^3 \leq x + K - f$, and to turn that into an upper bound on f you must control the $-f$ term, which is exactly a lower bound on f.

Block 5. Cue. You need a lower bound, and the equation gives $f' \geq -\frac{1}{x^2}$ with $\frac{1}{x^2}$ integrable at infinity. **Why natural.** The quantity $\frac{1}{x^2}$ is the derivative of $-\frac{1}{x}$, so $f - \frac{1}{x}$ has positive derivative. The identity $f' + \frac{1}{x^2} = \frac{x^2+1}{x^2(1+f^2)}$ is an algebraic identity, not an estimate, so there is nothing to check: put the two terms over a common denominator and the numerator is visibly positive. **Link to the next block.** With $f > m$ and $\frac{1}{3}f^3 \leq x + K - m$ you have $f = O(x^{1/3})$, and a sublinear bound is exactly what the correction term in g' needs.

Block 6. Cue. $g' = 1 - f^2/x^2$ and $f = O(x^{1/3})$, so the correction is $O(x^{-4/3})$. **Why natural.** This is bootstrapping: a crude bound on f, substituted back into the equation, sharpens the information about g', which in turn sharpens g and hence f. It is the standard loop in every asymptotic argument, and here one turn of the loop suffices. **Link to the next block.** $g' \to 1$ means g eventually increases at rate at least $\frac{1}{2}$, and the mean value theorem turns that into $g \to \infty$.

Block 7. Cue. You have $\phi(f) \to \infty$ with ϕ strictly increasing, and you want $f \to \infty$. **Why natural.** Monotone functions transfer limits to infinity in both directions: if f failed to exceed M at some large x, then $\phi(f)$ would fail to exceed $\phi(M)$ there. Write it as that one line contradiction rather than invoking an inverse function theorem. **Link to the next block.** Done. Note that you never needed f itself to be monotone, which is exactly what made this route shorter than the trapping routes.

Layer 3: WHY

The truth beneath the whole problem is that the equation is a perturbation of one you can solve exactly. Discard the term f^2/x^2 and you are left with $f' = \frac{1}{1+f^2}$, whose solutions satisfy $f + \frac{1}{3}f^3 = x + c$ exactly. That equation clearly forces $f \to \infty$ like $(3x)^{1/3}$. So the mathematical content of B5 is not "prove a limit", it is "prove the perturbation is harmless", and once you have said that sentence the route is forced: name the exactly solvable core, bound the perturbation, show it vanishes, transfer the conclusion.

The discernment mechanism is a two part reflex. Part one: when f' has a function of f in the denominator, the correct new unknown is the antiderivative of that function. Dividing to isolate f' is what a calculator does; multiplying to create an exact derivative is what a mathematician does, because $B(f)f' = \frac{d}{dx}\left[\int B\right](f)$ is the only way the chain rule can help you here. Part two: when the goal is a limit rather than a formula, you are always looking for a quantity with a signed derivative, because the mean value theorem is the only mechanism that converts local information (the sign

of f') into global information (behaviour at infinity). Everything else in analysis at this level is a repackaging of that.

How do you train it? Take every differential equation you meet and, before doing anything, write the right hand side in the form "a solvable core times a correction" and identify the correction's size. Then ask which combination of x and f has an unambiguously signed derivative. On this problem there are three good answers, $f - \frac{1}{x}$, $x - f$ and $g - x$, and the solution uses two of them. A route that uses none of them, such as trying to solve the equation, is a route with no mechanism for producing a conclusion at infinity.

One more structural point that is worth repeating, because it recurs across the whole Putnam. The problem says f is differentiable, not continuously differentiable. You do not need extra regularity here, since the argument is built on the mean value theorem alone. But note that the equation upgrades itself: f differentiable makes f continuous, which makes the right hand side continuous, which makes f' continuous, so f is automatically C^1; repeating the argument gives $f \in C^\infty$. That bootstrap is free and is a standard remark to have ready, though a full marks solution does not need it.

The examiners nudged in three ways. They put $f^2 + 1$ in the denominator, which is a pointer at $f + \frac{1}{3}f^3$ and is the only reason the cube appears in the asymptotic. They wrote the numerator as $x^2 - f^2$ rather than expanding, so the nullclines $f = \pm x$ are visible. And they set the domain to $(1, \infty)$ so that $1/x^2$ is small and integrable at infinity, which is what makes the lower bound in Step 1 a constant rather than a drifting function.

Revolving concepts

Monotonicity from the sign of the derivative. If F is differentiable on an interval and $F' \geq 0$ there, then F is non decreasing on that interval, and strict inequality gives strict monotonicity. The proof is the mean value theorem. This is the only tool used in the ideal solution, and it is the reason the solution avoids every integration. See Book 1, field: Real analysis, topic: mean value theorem.

The barrier trick. To convert a differential inequality $F'(x) \geq -h(x)$ into a bound, name H with $H' = h$ and observe that $F + H$ is non decreasing. Here $h(x) = 1/x^2$, $H(x) = -1/x$, and the conclusion is $f(x) \geq f(2) - \frac{1}{2} + \frac{1}{x}$. This replaces an integration of an inequality by a monotonicity statement, which is cheaper to justify. See Book 1, field: Real analysis, topic: differential inequalities.

The limit lemma. If F is differentiable on (a, ∞) and $F'(x) \to L$ then $F(x)/x \to L$; if in addition $L > 0$ then $F(x) \to +\infty$. Proof: apply the mean value theorem to $F(x) - Lx$ on $[X, x]$, where $|F' - L| < \varepsilon$ beyond X. This is the Cesaro and L'Hopital fact in the form you actually use. See Book 1, field: Real analysis, topic: asymptotics of derivatives.

Exact derivative substitutions. If $f' = \frac{A(x)}{B(f)}$, put $\Phi(t) = \int_0^t B$ and the equation becomes $\frac{d}{dx}\Phi(f) = A(x)$, hence $\Phi(f(x)) = \int A$. This is what separation of variables really is. When the equation is only approximately of that form, the substitution still helps: $\frac{d}{dx}\Phi(f) = A(x)\,(1 + \text{small})$. See Book 1, field: Calculus and integrals, topic: separable equations.

Bootstrapping, stated as a recursion. You have $y' = F(x, y)$ and a crude bound $|y| \leq C_0 x^{\alpha_0}$. Substituting it into the equation produces a bound on y', hence by integration a bound $|y| \leq C_1 x^{\alpha_1}$ with $\alpha_1 = T(\alpha_0)$ for some map T determined by F. Iterating gives $\alpha_{k+1} = T(\alpha_k)$, and the fixed point of T is the true growth exponent. Here $\alpha_0 = 1$ (from $|f| \leq x + C$), the map produces $\alpha_1 = 1/3$, and $1/3$ is already the fixed point, so one turn suffices; continuing the same loop on the constant rather than the exponent produces the full asymptotic expansion $f = (3x)^{1/3}\left(1 + c_1 x^{-2/3} + \cdots\right)$. The identical loop is how you extract asymptotics from every implicitly defined sequence or function. See Book 1, field: Real analysis, topic: bootstrapping and asymptotic expansions.

Nullclines and the phase plane. For $y' = F(x, y)$ the nullcline is the curve $F = 0$; the sign of F on either side of it dictates whether solutions rise or fall, and solutions can cross a nullcline only in the direction the sign change permits. Here the nullclines are $f = \pm x$, and the observation

that $(x-f)' \geq 0$ says that once $f < x$ the gap never closes. See Book 1, field: Real analysis, topic: qualitative theory of first order equations.

Existence and uniqueness. The right hand side $F(x,y) = \frac{x^2-y^2}{x^2(y^2+1)}$ is continuously differentiable in (x,y) for $x > 1$, so by the Picard and Lindelof theorem solutions exist locally and are unique for each initial value; the problem hands you one and asks for its behaviour. Regularity bootstraps: f differentiable implies f' continuous implies $f \in C^1$ implies $f \in C^2$, and so on, so $f \in C^\infty$. See Book 1, field: Real analysis, topic: existence and uniqueness for ODEs.

Circuit Bank

- **WHEN** f' has a polynomial in f in the denominator **DO** multiply through by that polynomial and recognise the left side as $\frac{d}{dx}\Phi(f)$ where Φ' is that polynomial **BECAUSE** $\Phi(f)$ is the natural unknown; the equation then has no denominator in f and its right side depends on x and on a bounded correction only
- **WHEN** a differential equation is given with no initial condition and the demand is a limit **DO** stop trying to solve it and hunt for a combination of x and f whose derivative has a fixed sign **BECAUSE** a conclusion that must hold for every solution cannot depend on a constant of integration, and monotone plus unbounded is the cheapest route to a limit
- **WHEN** you need a bound on f from a differential inequality $f' \geq -h(x)$ with h having an explicit antiderivative H **DO** state that $f + H$ is non decreasing **BECAUSE** monotonicity of an explicit combination replaces integrating an inequality and needs only the mean value theorem, so there is nothing for a grader to object to
- **WHEN** you have shown $F'(x) \to L > 0$ **DO** conclude $F \to +\infty$ and $F(x)/x \to L$ **BECAUSE** beyond some X you have $F' \geq L/2$, and the mean value theorem gives $F(x) \geq F(X) + \frac{L}{2}(x - X)$
- **WHEN** you have proved $\Phi(f) \to \infty$ for a strictly increasing Φ **DO** conclude $f \to \infty$ in one line **BECAUSE** if $f(x) \leq M$ at some large x then $\Phi(f(x)) \leq \Phi(M)$ there, contradicting the divergence of $\Phi(f)$

Backtesting

1. First useful cue: the factor $f^2 + 1$ in the denominator, which is the derivative of $f + \frac{1}{3}f^3$; the secondary cue is the absence of an initial condition, which tells you the answer must be solution independent.
2. Method the expression suggested: multiply by $1 + f^2$ to obtain the exact derivative $g' = 1 - f^2/x^2$, then run monotonicity arguments on $g - x$ and on $f - \frac{1}{x}$.
3. Where you would hesitate, and the thought to reinforce: the hesitation is at the upper bound, where $\frac{1}{3}f^3 = g - f \leq x + K - f$ is useless until f is bounded below. Reinforce this: whenever a chain of bounds stalls, look for the missing bound in the other direction, and expect the equation to supply it through a different rearrangement of the same identity.
4. The trap the question sets: the equation looks separable at a glance, and the estimate $|f'| \leq 1$ looks useful. Neither is. A bounded derivative says nothing about the limit, and the coupling f^2/x^2 blocks separation. The second trap is assuming f is eventually monotone and using it without proof.
5. What makes you recognise it faster next time: the shape $\frac{\text{something in } x}{\text{polynomial in } f}$ on the right hand side. That shape means "integrate the denominator". Also the shape $x^2 - f^2$, which announces the nullclines $f = \pm x$.

6. The reusable decision rule: to prove divergence of an implicitly defined function, build a quantity whose derivative you can sign, prove that quantity diverges, and transfer back through a strictly monotone map.

Mirror drills

1. Let f satisfy $f'(x) = \frac{1}{1+f(x)^2}$ on $(0,\infty)$ with $f(0) = 0$. Find the asymptotic behaviour of f. *Answer:* multiply by $1 + f^2$ to get $\left(f + \frac{1}{3}f^3\right)' = 1$, so $f + \frac{1}{3}f^3 = x$ exactly and $f(x) \sim (3x)^{1/3}$.
2. Let F be differentiable on $(1,\infty)$ with $F'(x) \to L$. Prove $F(x)/x \to L$, and that $F \to +\infty$ when $L > 0$. *Answer:* given $\varepsilon > 0$ pick X with $|F' - L| < \varepsilon$ on $[X,\infty)$ and apply the mean value theorem to $F(x) - Lx$ on $[X, x]$; divide by x.
3. For the f of the problem, prove $f(x)/(3x)^{1/3} \to 1$. *Answer:* Steps 1 to 5 give $f \to \infty$ and $g' \to 1$; the previous drill gives $g(x)/x \to 1$, and $g \sim \frac{1}{3}f^3$ because $f \to \infty$, so $\frac{1}{3}f^3 \sim x$.

17.12 B6. Reaching every integer in a fixed number of steps

Prove that for every positive integer n, there is a sequence of integers $a_0, a_1, \ldots, a_{2009}$ with $a_0 = 0$ and $a_{2009} = n$ such that each term after a_0 is either an earlier term plus 2^k for some nonnegative integer k, or of the form $b \bmod c$ for some earlier positive terms b and c. [Here $b \bmod c$ denotes the remainder when b is divided by c, so $0 \leq (b \bmod c) < c$.]

Read it out loud

Read the quantifiers first, because they carry the whole difficulty. *For every positive integer n*, there is a sequence of *fixed length* 2010. So n is unbounded and the budget is not. That mismatch is the problem. Everything else, the two allowed moves and the bracketed definition of $b \bmod c$, is machinery.

Now read the machinery. You are building a straight line program: a list of values, each produced from earlier values by one of two instructions. Instruction one, add a power of two to an earlier term. Instruction two, reduce one earlier positive term modulo another. Ask the only question that matters: how much can one step change the description length of a number? Instruction one adds at most one binary digit. If you only ever add powers of two, then reaching n requires at least as many steps as there are ones in the binary expansion of n, and $n = 2^{3000} - 1$ has three thousand of them. So addition of powers of two is not the engine; it is the cheap way to build numbers with a small number of binary digits. The mod is the only instruction that can output something whose binary expansion is long and complicated when both inputs are simple. Therefore the mod must do essentially all of the work, and there will be at most a couple of them.

The fields wired in are elementary number theory (base representations, the uniqueness of the remainder, congruences) and polynomial algebra (the factor theorem and Taylor expansion in $\mathbb{Z}[x]$), with a light coating of computational complexity, since "sequence of fixed length from a fixed instruction set" is exactly the definition of a straight line program and the underlying model is that of addition chains.

Within thirty seconds you should have written the following. Which integers are free? Exactly those with few ones in binary. So fix $x = 2^h$ and think in base x: any integer whose base x digits are powers of two and few in number can be assembled by a handful of additions. Then ask the operative question: what pair of base x sparse integers has a remainder that reveals n?

Approaches, ranked worst to best

1. **Binary expansion.** *Cue:* "an earlier term plus 2^k" looks like an instruction to build n digit by digit. *Circuit:* greedily add the powers of two occurring in n. It produces n in exactly $s(n)$ steps where $s(n)$ is the binary digit sum, and $s(n)$ is unbounded. Dead for any n with more than 2009 ones. Its only value is diagnostic: it tells you precisely what the mod is for.

2. **Euclidean descent.** *Cue:* "$b \bmod c$" is the Euclidean algorithm step. *Circuit:* shrink large numbers towards n by repeated reduction. You can certainly steer numbers downwards, but the number of reductions needed grows with the numbers involved and there is no uniform bound. Same failure mode as the previous route, dressed differently, and it wastes more time because it feels productive.

3. **Primitive root construction.** *Cue:* 2 is a primitive root modulo 3^h, so every residue coprime to 3 is a power of two. *Circuit:* realise n as $2^c \bmod 3^{2h}$, and manufacture the modulus 3^{2h} as $2^{2hb} \bmod \left(3 + 2^b\right)$. This works and is genuinely short, but it imports the theorem that 2 is a primitive root modulo every power of 3, and it needs a separate patch when $3 \mid n$, since then n is not a power of two modulo 3^{2h}. Two knowledge costs and a case split.

4. **Euler inverse variant.** *Cue:* a remainder can be forced to be a quotient of sparse numbers if you can invert modulo the modulus. *Circuit:* use $x^{\varphi(m)-1} \equiv x^{-1} \pmod{m}$ to obtain $\frac{x^n+1}{x+1}$ as a single remainder, then reduce modulo $x+1$. Six steps rather than seven, and elegant, but it costs Euler's theorem and the observation that $\gcd(x, x^n + x + 1) = 1$. Worth knowing as a remark; not the route to write in the arena.

5. **Base x Taylor construction.** *Cue:* n must appear as a coefficient, and coefficients are exactly what a remainder modulo the square of a linear factor reveals. *Circuit:* $x^n + 1 \equiv n(x+1) \pmod{(x+1)^2}$ for odd n, then one further mod strips the base x digit. Best. Seven steps, entirely elementary, uniform in n, and the reduction to odd n is free because the instruction set is invariant under doubling. Nothing beyond the binomial theorem and the uniqueness of remainders is used.

The ideal solution

Call a finite sequence of integers $a_0, a_1, \ldots, a_N$ *legal* if $a_0 = 0$ and each later term is either $a_j + 2^k$ for some earlier index j and some integer $k \geq 0$, or $a_j \bmod a_l$ for earlier indices j, l with $a_j, a_l > 0$.

Lemma 17.12.1. *If $a_0, \ldots, a_N$ is legal then so is $2a_0, \ldots, 2a_N$.*

Proof. Certainly $2a_0 = 0$. If $a_i = a_j + 2^k$ then $2a_i = 2a_j + 2^{k+1}$, again an earlier term plus a power of two. If $a_i = a_j \bmod a_l$ with $a_j, a_l > 0$, write $a_j = qa_l + a_i$ with $0 \leq a_i < a_l$; then $2a_j = q(2a_l) + 2a_i$ with $0 \leq 2a_i < 2a_l$, so by uniqueness of the remainder $2a_i = (2a_j) \bmod (2a_l)$, and $2a_j, 2a_l$ are earlier positive terms. □

Lemma 17.12.2. *Let n be an odd positive integer and let x be an integer with $x > n$. Then*

$$(x^n + 1) \bmod (x+1)^2 = n(x+1).$$

Proof. Work in $\mathbb{Z}[x]$ and substitute $u = x + 1$, so $x = u - 1$. By the binomial theorem,

$$x^n + 1 = (u-1)^n + 1 = \sum_{k=0}^{n} \binom{n}{k} u^k (-1)^{n-k} + 1.$$

Because n is odd, the $k = 0$ term is $(-1)^n = -1$, which cancels the added 1; the $k = 1$ term is $nu(-1)^{n-1} = nu$; and every term with $k \geq 2$ is divisible by u^2. Hence there is an integer R with

$$x^n + 1 = n(x+1) + R(x+1)^2.$$

Since $1 \leq n < x + 1$ we have $0 \leq n(x+1) < (x+1)^2$, so by uniqueness of the remainder $n(x+1)$ is exactly the remainder of $x^n + 1$ on division by $(x+1)^2$. □

Lemma 17.12.3. *If $x > n \geq 1$ are integers then $n(x+1) \bmod x = n$.*

Proof. $n(x+1) = n \cdot x + n$ and $0 \leq n < x$. □

Proof of the statement. By Lemma 1 it suffices to construct a legal sequence of length 2010 ending in n for every *odd* n: for general n write $n = 2^s n_0$ with n_0 odd, take the sequence ending in n_0, and apply Lemma 1 exactly s times, which multiplies every term by 2^s and so ends in n while keeping $a_0 = 0$.

So let n be odd and choose $h \geq 1$ with $x := 2^h > n$. Define

$$\begin{aligned} a_0 &= 0, \\ a_1 &= 1 = a_0 + 2^0, \\ a_2 &= 2x + 1 = a_1 + 2^{h+1}, \end{aligned}$$

$$a_3 = (x+1)^2 = x^2 + 2x + 1 = a_2 + 2^{2h},$$
$$a_4 = x^n + 1 = a_1 + 2^{hn},$$
$$a_5 = n(x+1) = a_4 \bmod a_3,$$
$$a_6 = x = a_0 + 2^h,$$
$$a_7 = n = a_5 \bmod a_6,$$

and $a_i = a_{i-1} \bmod a_4$ for $8 \le i \le 2009$.

Every step is legal. The terms a_1, a_2, a_3, a_4, a_6 are each an earlier term plus a single power of two, as displayed. The term a_5 is Lemma 2 applied with this $x > n$, and its inputs $a_4 = x^n + 1$ and $a_3 = (x+1)^2$ are earlier and positive. The term a_7 is Lemma 3, with inputs $a_5 = n(x+1) > 0$ and $a_6 = x > 0$, both earlier. Finally each padding term is legal because $0 \le n < x^n + 1 = a_4$, so $n \bmod a_4 = n$, and the inputs $a_{i-1} = n > 0$ and $a_4 > 0$ are earlier and positive.

The sequence has $a_0 = 0$ and $a_{2009} = n$, as required. □

Remark 17.12.4. Seven steps suffice; the number 2009 in the problem is theatre, and the padding is the only place where it does any work at all. A variant of Lenstra, van Luijk and Della Torre reaches n in six: with n odd and $x = 2^h > n$, take $a_2 = x + 1$, $a_3 = x^n + x + 1$, $a_4 = x^{(n-1)(\varphi(a_3)-1)}$, $a_5 = a_4 \bmod a_3 = \frac{x^n+1}{x+1}$ and $a_6 = a_5 \bmod a_2 = n$. It is shorter because Euler's theorem lets one remainder perform a division, but it costs the theorem.

Layer 1: WHAT

Block 1. Compare budget with target: 2009 steps, n unbounded. Conclude that some instruction must be able to increase description length without bound, and identify it as the mod.

Block 2. Ask which numbers are free. Answer: those with few ones in binary. Fix $x = 2^h$ and work in base x, where a number is free exactly when it has few base x digits, each a power of two.

Block 3. Ask where an arbitrary n can appear as an output of a mod applied to sparse inputs. Since n enters algebra as an exponent, and remainders read off coefficients, the conversion of exponent into coefficient is differentiation: $\frac{d}{dx}x^n = nx^{n-1}$.

Block 4. Recall that the remainder of F modulo $(x-a)^2$ is $F(a) + F'(a)(x-a)$, the first order Taylor polynomial. So choose an F that is sparse, has $F(-1) = 0$ and $F'(-1) = \pm n$. That is $F(x) = x^n + 1$ with n odd, and the modulus is $(x+1)^2$, also sparse.

Block 5. Handle even n by the symmetry of the instruction set under doubling, which is exactly what removes the obstruction, since $x + 1$ divides $x^n + 1$ only for odd n.

Block 6. The remainder is $n(x+1) = nx + n$. Its base x digits are n and n, so one more reduction, modulo x, delivers n. This is where the condition $x > n$ earns its keep.

Block 7. Pad to index 2009 by repeatedly writing $n \bmod (x^n + 1)$.

The nominal route is Block 1 followed by writing n in binary and adding powers of two, or by an aimless Euclidean descent. The bifurcation point is inside Block 1: the moment you notice that the step count is independent of n and therefore refuse to spend even one step per binary digit. Once you have refused, the search space collapses to "which identity produces n from a mod of two sparse numbers", and there are only a few such identities in existence.

Layer 2: HOW

Block 1. Cue. "For every positive integer n" against "$a_0, \ldots, a_{2009}$". **Why natural.** A fixed length program with a fixed instruction set can only reach numbers whose complexity in that model is bounded. Addition of a power of two changes the binary description by one digit, so a program of pure additions has bounded digit sum. Since digit sums are unbounded, the mod is forced to be the load bearing instruction. Counting the resources before starting is the standard opening on any

construction problem with a budget. **Link to the next block.** If the mod carries the information, you must decide what its two inputs look like, which means deciding which numbers are cheap.

Block 2. **Cue.** "an earlier term plus 2^k". **Why natural.** The cheap numbers are exactly the sums of a few powers of two. Writing $x = 2^h$ turns "a few powers of two" into "a few base x digits", and a polynomial expression in x with small nonnegative coefficients, each a power of two, is cheap. This reframing is what lets you think about polynomials instead of integers, which is the only way the algebra becomes visible. **Link to the next block.** You are now looking for a polynomial identity: sparse F, sparse G, with F mod G revealing n.

Block 3. **Cue.** n appears in the problem only as a target value, but in any expression you can cheaply build it will appear as an exponent. **Why natural.** Exponents and coefficients are different slots. There are exactly two elementary devices that move a number from the exponent slot to the coefficient slot: differentiating x^n to get nx^{n-1}, and summing a geometric series with n terms so that the value at the special point is n. Both are the same fact seen from two sides, and both put n next to a linear factor. **Link to the next block.** Differentiation suggests a second order phenomenon at a root, and second order phenomena at a root are visible modulo the square of the corresponding linear factor.

Block 4. **Cue.** "$b \bmod c$" with c allowed to be any earlier term, so you may choose the modulus. **Why natural.** Division with remainder in $\mathbb{Z}[x]$ by $(x-a)^k$ returns the truncated Taylor expansion of the dividend at a: $F(x) \equiv F(a) + F'(a)(x-a) \pmod{(x-a)^2}$. Choosing $a = -1$ and $F(x) = x^n + 1$ makes $F(a) = 0$ for odd n and $F'(a) = n$, so the remainder is precisely $n(x+1)$. Both F and the modulus $(x+1)^2 = x^2 + 2x + 1$ are sparse, so both are cheap. Nothing here was guesswork: you asked for a sparse F with a double root structure at -1 and there is essentially one. **Link to the next block.** The polynomial identity has to be transported to integers, which requires the digits to be small enough not to interfere, and it also requires n odd.

Block 5. **Cue.** The identity fails for even n, because then $(-1)^n + 1 = 2 \neq 0$. **Why natural.** Before patching a case, check whether the problem has a symmetry that normalises it away. The instruction set here is homogeneous under doubling: adding 2^k becomes adding 2^{k+1}, and remainders scale, because $b = qc + r$ with $0 \leq r < c$ gives $2b = q(2c) + 2r$ with $0 \leq 2r < 2c$. So the set of reachable values is closed under multiplication by two, and it suffices to reach every odd n. **Link to the next block.** With n odd, run the identity, then convert the resulting integer $n(x+1)$ into n.

Block 6. **Cue.** The remainder $n(x+1) = nx + n$ written in base x. **Why natural.** Reducing modulo x deletes every digit except the last, and the last digit is n provided $n < x$. That proviso is exactly the condition under which the polynomial identity survives specialisation at $x = 2^h$: a polynomial identity with coefficients smaller than the base is a statement about digits, and digits do not carry. This is the same principle as Kronecker substitution, where polynomial multiplication is performed by multiplying large integers in a base big enough to stop carrying. **Link to the next block.** All that remains is bookkeeping: name the powers of two used, and pad.

Block 7. **Cue.** The index must reach exactly 2009. **Why natural.** Padding is not free, because there is no "do nothing" instruction. But $n \bmod c = n$ for any $c > n$, and you already own such a c, namely $x^n + 1$. The padding must be justified explicitly; a write up that says "pad the sequence" without naming the instruction is leaving a hole a grader is entitled to charge for. **Link to the next block.** The construction is complete and every step has been certified.

Layer 3: WHY

The underlying truth is that remainders compute Taylor coefficients, and that this survives specialisation to integers whenever the coefficients are smaller than the base. Both halves deserve to be stated plainly, because together they are the engine of a whole family of Putnam problems.

First half. In $\mathbb{Z}[x]$, dividing F by $(x-a)^k$ leaves the truncated Taylor polynomial $\sum_{j<k} \frac{F^{(j)}(a)}{j!}(x-a)^j$. For $k=1$ this is the factor theorem. For $k=2$ it is the statement that the remainder sees both the value and the derivative at a. So if you want a specific integer n to appear from an expression in which n is an exponent, reduce modulo the square of a linear factor at a root: the derivative brings the exponent down into a coefficient. That is why x^n+1 against $(x+1)^2$ is not a lucky pairing but the unique cheap pairing.

Second half. An integer written in base b is a polynomial evaluated at b, and the correspondence is faithful, meaning digits do not interact, exactly while all the coefficients lie in $[0,b)$. In the construction the relevant coefficients are 1, 2 and n, so the single condition $n < x$ makes every polynomial statement above a statement about the base x digits of an integer, and the integer remainder equals the specialised polynomial remainder. The same principle is behind Kronecker substitution, behind reading a generating function coefficient by evaluating at a large integer, and behind the standard proof that a polynomial with nonnegative integer coefficients can be reconstructed from two evaluations.

The discernment mechanism to train is a resource count followed by an identity search. Resource count: how much can each instruction change the complexity of the object, and how many instructions do you have? If the budget is finite and the target is unbounded, exactly one instruction is doing the work, and you should identify it in the first minute. Identity search: with the load bearing instruction identified, ask what identities produce your target as its output from cheap inputs, and go through your list. For remainders the list is short and you should have it memorised: the Taylor and factor theorem family ($x^n \pm 1$ against $(x\pm1)^2$), the geometric series family ($\frac{x^n-1}{x-1} \equiv n \pmod{x-1}$), Fermat and Euler, and orders and primitive roots. Every published solution to this problem uses one of those four.

Knowledge gaps, stated without cosmetics. If you do not already know that the remainder modulo $(x-a)^2$ is the first order Taylor polynomial, this problem is not approachable, because you will never generate the pairing x^n+1 with $(x+1)^2$ from scratch under time pressure. If you do not know Euler's theorem and the trick $x^{\varphi(m)-1} \equiv x^{-1} \pmod{m}$, the six step variant is invisible to you. If you do not know that 2 is a primitive root modulo every power of 3, and why lifting from modulus 9 suffices, the second published route is invisible to you. And if you have never met the notion of a straight line program or an addition chain, you will not perform the resource count in Block 1 with any confidence, and without that count you will spend the whole session writing n in binary. Install those four items before you claim this problem is solved.

Revolving concepts

Base b representation and digit extraction. Every nonnegative integer has a unique representation $N = \sum_j d_j b^j$ with $0 \le d_j < b$, and $N \bmod b^k$ keeps exactly the lowest k digits. An integer is cheap in this problem exactly when it has few nonzero binary digits, and choosing $x = 2^h$ makes "few base x digits, each a power of two" the operative notion of cheapness. See Book 1, field: Number theory, topic: base representations.

Division with remainder and its uniqueness. For integers b and $c > 0$ there are unique q and r with $b = qc + r$ and $0 \le r < c$. Uniqueness is what lets you certify a step: it is not enough that $x^n + 1 \equiv n(x+1)$ modulo $(x+1)^2$, you must also check $0 \le n(x+1) < (x+1)^2$, which is where $n < x$ is used. Half the available marks on a construction problem live in checks of this kind. See Book 1, field: Number theory, topic: the division algorithm.

Taylor expansion in $\mathbb{Z}[x]$ and Hensel lifting. For $F \in \mathbb{Z}[x]$ and $a \in \mathbb{Z}$, $F(x) = \sum_{j \ge 0} c_j (x-a)^j$

with $c_j = \frac{F^{(j)}(a)}{j!} \in \mathbb{Z}$, and $F \bmod (x-a)^k = \sum_{j<k} c_j (x-a)^j$. The recursion is $F_0 = F$, $c_j = F_j(a)$, $F_{j+1} = \frac{F_j - c_j}{x-a}$, which is synthetic division repeated. The same recursion over $\mathbb{Z}_p$ is Hensel lifting, where a simple root modulo p is refined to a root modulo p^k one digit at a time. Wherever you see "modulo a square", expect a derivative. See Book 1, field: Polynomials, topic: Taylor expansion and repeated division.

The two standard exponent to coefficient identities. For odd n, $x^n + 1 \equiv n(x+1) \pmod{(x+1)^2}$; for all n, $x^n - 1 \equiv n(x-1) \pmod{(x-1)^2}$. Both are the derivative statement in disguise, and both have geometric series proofs: $\frac{x^n-1}{x-1} = \sum_{j=0}^{n-1} x^j \equiv n \pmod{x-1}$ since each of the n terms is congruent to 1, and likewise $\frac{x^n+1}{x+1} = \sum_{j=0}^{n-1} (-1)^j x^{n-1-j} \equiv n \pmod{x+1}$ for odd n. Generalise the recursion: $\sum_{j=0}^{n-1} x^j$ satisfies $S_n = xS_{n-1} + 1$, and reducing that recursion modulo $x-1$ gives $S_n \equiv S_{n-1} + 1$, so $S_n \equiv n$, which is the cleanest proof and the one to carry. See Book 1, field: Number theory, topic: cyclotomic identities.

Euler's theorem and modular inversion by exponentiation. If $\gcd(x, m) = 1$ then $x^{\varphi(m)} \equiv 1 \pmod{m}$, so $x^{-1} \equiv x^{\varphi(m)-1}$. This is what allows a single remainder to perform a division and produces the six step variant. See Book 1, field: Number theory, topic: Euler's theorem.

Primitive roots modulo prime powers. If g is a primitive root modulo p^2 for odd prime p then it is a primitive root modulo p^h for every $h \geq 1$; 2 is a primitive root modulo 9, hence modulo every 3^h. Consequently every residue coprime to 3 is a power of 2 modulo 3^{2h}, which is the engine of the second published route. See Book 1, field: Number theory, topic: primitive roots.

Straight line programs and addition chains. An addition chain for n is a sequence starting at 1 in which every term is a sum of two earlier terms, ending at n; its length is between $\log_2 n$ and about $2\log_2 n$. The instruction "earlier term plus 2^k" is an addition chain with a restricted summand set, so its length is at least the binary digit sum. Adding the mod instruction changes the model completely, since a remainder can produce a number of high complexity from two of low complexity. The moral generalises: when a construction budget is fixed and the target is unbounded, find the instruction that is not complexity bounded. See Book 1, field: Discrete structures and graphs, topic: addition chains and complexity of representations.

Circuit Bank

- **WHEN** a construction must have length independent of an unbounded parameter **DO** identify which single instruction can increase the description length of the output without bound, and plan for the others to be mere preparation **BECAUSE** a bounded number of bounded increments is bounded, so every other instruction can only assemble simple objects
- **WHEN** you need an arbitrary integer n to appear as a value when n can only enter as an exponent **DO** look for n as a derivative, that is, reduce modulo the square of a linear factor, or as the number of terms of a geometric series **BECAUSE** differentiation and summation are the only cheap conversions of an exponent into a coefficient, and both place n beside a linear factor
- **WHEN** a problem asks for the Taylor data of a polynomial at a point **DO** divide by $(x-a)^k$ and read the remainder **BECAUSE** the remainder is exactly the degree $k-1$ Taylor polynomial at a, so remainders are a coefficient extraction device, not just a size reduction device
- **WHEN** you specialise a polynomial identity at an integer base b and want to read a coefficient with a mod **DO** check that every coefficient involved is smaller than b **BECAUSE** only then are the coefficients the base b digits with no carrying, so the integer remainder equals the specialised polynomial remainder
- **WHEN** an instruction set is invariant under a symmetry such as scaling **DO** use the symmetry to normalise the target, for instance to the odd case **BECAUSE** the reduction is free, and it

frequently removes precisely the obstruction, here that $x+1$ divides x^n+1 only when n is odd

- **WHEN** a construction problem specifies an exact length **DO** state explicitly which legal instruction performs the padding **BECAUSE** there is no do nothing instruction, so unjustified padding is a genuine hole, and here $n \bmod c = n$ for any earlier $c > n$ closes it

Backtesting

1. First useful cue: the fixed length 2010 against the unbounded n, which immediately demotes the addition instruction to preparation and promotes the mod to the engine.
2. Method the expression suggested: work in base $x = 2^h$ so that cheap integers are sparse polynomials in x, then use the remainder modulo $(x+1)^2$ to convert the exponent n into the coefficient n, and one further remainder modulo x to read the digit.
3. Where you would hesitate, and the thought to reinforce: the hesitation is at even n, where the identity collapses. Reinforce this: before patching a case, test whether the problem's own instruction set has a symmetry that normalises it, and here doubling is that symmetry.
4. The trap the question sets: the number 2009 makes the budget look generous, so you start spending steps. It is not generous, it is irrelevant, and the true budget is a small constant. The second trap is the padding, which looks free and is not.
5. What makes you recognise it faster next time: the shape "fixed number of operations, unbounded target", which is a complexity question in disguise; and the pairing of a sparse dividend with the square of a linear divisor, which always means a derivative.
6. The reusable decision rule: count the resources first, identify the one instruction with unbounded output complexity, then search your list of identities for one that produces the target from cheap inputs under that instruction.

Mirror drills

1. Prove that $x^n + 1 \equiv n(x+1) \pmod{(x+1)^2}$ for odd n, and state the analogue for $x^n - 1$. *Answer:* substitute $u = x+1$ and expand $(u-1)^n + 1$ by the binomial theorem, or Taylor expand at $x = -1$; the analogue is $x^n - 1 \equiv n(x-1) \pmod{(x-1)^2}$ for all n.
2. Show that if $a_0, \ldots, a_N$ is a legal sequence then so is the sequence of doubled terms, and deduce that it suffices to reach every odd n. *Answer:* $a_j + 2^k$ doubles to $a_j + 2^{k+1}$, and $b = qc + r$ with $0 \le r < c$ doubles to $2b = q(2c) + 2r$ with $0 \le 2r < 2c$.
3. With $x = 2^h > n$, verify by hand for $n = 5$, $h = 3$ that $a_4 = x^5 + 1 = 32769$, $a_3 = (x+1)^2 = 81$, $a_5 = a_4 \bmod a_3 = 45$ and $a_7 = 45 \bmod 8 = 5$. *Answer:* $32769 = 404 \cdot 81 + 45$ and $45 = 5 \cdot 9 = n(x+1)$, then $45 = 5 \cdot 8 + 5$; note where $n < x$ is used in each of the two reductions.

Chapter 18

Putnam 2008

18.1 A1. a cyclic zero condition forces a potential

Let $f : \mathbb{R}^2 \to \mathbb{R}$ be a function such that $f(x, y) + f(y, z) + f(z, x) = 0$ for all real numbers x, y, and z. Prove that there exists a function $g : \mathbb{R} \to \mathbb{R}$ such that $f(x, y) = g(x) - g(y)$ for all real numbers x and y.

Read it out loud

You are given one identity in three free variables, and asked to produce a two variable object (indeed, ultimately a one variable function g) that satisfies it. Say that out loud and the shape of the problem is already visible: you have a spare degree of freedom sitting inside the hypothesis that the conclusion does not need. Whenever a hypothesis is quantified over more variables than the conclusion mentions, your first reflex should be to spend that extra variable by fixing it to a convenient constant, because a universally quantified identity remains true under any substitution you like.

There is no continuity, no differentiability, not even monotonicity attached to f. That silence is not an oversight, it is the examiners telling you plainly that this is an algebra problem, not an analysis problem. f is an arbitrary function on $\mathbb{R}^2$ subject to one constraint, and the constraint is an identity, so the entire solution has to come from substitution and nothing else. If your hand drifts toward a derivative or an integral here, that is the bifurcation point where you have left the ideal route.

Structurally, the identity $f(x, y) + f(y, z) + f(z, x) = 0$ is a statement that summing f around any directed triangle $x \to y \to z \to x$ gives zero. That is the signature of a quantity that is secretly a difference of a potential, the discrete cousin of a closed one form being exact. The first thing worth writing down inside thirty seconds is the most symmetric substitution available, $x = y = z$, because it costs nothing and immediately tells you how f behaves on the diagonal, before you commit to any particular strategy for building g.

Approaches, ranked worst to best

1. **impose regularity and integrate.** *Cue:* the shape $f(x, y) = g(x) - g(y)$ looks like it wants a fundamental theorem of calculus argument. *Circuit:* treat f as if it were smooth, differentiate the identity with respect to one variable, and try to integrate the result. (why it ranks here: the problem never grants continuity or differentiability, so any step that assumes it is invalid on the general function the problem actually hands you; you would be proving a strictly weaker statement while believing you had proved the real one, which on the Putnam scale is worth close to nothing).

2. **scattered numerical substitution.** *Cue:* a functional equation invites you to plug in numbers. *Circuit:* try several unrelated triples (x, y, z), hope a pattern for f emerges. (why it ranks here: it can work by luck, but it wastes ink chasing substitutions that do not obviously combine into a general argument, and in the arena you cannot afford to discover the right three substitutions by trial when a structural read of the identity hands them to you directly).

3. **structural substitution: diagonal, then a fixed basepoint.** *Cue:* the identity is symmetric under cycling x, y, z and holds for all reals, so it is safe to fix any of them. *Circuit:* collapse two variables to extract a symmetry property of f, then freeze one variable to a basepoint to expose a candidate for g. (this is the ideal route: every substitution is chosen because it isolates exactly one unknown, so the whole proof is three lines of algebra with nothing left to verify by guesswork).

The ideal solution

Substitute $x = y = z = t$ for an arbitrary real t. The identity gives $f(t,t) + f(t,t) + f(t,t) = 0$, so $3f(t,t) = 0$ and therefore

$$f(t,t) = 0 \quad \text{for every real } t.$$

Next substitute $z = x$ in the original identity, keeping x, y free. This gives

$$f(x,y) + f(y,x) + f(x,x) = 0.$$

Using $f(x,x) = 0$ from the previous step, this collapses to $f(x,y) + f(y,x) = 0$, so

$$f(y,x) = -f(x,y) \quad \text{for all real } x, y.$$

This is genuine full antisymmetry of f, not merely a coincidence at the point 0; it holds for every pair of reals.

Now fix the basepoint $z = 0$ and let x, y be free. The identity gives

$$f(x,y) + f(y,0) + f(0,x) = 0.$$

By antisymmetry, $f(0,x) = -f(x,0)$, so substituting,

$$f(x,y) + f(y,0) - f(x,0) = 0, \qquad \text{hence} \qquad f(x,y) = f(x,0) - f(y,0).$$

Define $g : \mathbb{R} \to \mathbb{R}$ by $g(x) := f(x,0)$. The last display reads exactly

$$f(x,y) = g(x) - g(y) \quad \text{for all real } x, y,$$

which is precisely the claim. This proves existence.

It is worth recording uniqueness as well, since it costs one more line and sharpens your understanding of the construction. Suppose g and h both satisfy $f(x,y) = g(x) - g(y) = h(x) - h(y)$ for all x, y. Fixing $y = 0$ gives $g(x) - g(0) = h(x) - h(0)$ for every x, so $g(x) - h(x) = g(0) - h(0)$ is the same constant for every x. Hence any two valid choices of g differ by a constant, and the full family of functions that work is exactly $f(x,0) + c$ for $c \in \mathbb{R}$, the discrete analogue of two antiderivatives of the same function differing by a constant.

Layer 1: WHAT

Block 1: substitute $x = y = z$ to learn $f(t,t) = 0$ for every t. Block 2: substitute $z = x$ to upgrade this diagonal fact into full antisymmetry, $f(y,x) = -f(x,y)$. Block 3: substitute $z = 0$ to write $f(x,y)$ purely in terms of $f(\cdot,0)$, using antisymmetry to remove the awkward term $f(0,x)$. Block 4: name $g(x) := f(x,0)$ and read off the required identity; optionally record that g is unique up to an additive constant.

The nominal route reaches for calculus, treating $f(x,y) = g(x) - g(y)$ as an invitation to differentiate and integrate, or else scatters numerical substitutions hoping to stumble onto the pattern that Blocks 1 to 3 produce directly. The bifurcation point sits at the very first line you write: whether you assume any regularity of f at all, or whether you commit immediately to spending the three free variables of the hypothesis on structurally chosen values (the diagonal, then a basepoint) rather than on arbitrary ones.

Layer 2: HOW

Block 1. Cue. The identity is universally quantified over three independent reals, and $x = y = z$ is the single substitution that uses none of that independence, so it is the cheapest possible test and should always be tried first on a multivariable identity. **Why natural.** Setting all three variables equal collapses three unknown values of f into three copies of the same value $f(t,t)$, turning the identity into a one term equation for free. **Link to the next block.** Having learned f vanishes on the diagonal, the natural next move is to see what else collapsing only two of the three variables reveals, since the diagonal fact must be a special case of something more general.

Block 2. **Cue.** The identity is unchanged if you set $z = x$ rather than $z = y$ or any other coincidence, and doing so leaves you with a live pair x, y, which is exactly the shape of the object you are trying to describe. **Why natural.** Setting $z = x$ produces $f(x, y) + f(y, x) + f(x, x) = 0$, and Block 1 has already told you $f(x, x) = 0$, so the third term vanishes and you are left with a direct relation between $f(x, y)$ and $f(y, x)$. **Link to the next block.** Antisymmetry is precisely the tool you need to simplify the awkward term $f(0, x)$ that will appear once you fix a basepoint, since it lets you rewrite any $f(0, \cdot)$ term as $-f(\cdot, 0)$.

Block 3. **Cue.** You want a formula for $f(x, y)$ using only a one variable object, so you should freeze the third slot z to a fixed value and see what falls out; $z = 0$ is the most convenient choice only because 0 is a familiar constant, any fixed real would do equally well. **Why natural.** Fixing $z = 0$ turns the three variable identity into a two variable one, $f(x, y) + f(y, 0) + f(0, x) = 0$, and antisymmetry from Block 2 converts the term $f(0, x)$ into $-f(x, 0)$, leaving an equation entirely in terms of $f(\cdot, 0)$ and $f(x, y)$. **Link to the next block.** Once every term is expressed through the single variable expression $f(\cdot, 0)$, that expression is visibly a candidate for g, and naming it is the only step left.

Block 4. **Cue.** The algebra in Block 3 already reads $f(x, y) = f(x, 0) - f(y, 0)$, so the function $g(x) := f(x, 0)$ is not invented, it is read directly off the page. **Why natural.** Defining g this way and observing the previous line is exactly $f(x, y) = g(x) - g(y)$ closes the existence claim with no further work; checking uniqueness up to a constant is one further substitution ($y = 0$) applied to two hypothetical representations. **Link to the next block.** None; this is the terminal block. Any generalisation (longer cycles, other domains) is deferred to the revolving concepts.

Layer 3: WHY

The identity $f(x, y) + f(y, z) + f(z, x) = 0$ says that summing f around any directed triangle returns to zero, whatever the three vertices. That is the discrete analogue of a closed differential form: on a connected space, a closed form is exact, meaning it can be written as the difference of values of a single potential function at the two endpoints. Here the connecting structure is trivial, every pair of reals is joined through the single basepoint 0, so the potential is recovered in one substitution rather than by any limiting or integrating process.

The discernment mechanism to train is this: whenever a functional identity is stated over more free variables than the conclusion needs, and the identity is symmetric under permuting or cycling those variables, treat the surplus variables as currency to be spent, not as further unknowns to solve for. The spending has an order: collapse variables against each other first (as in Blocks 1 and 2) to extract symmetry properties of the object, because those properties are usually needed to simplify what a basepoint substitution produces; only then fix a variable to a constant to expose the final formula. Doing the basepoint substitution first, before knowing the antisymmetry, would have left you staring at $f(0, x)$ with no way to relate it to $f(x, 0)$, forcing you to invent a second substitution mid-proof rather than having it ready.

The examiners nudge you toward this reading by giving you three completely free variables for a two variable conclusion and by giving you no regularity hypothesis whatsoever; a problem setter who wanted you to use calculus would have handed you continuity, since without it no calculus argument is even well posed. The total absence of hypotheses beyond the identity itself is therefore itself a cue, telling you the entire solution must be extractable by pure substitution.

Revolving concepts

Coboundaries and potential functions. A function f on pairs from a set X satisfying $f(x, y) + f(y, z) + f(z, x) = 0$ for all $x, y, z \in X$ is called a coboundary: there is a basepoint independent way

to write $f(x,y) = g(x) - g(y)$, obtained by fixing any basepoint $b \in X$ and setting $g(x) = f(x,b)$. This is the discrete, purely algebraic shadow of the statement that a closed one form on a simply connected domain is exact. See Book 1, field: Functional equations, topic: cyclic identities and potential constructions.

Antisymmetric two variable functions. A function with $f(y,x) = -f(x,y)$ for all x, y is called antisymmetric or skew symmetric; it automatically vanishes on the diagonal, $f(x,x) = 0$, since $f(x,x) = -f(x,x)$ forces this. Determinants of two vectors in the plane and the signed area of a triangle are the familiar antisymmetric objects from geometry; here antisymmetry is derived rather than assumed. See Book 1, field: Functional equations, topic: symmetry extraction by variable collapse.

Cauchy's functional equation, as a contrast. The equation $f(x+y) = f(x) + f(y)$ for $f : \mathbb{R} \to \mathbb{R}$ looks similarly innocent but is genuinely under determined by algebra alone: without continuity, monotonicity, or boundedness on some interval, it admits pathological solutions built from a Hamel basis of $\mathbb{R}$ over $\mathbb{Q}$, using the axiom of choice. The present problem needs no such hypothesis precisely because it hands you a full triangle of free variables to substitute into, giving pure algebra enough leverage to pin f down completely; recognising which functional equations have this extra leverage and which do not is the key discernment skill in this family. See Book 1, field: Functional equations, topic: when regularity hypotheses are load bearing.

Cyclic sums of any length. The three term identity generalises: for every $n \geq 2$ and all $x_1, \ldots, x_n \in \mathbb{R}$,

$$f(x_1,x_2) + f(x_2,x_3) + \cdots + f(x_{n-1},x_n) + f(x_n,x_1) = 0.$$

The general recursion and its solution: let $S(n)$ denote this n term cyclic sum. The base case $S(2) = f(x_1,x_2) + f(x_2,x_1) = 0$ holds by antisymmetry, and $S(3) = 0$ is the given identity. For $n \geq 4$, apply the three term identity to the triple (x_{n-1}, x_n, x_1) to get $f(x_{n-1},x_n) + f(x_n,x_1) = -f(x_1,x_{n-1}) = f(x_{n-1},x_1)$, which replaces the last two edges of the n cycle by a single shortcut edge, showing $S(n) = S(n-1)$. Induction downward to $S(2) = 0$ finishes the general claim. This shortcut chord reduction is the standard way to promote a local (three term) identity to a global (any length cycle) one, and it reappears whenever a relation is only given locally but you need it to hold along an arbitrarily long path. See Book 1, field: Functional equations, topic: telescoping identities and cycle reduction by induction.

Circuit Bank

- **WHEN** a functional identity is stated over more free variables than the conclusion mentions, with a cyclic or fully symmetric structure **DO** immediately test the most degenerate substitution, collapsing two or more of the variables to each other, before trying to solve for the object directly **BECAUSE** collapsing variables is the cheapest way to strip a cyclic identity down to a single variable fact, and it usually hands you a symmetry property for free that you will need later

- **WHEN** you need to build a one variable potential function g from a two variable difference type constraint $f(x,y)$ **DO** fix one variable to a convenient basepoint and define $g(x) := f(x, \text{basepoint})$ **BECAUSE** freezing a spare degree of freedom converts an identity that has more unknowns than equations into an explicit formula, and the resulting candidate only needs one line to verify

- **WHEN** a problem hands you a completely arbitrary function with no continuity, differentiability, or monotonicity stated **DO** treat every calculus tool as forbidden and solve purely by algebraic substitution **BECAUSE** a valid proof must work for every function satisfying the constraint as a set theoretic object, and any argument that silently assumes regularity is proving a different, weaker problem

- **WHEN** you have proved a short instance of a cyclic identity (length two or three) and suspect it extends to any cycle length **DO** state and prove the general n cycle claim by induction, reducing an n cycle to an $n-1$ cycle with one application of the base identity **BECAUSE** Putnam write ups reward the fully general closed form vanishing lemma, and the shortcut chord reduction is one line once you see it, so it is nearly free insurance against a grader asking for the general case

Backtesting

1. First useful cue: the identity holds for every real x, y, z, three independent degrees of freedom, while the conclusion only needs a one variable function, so before writing anything you already know you can afford to spend one whole variable freezing it to a constant.
2. Method the expression suggested: the cyclic symmetry under $x \to y \to z \to x$ in the constraint is the signature of a coboundary, and it suggests the potential function ansatz $g(x) = f(x, c)$ for a fixed c immediately, before any calculation.
3. Where you would hesitate, and the thought to reinforce: the natural hesitation is whether $f(0, x)$ and $f(x, 0)$ are related at all; reinforce the habit of collapsing the diagonal first, before touching a basepoint, since that always buys antisymmetry for free and removes the hesitation in advance.
4. The trap the question sets: nothing in the statement suggests f is continuous, and under time pressure the instinct is to reach for a derivative; the fix is recognising that a problem's silence about regularity is deliberate, not an omission you are meant to patch with an assumption.
5. What makes you recognise it faster next time: any functional equation whose left side is a sum of the same two variable function evaluated around a cycle of variables, equalling a constant, belongs to this family, and the diagonal collapse followed by a basepoint fix applies without exception.
6. The reusable decision rule: a cyclic sum of a two variable function that vanishes identically forces that function to be a coboundary; construct the potential by freezing one argument to a basepoint, after first extracting antisymmetry from a diagonal substitution.

Mirror drills

1. Let $h : \mathbb{R}^2 \to \mathbb{R}$ satisfy $h(x, y) + h(y, z) + h(z, x) = c$ for a fixed constant c and all real x, y, z. For which c does a function g with $h(x, y) = g(x) - g(y)$ exist, and what is g? *Answer:* setting $x = y = z = t$ forces $h(t, t) = c/3$ for every t, but any difference $g(t) - g(t)$ is always 0, so a representation of this shape forces $h(t, t) = 0$, which is only consistent with $c = 0$; when $c = 0$ the argument is identical to A1 and $g(x) = h(x, 0)$.
2. Suppose $f : \mathbb{R}^3 \to \mathbb{R}$ (now a genuinely three argument function) satisfies $f(x, y, z) + f(y, z, x) + f(z, x, y) = 0$ for all x, y, z. Must f decompose as a difference of two variable potentials the way A1's f does? *Answer:* no in general; A1's argument relied on f being built from pairs drawn out of a common domain, so that fixing one slot to a basepoint reduces the arity by exactly one and lands you back on a one variable object. Here cyclic invariance under permuting three genuinely independent arguments gives you an invariance property, not a telescoping decomposition, since there is no basepoint substitution that collapses three slots down to two while preserving the structure of the claim.
3. A function $k : \mathbb{Z}^2 \to \mathbb{Z}$ satisfies $k(m, n) + k(n, p) + k(p, m) = 0$ for all integers m, n, p. Show $k(m, n) = a(m) - a(n)$ for some $a : \mathbb{Z} \to \mathbb{Z}$, and that a is unique up to an additive constant. *Answer:* identical proof with basepoint 0, setting $a(m) := k(m, 0)$; uniqueness up to a constant

follows exactly as in the ideal solution's closing remark, by comparing two hypothetical representations at $n = 0$.

18.2 A2. a determinant game decided by pairing

Alan and Barbara play a game in which they take turns filling entries of an initially empty 2008×2008 *array. Alan plays first. At each turn, a player chooses a real number and places it in a vacant entry. The game ends when all the entries are filled. Alan wins if the determinant of the resulting matrix is nonzero; Barbara wins if it is zero. Which player has a winning strategy?*

Read it out loud

Strip away the game dressing and read what the winning condition actually is: Alan wants the final matrix to have full rank, Barbara wants it to have dependent rows. That single observation reclassifies this from a combinatorial game about 2008^2 individual real numbers into a linear algebra question about the row vectors of the matrix. You should have that translation written down within the first thirty seconds, because everything else follows from asking what structural property of the rows a player can force, not from thinking about entries one at a time.

Once you see it as a rank question, the next thing to notice is who is trying to force what. Alan cannot force independence directly, since Barbara gets to choose half of the entries and can always choose adversarially. Barbara, on the other hand, only needs to force some fixed linear relation among the rows, and a fixed relation is a much easier target than full rank is, because a relation just needs to hold once, robustly, no matter what real numbers Alan throws at the board.

The board size, 2008×2008, is chosen with a purpose: 2008 is even. Whenever a combinatorial game hands you an even sized board and a second moving player, the examiners are all but telling you to look for a pairing or mirroring strategy, since an even number of cells splits cleanly into pairs with nothing left over. The fields in play here are matrices and determinants for the target condition, and games and invariants for the mechanism that forces it; no case analysis on the actual sizes of Alan's numbers should appear anywhere in a correct solution, since the strategy has to work against every real number simultaneously.

Approaches, ranked worst to best

1. **heuristic guessing.** *Cue:* a game with a first mover suggests a first mover advantage. *Circuit:* guess an outcome from intuition about who moves first, without exhibiting a strategy. (why it ranks here: a competition proof of a game result requires an explicit strategy for the winning player together with a verification that it always succeeds; a correct guess with no construction earns essentially nothing, since the problem is asking you to prove a claim about all possible plays, not to state an opinion).

2. **small board exhaustion.** *Cue:* tiny cases such as 2×2 or 3×3 are checkable by hand. *Circuit:* play out or enumerate small boards, hoping the pattern generalises to 2008×2008. (why it ranks here: it costs enormous time relative to the insight gained, and worse, it risks a wrong generalisation, since a strategy that happens to work on a 2×2 board by coincidence need not reveal the mechanism that scales; you need the mechanism, not the outcome, and small cases do not hand you the mechanism for free).

3. **row copying pairing.** *Cue:* Barbara only needs two equal rows to force determinant zero. *Circuit:* pair each entry of row one with the entry directly below it in row two, and whenever Alan plays in either row, Barbara completes the pair with the identical value. (this is correct and legitimate, but it needs a second, separate rule to cover every cell outside rows one and two, since those cells must still be filled legally even though their values are irrelevant to the argument; the proof is correct but structurally two strategies stitched together, one load bearing and one not, and the underlying reason the determinant vanishes, namely two identical rows, is a comparatively narrow fact about the alternating property of the determinant rather than a fact about its rank in general).

4. **row negation pairing.** *Cue:* Barbara can force every row into a fixed hyperplane rather than merely duplicating one row. *Circuit:* pair the columns within every row into disjoint pairs, and whenever Alan writes a value x into a cell, Barbara writes $-x$ into its partner cell in the same row. (this is the ideal route: it is a single uniform rule applying to every move anywhere on the board with no special casing, it uses the evenness of 2008 exactly once and exactly where the problem places it, and the reason the determinant vanishes generalises immediately, more vectors than the dimension of the space confining them are automatically dependent).

The ideal solution

Claim. Barbara has a winning strategy.

Partition the 2008 columns into 1004 disjoint pairs, for instance column $2t-1$ with column $2t$ for $t = 1, \ldots, 1004$; any fixed pairing works equally well. This induces, inside every one of the 2008 rows, a partition of that row's 2008 cells into 1004 column pairs, and hence a partition of the entire grid of 2008^2 cells into $2008^2/2$ *cell pairs*, where a cell pair consists of two cells lying in the same row, in two columns that are partnered.

Barbara's strategy. Whenever Alan writes a real number x into a vacant cell, Barbara immediately writes $-x$ into the partner cell of that cell pair.

This is always legal. We show by induction on the number of completed rounds (one round is one move of Alan's followed by Barbara's response) that immediately after each of Barbara's moves, every cell pair is either both empty or both filled. This holds trivially before play begins, when every cell pair is empty. Suppose it holds after round k. On round $k+1$, Alan plays into some vacant cell; by the invariant, its partner cell was also vacant, so the partner cell remains a legal target for Barbara. Barbara writes $-x$ there, filling both cells of that pair and leaving every other pair exactly as it was. The invariant is restored, so it holds after round $k+1$. Since 2008^2 is even, the game consists of exactly $2008^2/2$ such rounds, and Barbara always has a legal reply until the board is completely filled.

The determinant vanishes. Fix a row i. Its 1004 cell pairs each contribute a value x from one cell and $-x$ from its partner, so their contribution to the row sum is $x + (-x) = 0$; summing over all 1004 pairs, the entries of row i sum to 0. Writing $r_i \in \mathbb{R}^{2008}$ for row i and $\mathbf{1} = (1, 1, \ldots, 1)$, this says $r_i \cdot \mathbf{1} = 0$ for every $i = 1, \ldots, 2008$. Hence every one of the 2008 row vectors lies in the hyperplane

$$H = \{v \in \mathbb{R}^{2008} : v \cdot \mathbf{1} = 0\},$$

which is the orthogonal complement of the line spanned by $\mathbf{1}$ and therefore has dimension 2007. A linear subspace of dimension 2007 cannot contain 2008 linearly independent vectors, since a subspace of dimension d contains no more than d linearly independent vectors. So the 2008 rows of the completed matrix are linearly dependent, which is exactly the condition

$$\det = 0.$$

Since Barbara's rule is fully explicit, is always legal by the invariant argument, and forces $\det = 0$ regardless of every real number Alan chooses at every stage, it is a genuine winning strategy for Barbara, independent of how Alan plays. Therefore

$$\boxed{\text{Barbara has a winning strategy.}}$$

Layer 1: WHAT

Block 1: translate the winning condition, det equals zero if and only if the rows are linearly dependent, so Barbara's task becomes forcing a dependence relation among the rows. Block 2: recognise that the cleanest way to force dependence against an adversary choosing arbitrary reals is to confine every row to one fixed hyperplane, since a subspace of dimension less than the number

of vectors automatically forces dependence, whatever those vectors turn out to be. Block 3: design a response rule that guarantees each row lands in the hyperplane of coordinates summing to zero, by pairing columns within a row and always answering a move with its negative in the paired cell. Block 4: verify the pairing rule is always legal, using an invariant maintained by induction on the number of completed rounds. Block 5: conclude det equals zero via the dimension bound, and note the argument holds for every possible sequence of Alan's moves, so it is a genuine winning strategy.

The nominal route reasons about individual entries, or guesses an outcome from who moves first, or exhausts tiny boards hoping a pattern emerges. The bifurcation point is the very first line: whether you translate the determinant condition into a linear algebra statement about the rows before searching for a strategy, or whether you start hunting for a strategy while still thinking entrywise. Everything downstream, the choice of hyperplane, the pairing rule, the legality proof, follows mechanically once that translation is made; none of it is available before it.

Layer 2: HOW

Block 1. **Cue.** The winning condition is stated purely in terms of the determinant of the finished matrix, a property of the rows as vectors, not a property of any individual entry. **Why natural.** Determinant zero is, by definition, equivalent to the rows being linearly dependent, so restating Barbara's goal in these terms costs nothing and immediately opens up the entire toolkit of linear algebra rather than leaving you stuck reasoning about 2008^2 separate real numbers. **Link to the next block.** Dependence is not something you can force by controlling individual numeric values against an adversary, but it is something you can force by confining every row to a common proper subspace, which suggests the next question, which subspace, and how do you confine a row to it turn by turn.

Block 2. **Cue.** You need a linear condition, satisfied by every row, that is forced regardless of the specific real numbers Alan chooses, which means the condition has to be additive or otherwise insensitive to the actual magnitudes involved. **Why natural.** A subspace of dimension d in $\mathbb{R}^{2008}$ can contain at most d independent vectors; if $d < 2008$ and all 2008 rows are confined to it, dependence is automatic with no further argument needed about the specific values, only about the confinement. **Link to the next block.** The simplest linear condition to force turn by turn on an adversarially filled row is that its coordinates sum to zero, since a sum is exactly the kind of quantity that a pairing and cancelling rule can guarantee.

Block 3. **Cue.** The board has 2008 columns, an even number, so every row can be split into whole pairs of columns with nothing left over; evenness is precisely what makes a pairing rule exact rather than approximate. **Why natural.** Pairing the columns of each row and always answering Alan's value x in one cell with $-x$ in its partner cell guarantees that every pair contributes exactly zero to the row sum, so the full row sum is a sum of zeros, forcing the row into the hyperplane orthogonal to $(1, \ldots, 1)$. **Link to the next block.** A rule stated this way is uniform, it says exactly the same thing regardless of which cell Alan chooses anywhere on the board, which is what makes its legality provable by a single invariant rather than by casework on where Alan plays.

Block 4. **Cue.** Before trusting that the rule always has somewhere legal to respond, you should ask explicitly what could go wrong, namely Barbara's target cell already being filled. **Why natural.** Proving the invariant, every cell pair is jointly empty or jointly filled immediately after each of Barbara's moves, by induction on the number of completed rounds, closes this gap completely: the invariant holding after round k guarantees Alan's move in round $k+1$ disturbs exactly one pair, which Barbara's response exactly repairs. **Link to the next block.** With legality secured for the entire length of the game, the only thing left is to read off the consequence for the determinant once the board is full.

Block 5. **Cue.** Every row now satisfies one fixed linear equation, membership in a 2007 dimensional hyperplane, and there are 2008 rows. **Why natural.** The dimension count, 2008 vectors inside a 2007 dimensional space, forces linear dependence by the basic fact that a subspace cannot contain more independent vectors than its dimension, which is exactly the condition for the determinant to vanish. **Link to the next block.** None; this is the terminal block. The strategy did not depend on any choice Alan made, so it succeeds against every possible sequence of his moves, which is what a winning strategy means.

Layer 3: WHY

The determinant is an alternating multilinear function of the rows, and it vanishes exactly when the rows fail to be independent. Against an adversary who is free to choose any real number at all, you cannot hope to control the actual value of the determinant, since Alan's freedom over magnitudes defeats any attempt to steer a numeric outcome directly. What you can control, turn by turn, is a linear relation, because linear relations are additive and are exactly the kind of property preserved by a pairing and cancelling response. This is the deep reason the problem reduces to a subspace confinement argument rather than a numeric one: rank and dependence are properties of the configuration of vectors, invariant under exactly the operations, negation and pairing, that a second player moving in response can enforce.

The discernment mechanism to train is recognising, as early as possible, when a combinatorial game's winning condition is secretly a linear algebraic one. The signal is a winning condition phrased about the whole configuration (rank, determinant, a system having a solution) rather than about any single entry; whenever you see that signal, translate immediately, then ask what fixed subspace or fixed relation the second (or sometimes first) player can force using a pairing argument, exploiting the board decomposing into an even number of symmetric slots. The examiners chose 2008, an even number, and phrased the win condition through the determinant rather than through any individual entry, precisely to make both of these signals available to you from the first reading.

It is also worth naming, as a matter of general strategy design, that a strategy proof for a game has two separate obligations that are easy to conflate: showing the response rule is always legal, and showing it always achieves the target condition. Confusing these, for instance checking legality only in a few example rounds and treating the target condition as obviously achieved, is the most common way a game solution loses marks; each obligation gets its own short, separately checkable argument here, legality by the round by round invariant, and the target condition by the direct row sum computation.

Revolving concepts

Determinant, rank, and dependence. For a square matrix, $\det = 0$ if and only if the rows, equivalently the columns, are linearly dependent; this converts any determinant vanishing question into a dependency question about vectors, and it is the single fact that opens up this entire problem. See Book 1, field: Matrices and determinants, topic: rank and dependency criteria for the determinant.

Dimension bounds on independent sets. In a vector space or subspace of dimension d, any set of more than d vectors is linearly dependent; equivalently a subspace of dimension d contains at most d linearly independent vectors. See Book 1, field: Linear algebra, topic: dimension and the exchange lemma.

Hyperplanes as orthogonal complements. For a fixed nonzero vector $u \in \mathbb{R}^n$, the set $\{v : v \cdot u = 0\}$ is a linear subspace of dimension $n-1$, the orthogonal complement of the line spanned by u. Here $u = (1, \ldots, 1)$ names the specific hyperplane that the pairing strategy forces every row into, turning an abstract dimension count into a concrete, checkable subspace. See Book 1, field: Linear algebra, topic: orthogonal complements and hyperplanes.

Pairing and mirroring strategies in combinatorial games. When a game's move set decomposes into an even number of symmetric slots that group into pairs, the second player can maintain the invariant that after every one of their turns each pair is jointly filled or jointly empty, by always responding inside the same pair as the opponent's most recent move. This lets the second player force any algebraic relation between paired slots, equal values, sums to zero, negatives, regardless of the opponent's actual choices. See Book 1, field: Games and invariants, topic: pairing and mirroring strategies on even sized boards.

Invariant maintenance as an induction on rounds. Proving a pairing strategy is well defined for the entire length of a game is, structurally, an induction on the number of completed rounds: state the invariant, verify it initially, then show that one round of play, the opponent's move together with the prescribed response, restores it. *General recursion and its solution:* for any pairing based strategy, let $I(k)$ be the invariant after round k. $I(0)$ holds trivially before any moves are made. If $I(k)$ holds, the opponent's move in round $k+1$ disturbs exactly one paired unit, and the prescribed response repairs it, so $I(k+1)$ holds. By induction, $I(k)$ holds for every k up to the last round, so the strategy is legal throughout and its target invariant, here the row sum condition, holds at the final round when the board is full. This template applies to any board filling or token based two player game where the total move count is even and the board decomposes into pairs. See Book 1, field: Games and invariants, topic: loop invariants for turn based strategies.

Circuit Bank

- **WHEN** a combinatorial game's winning condition is really a linear algebraic property of a matrix or a vector configuration, such as rank, determinant, or dependency **DO** translate the winning condition into the equivalent linear algebra statement before searching for a strategy **BECAUSE** the translated condition suggests concrete structural targets, equal rows, a shared hyperplane, that a pairing strategy can force, while the entrywise determinant formula suggests nothing constructive on its own
- **WHEN** the board or move set splits naturally into an even number of symmetric slots, such as pairable columns within each row, or pairable rows overall **DO** design a strategy where the second player always responds inside the same pair as the opponent's most recent move, and prove legality by an invariant maintained through the whole game rather than by checking a few sample rounds **BECAUSE** pairing keeps the invariant every pair is jointly empty or jointly filled trivially inductive, guaranteeing a legal response exists at every single turn until the board is full
- **WHEN** you want to force a specific linear relation, such as a sum to zero or two rows equal, onto data that an adversary is filling with arbitrary real numbers **DO** make the forcing rule purely algebraic and local, copying or negating a value into a fixed partner cell, rather than any rule that depends on the actual size of the numbers played **BECAUSE** a purely algebraic pairing rule works identically for every real number the adversary could ever choose, so no casework on the magnitude of Alan's numbers is ever needed
- **WHEN** you have more vectors than the dimension of the space you have confined them to **DO** state linear dependence as the immediate conclusion, with no further computation **BECAUSE** this is a one line consequence of the definition of dimension, and re deriving it from scratch inside a competition proof spends ink for no additional credit

Backtesting

1. First useful cue: the win condition is stated purely through the determinant of the completed matrix, never through any individual entry, signalling immediately that this is a linear algebra game rather than an arithmetic one.

2. Method the expression suggested: since determinant zero is equivalent to dependent rows, and Barbara moves second on an even sized board, a pairing or mirroring strategy is the natural mechanism for a second player to force a structural condition on the rows.
3. Where you would hesitate, and the thought to reinforce: the hesitation is whether Barbara always has a legal empty cell to respond into; reinforce proving this as an invariant maintained through the whole game by induction on the number of completed rounds, rather than assuming it is obvious.
4. The trap the question sets: it is tempting to assume the first player has the advantage by default, since Alan moves first and sets the tone; the trap is not questioning that assumption, when in a game about forcing a linear relation it is the second player who has the advantage, because the second player can always react to and cancel the most recent move.
5. What makes you recognise it faster next time: any $n \times n$ array filling game whose winning condition is determinant zero versus determinant nonzero, with n even, is solved by a pairing strategy for whichever player wants determinant zero, provided that player moves second.
6. The reusable decision rule: when the losing condition for a player is that the configuration lies in a proper subspace, and that player moves second on a board whose slots divide evenly, force the configuration into a fixed hyperplane using a pairing or negation response to every move of the opponent.

Mirror drills

1. Redo the game on a 5×5 board, so n is odd, under the same rules. Does the row negation pairing strategy still work directly? *Answer:* not directly, since a row of length 5 cannot be split into whole column pairs; but the row copying strategy, pairing row one with row two and mirroring exactly, still works whenever there are at least two rows to pair, giving two identical rows regardless of the parity of n, so Barbara wins for every $n \geq 2$ by that alternative strategy.
2. In the same 2008×2008 game, suppose instead Barbara wins whenever the determinant is a perfect square and Alan wins otherwise. Does the row negation pairing strategy still help Barbara? *Answer:* no; the pairing mechanism was tailored to force linear dependence, which pins the determinant at exactly zero, but it gives no control over the actual nonzero value of a determinant, so a restated target about the determinant's value, rather than its vanishing, needs an entirely different mechanism.
3. Two players alternately fill an 8×8 grid with values chosen from $\{1, -1\}$, Alan first, and Barbara wants the sum of all 64 entries to equal 0. Does Barbara have a winning strategy, and what is it? *Answer:* yes; since 64 is even, Barbara pairs the cells arbitrarily into 32 pairs, and whenever Alan writes a value v in one cell of a pair, Barbara writes $-v$, the opposite sign, in the other cell of that pair; every pair then contributes 0 to the total, forcing the grand total to be exactly 0, the same pairing and cancelling circuit as A2.

18.3 A3. gcd lcm swaps as sorting valuations by prime

Start with a finite sequence $a_1, a_2, \ldots, a_n$ of positive integers. If possible, choose two indices $j < k$ such that a_j does not divide a_k, and replace a_j and a_k by $\gcd(a_j, a_k)$ and $\operatorname{lcm}(a_j, a_k)$, respectively. Prove that if this process is repeated, it must eventually stop and the final sequence does not depend on the choices made.

Read it out loud

Read the problem as two separate claims stitched together by one shared operation. The first claim, that the process eventually stops, is a termination question: you need one quantity that only ever moves in one direction and cannot move forever. The second claim, that the final sequence does not depend on which legal pair you chose at each stage, is a confluence question: it says that however adversarially or however carefully you play this, you always land in the same place. These are logically independent statements, and you should resist any temptation to find a single argument that magically delivers both, because a proof that quietly uses one to justify the other is usually hiding a gap.

The operation itself is the real cue. Whenever gcd and lcm appear together acting on a pair, the identity $\gcd(a, b) \cdot \operatorname{lcm}(a, b) = ab$ should be the first thing you write down, since it is the reason the product of the whole sequence never changes, and it immediately supplies a uniform upper bound on every term forever after. But the deeper cue is that gcd and lcm are defined prime by prime, as the minimum and the maximum of exponents in a factorisation. That means the entire multiplicative process, once you fix a single prime p and look only at the exponent of p in each a_i, becomes a process on ordinary integers where a pair out of order gets replaced by its minimum and its maximum. That is exactly one comparator step of a sorting network, and once you see that, both halves of the problem separate cleanly: termination needs its own monovariant, because a sorting network with an adversarial firing order is not obviously finite in general, while confluence is close to automatic once you know that sorting by comparator exchanges always preserves which values are present, no matter the order the comparators fire in.

The field embedded here is number theory, through valuations and unique factorisation, married to a combinatorial idea, sorting networks, with the whole thing packaged as a termination and confluence question for a rewriting process. Within thirty seconds you should have written both the product identity and the phrase valuation, prime by prime, since those two observations are what the entire solution is built from.

Approaches, ranked worst to best

1. **empirical tracking.** *Cue:* small sequences with two or three terms are easy to compute by hand. *Circuit:* chase the actual integer values through several arbitrary sequences of moves, hoping to see why the endpoint is always the same. (why it ranks here: it conflates the multiplicative structure of several primes at once, obscures the actual reason uniqueness holds, and does not scale to a general proof no matter how many small examples you check).

2. **bad pair counting.** *Cue:* the stopping condition is that no out of order pair remains, so counting out of order pairs directly measures progress. *Circuit:* let a bad pair be a pair $j < k$ with a_j not dividing a_k, and show the count of bad pairs strictly decreases at every move by checking, case by case, that fixing one bad pair never creates a new one elsewhere. (this is a genuinely valid route to termination, and it gives an attractive explicit bound of at most $\binom{n}{2}$ moves, but the case analysis needed to show no new bad pair is ever created, splitting on whether a third index sits between, below, or above the two indices being fixed, costs more ink than a single scalar monovariant, for no gain on the harder uniqueness half of the problem, which still needs the prime by prime argument regardless).

3. **layered rightmost term stabilises first.** *Cue:* the last term of the sequence can only ever be the larger index in a legal move, so it can only grow. *Circuit:* show the last term is nondecreasing and bounded, hence eventually fixed, then repeat the argument one position to the left, and so on. (this is the standard route and its motivation is transparent, but write ups of it usually leave the induction from position n down to position 2 as an informal and so on, which a strict grader would want tightened into an explicit induction before granting full credit).
4. **single weighted product monovariant.** *Cue:* the layered idea says later positions matter more, and a strictly increasing sequence of weights is exactly how you compress a layered argument into one scalar. *Circuit:* define $Q = \prod_{i=1}^{n} a_i^i$ and show it strictly increases by an explicit factor at every move while staying bounded throughout. (this is the ideal route for termination: it captures the same rightward bias as the layered argument, but as one displayed inequality with an explicit bound, with no case split and no informal induction to tighten; uniqueness then has no competing family of approaches, the prime by prime valuation counting argument below is the natural and essentially forced route).

The ideal solution

Throughout, write $P = a_1 a_2 \cdots a_n$ for the product of the terms of the sequence at the start; this will turn out to be invariant.

A first invariant and a uniform bound. A single move replaces a_j, a_k ($j < k$) by $\gcd(a_j, a_k)$ and $\operatorname{lcm}(a_j, a_k)$. Since $\gcd(a_j, a_k) \cdot \operatorname{lcm}(a_j, a_k) = a_j a_k$, the product of all n terms is unchanged by every move, so it equals P at every stage of the process, forever. Moreover, at every stage every current term is at most P: if $x_1, \ldots, x_n$ are the current terms, with product P, then for any single index i, the remaining $n-1$ terms are positive integers, hence their product is at least 1, so $x_i \le P$. The same reasoning applied to any two current terms a_j, a_k gives $a_j a_k \le P$, and since $\operatorname{lcm}(a_j, a_k)$ divides $a_j a_k$ it satisfies $\operatorname{lcm}(a_j, a_k) \le a_j a_k \le P$ as well; combined with $\gcd(a_j, a_k) \le a_j \le P$, every value that can ever be written into the sequence, at any stage, is at most P.

Termination. Define

$$Q = \prod_{i=1}^{n} a_i^i,$$

using the current values of $a_1, \ldots, a_n$. Consider one move on positions $j < k$, and let $d = \gcd(a_j, a_k)$, $u = a_j/d$, $v = a_k/d$; then u, v are coprime positive integers and $\operatorname{lcm}(a_j, a_k) = duv$. The ratio of Q after the move to Q before the move is

$$\frac{d^j (duv)^k}{(du)^j (dv)^k} = \frac{d^{j+k} u^k v^k}{d^{j+k} u^j v^k} = u^{k-j}.$$

Since a_j does not divide a_k, we have $u = a_j/d \neq 1$, and u is a positive integer, so $u \ge 2$; since $k > j$, the exponent $k - j$ is a positive integer, so this ratio is at least $2^{k-j} \ge 2$. Hence Q is a positive integer that is at least doubled by every move. On the other hand, since every current term is at most P throughout the process, and each exponent i satisfies $i \le n$,

$$Q = \prod_{i=1}^{n} a_i^i \le \prod_{i=1}^{n} P^i = P^{n(n+1)/2}$$

at every stage. A positive integer that at least doubles at every step and stays below the fixed bound $P^{n(n+1)/2}$ can change only finitely many times, at most $\log_2\left(P^{n(n+1)/2}\right)$ times. So only finitely many moves can ever occur, and the process stops.

It remains to identify exactly when it stops: by definition the process stops precisely when no pair $j < k$ with $a_j \nmid a_k$ remains, that is, precisely when

$$a_j \mid a_k \quad \text{for every } j < k.$$

Uniqueness. Fix a prime p. For a positive integer x, write $v_p(x)$ for the exponent of p in the factorisation of x. Since gcd and lcm take the minimum and the maximum of exponents at every prime, a move on positions $j < k$ replaces the pair of valuations $\big(v_p(a_j), v_p(a_k)\big)$ by $\big(\min(v_p(a_j), v_p(a_k)), \max(v_p(a_j), v_p(a_k))\big)$, while every other position is untouched.

Claim. For every threshold $m \geq 0$, the count $c_m = \#\{\, i : v_p(a_i) \geq m \,\}$ is unchanged by every move.

Only positions j, k can change the count, so it suffices to check their combined contribution before and after. Write $x = v_p(a_j)$, $y = v_p(a_k)$ before the move. If $x, y \geq m$, both contribute before, and $\min(x, y) \geq m$ and $\max(x, y) \geq m$ both contribute after: 2 either way. If $x, y < m$, neither contributes before, and $\min(x, y) < m$ and $\max(x, y) < m$ (the larger of two values below m is still below m) neither contributes after: 0 either way. If exactly one of x, y is at least m, exactly one contributes before (1 total); after, $\min(x, y) < m$ (the smaller one, which is below m) does not contribute, while $\max(x, y) \geq m$ (the larger one) does: again 1 total. In every case the contribution is unchanged, proving the claim.

Now suppose the process terminates, in n terms $a'_1, \ldots, a'_n$. By the termination characterisation above, $a'_j \mid a'_k$ for every $j < k$, hence $v_p(a'_j) \leq v_p(a'_k)$ for every $j < k$ and every prime p; that is, for each fixed p the sequence $v_p(a'_1) \leq v_p(a'_2) \leq \cdots \leq v_p(a'_n)$ is nondecreasing. A nondecreasing sequence is recovered exactly from its threshold counts: because the sequence is sorted, the set of indices i with $v_p(a'_i) \geq m$, if nonempty, must be the top few indices $\{\, n - c_m + 1, \ldots, n \,\}$ (if some index qualifies, every later index qualifies too, since the sequence is nondecreasing), so

$$v_p(a'_i) = \max\{\, m : c_m \geq n - i + 1 \,\}$$

for each i, which depends only on the function $m \mapsto c_m$.

By the Claim, c_m is unchanged by every individual move, so by induction on the number of moves in any particular run, c_m at termination equals c_m for the original sequence, for every m, whichever legal moves were chosen along the way. Combined with the previous paragraph, this shows $v_p(a'_i)$ is the same value for every terminating run of the process, for every prime p and every index i. It suffices to check this for the finitely many primes dividing P, since a term's valuation at any other prime is identically 0 throughout. Since a positive integer is determined completely by its valuation at every prime, $a'_i = \prod_p p^{\,v_p(a'_i)}$ is therefore the same for every terminating run, for each i. This proves the final sequence does not depend on the choices made.

Layer 1: WHAT

Block 1: record the product identity $\gcd(a_j, a_k)\,\mathrm{lcm}(a_j, a_k) = a_j a_k$, giving an invariant product P and a uniform bound $x_i \leq P$ on every term forever. Block 2: for termination, define the weighted product $Q = \prod a_i^i$, show a single move multiplies it by an integer factor at least 2, and bound it above using Block 1, forcing finitely many moves. Block 3: characterise the stopping condition exactly as $a_j \mid a_k$ for all $j < k$. Block 4: for uniqueness, switch entirely to a fixed prime p and its valuations, and show a move replaces a pair of valuations by their minimum and maximum. Block 5: show the threshold count $c_m = \#\{i : v_p(a_i) \geq m\}$ is invariant under every move, for every m. Block 6: combine Block 3 (the final valuation sequence is sorted) with Block 5 (its threshold counts are choice independent) to recover the final valuation sequence uniquely for each prime, then recombine across primes by unique factorisation.

The nominal route tries to chase the raw integers a_i directly through several moves, which mixes the contributions of different primes together and hides why the endpoint is forced. The bifurcation point is the decision to decompose: termination is handled by compressing a layered, rightward biased improvement into a single weighted scalar, while uniqueness is handled by abandoning the integers entirely and working one prime at a time, because gcd and lcm are defined prime by prime and nowhere else do they have a simple description.

Layer 2: HOW

Block 1. **Cue.** gcd and lcm appear together acting on the same pair, and the identity relating their product to the original product of the pair is the single most standard fact attached to this combination. **Why natural.** Recording $\gcd(a_j, a_k)\,\mathrm{lcm}(a_j, a_k) = a_j a_k$ immediately gives an invariant, the total product P, and a moment's more work upgrades it to a uniform bound on every individual term at every stage, which is exactly the kind of control a termination argument needs. **Link to the next block.** A bounded uniform ceiling on every term is precisely what turns any candidate monovariant built from the a_i into a genuinely bounded quantity, so the next question is which monovariant to build.

Block 2. **Cue.** The move always replaces the term at the smaller index j by something no larger, and the term at the larger index k by something no smaller, so position matters, later positions are biased to grow. **Why natural.** Weighting each term by its position, $\prod a_i^i$, turns that positional bias into an exact algebraic statement: the ratio of Q after a move to Q before is u^{k-j} for an integer $u \geq 2$, hence at least 2, so Q strictly and substantially increases at every single move while Block 1's bound keeps it from increasing forever. **Link to the next block.** A bounded, strictly increasing positive integer can only change finitely many times, which is exactly the statement that the process stops; the only thing left is to say precisely what state it stops at.

Block 3. **Cue.** The process is defined to stop exactly when no legal move remains, and a legal move requires an out of order pair, so the stopping condition is the direct negation of that requirement. **Why natural.** No pair $j < k$ with $a_j \nmid a_k$ remaining means, by definition, $a_j \mid a_k$ for every $j < k$, and this is already the strongest possible divisibility statement about the final sequence, nothing further needs to be derived from it at this stage. **Link to the next block.** Divisibility between two positive integers is equivalent to an inequality between their valuations at every prime simultaneously, so this block is the bridge into the entirely separate, prime by prime argument that uniqueness needs.

Block 4. **Cue.** Uniqueness is a statement about the final integers themselves, but gcd and lcm have no simple additive or comparative description as integers; they do have an exact description as minimum and maximum once you pass to the exponent of a single fixed prime. **Why natural.** Fixing a prime p and tracking $v_p(a_j), v_p(a_k)$ converts the move into exactly one step of a sorting comparator, replace an out of order pair of numbers by their minimum, in position order, and by their maximum, which is a purely combinatorial operation with nothing multiplicative left in it. **Link to the next block.** Once the operation is recognised as a comparator step, the standard question for any comparator based process is what invariant survives every comparator firing, which is answered directly by counting how many values clear a threshold.

Block 5. **Cue.** A comparator step only touches two positions and replaces their values by the min and the max of the same two values, so any quantity that only cares how many values exceed a fixed threshold cannot be affected by the swap. **Why natural.** Checking the three cases, both above the threshold, both below, or exactly one above, shows the count of positions at or above any fixed threshold m is identical before and after a move, for every m and every prime p simultaneously, with no dependence on which of the two positions held the larger value. **Link to the next block.** An invariant count for every threshold is precisely the information needed to reconstruct a sorted sequence exactly, so the final step is purely about combining that reconstruction with the fact that the terminal valuation sequence is sorted.

Block 6. **Cue.** The terminal sequence is sorted in valuation, by Block 3, and its threshold counts are pinned down independently of any choices made, by Block 5. **Why natural.** A sorted sequence

is uniquely recoverable from its threshold counts, since the indices exceeding any threshold must be exactly the top few by sortedness, so the terminal valuation sequence at every prime is forced to be the same for every run; recombining across all primes dividing P via unique factorisation then pins down the terminal integers themselves. **Link to the next block.** None; this is the terminal block. Naming the wider frameworks this fits into, sorting networks and the structure theorem for finite abelian groups, is deferred to the revolving concepts.

Layer 3: WHY

The single structural truth underneath both halves of this problem is that gcd and lcm are, prime by prime, nothing but min and max of exponents. Every other fact used, the product identity, the bound on every term, the comparator description, the threshold counting, is a direct consequence of that one truth applied either multiplicatively across all primes at once, for the termination bound, or to a single prime in isolation, for uniqueness. Termination and uniqueness genuinely need different tools because they are different kinds of claims: termination is quantitative, it asks how long can this take, and needs a monovariant with an explicit bound; uniqueness is structural, it asks does the answer depend on the path, and needs an invariant that is exactly preserved, not merely bounded, at every step.

The discernment mechanism worth training is to recognise, the moment you see a process that repeatedly replaces a pair by its minimum and its maximum, that you are looking at one comparator of a sorting network, and that sorting networks have two separately provable properties: they terminate under any legal firing schedule if some potential function forces them to, and they are confluent, always landing on the same sorted output, because a threshold counting argument shows the underlying multiset of values is preserved by every single comparator firing regardless of order. Here that recognition has to be applied simultaneously at every prime, which is why decomposing into valuations first, before attempting either half of the proof, is the move that makes everything else routine rather than mysterious.

The examiners nudge you toward the prime decomposition by defining the operation entirely through gcd and lcm, objects with no natural description except through prime factorisations, and they nudge you toward a monovariant, rather than a direct combinatorial bound on the number of moves, by allowing the choice of which pair to fix at each stage to be completely adversarial, meaning no fixed schedule of moves can be assumed. A crude count of possible states is not available to you, so a genuine monovariant, one that improves under every conceivable choice, not just a convenient one, is the only tool suited to a process that a hostile or arbitrary chooser might run.

Revolving concepts

p-adic valuation. For a prime p and positive integer x, $v_p(x)$ is the exponent of p in the factorisation of x; $v_p(\gcd(a,b)) = \min(v_p(a), v_p(b))$ and $v_p(\operatorname{lcm}(a,b)) = \max(v_p(a), v_p(b))$ for every prime p, and since $\min(x,y) + \max(x,y) = x + y$, summing over all primes recovers $\gcd(a,b)\operatorname{lcm}(a,b) = ab$ without appealing to that identity directly. See Book 1, field: Number theory, topic: valuations and unique factorisation.

Monovariants and their construction by weighting position. A monovariant is a single quantity, attached to the current state of a process, that is bounded and moves in only one direction at every legal step, regardless of which legal step is chosen; boundedness together with strict monotonicity of an integer valued quantity forces termination. *General recursion and its solution:* when a process has a layered, lexicographic improvement, a later coordinate never gets worse and strictly improves whenever it changes, while earlier coordinates are secondary, choosing any strictly increasing weights $w_1 < w_2 < \cdots < w_n$ and combining via $\sum w_i x_i$ or $\prod x_i^{w_i}$ compresses that layered structure into one scalar monovariant, replacing an inductive argument carried out position by position with

a single displayed inequality; the exponent choice $w_i = i$ used here is the simplest such weighting, and the same compression applies to any finite process with a provable lexicographic improvement. See Book 1, field: Sequences and recurrences, topic: monovariants and weighted compression of a layered argument.

Sorting networks and confluence. A process that repeatedly finds any out of order pair, by position and value, and replaces it with its minimum and maximum in position order, applied in any sequence of choices, always terminates at the same fully sorted arrangement of the original multiset; this is the correctness property of comparator based sorting, and its standard proof is exactly the threshold counting argument used above, tracking how many elements clear each threshold. See Book 1, field: Discrete structures and graphs, topic: sorting networks and comparator based confluence.

Reconstructing a sorted sequence from its threshold counts. A nondecreasing sequence of n nonnegative integers is uniquely determined by the function $m \mapsto \#\{i : x_i \geq m\}$; this is the classical duality between a partition and its conjugate, the transpose of its Young diagram. See Book 1, field: Combinatorics, topic: partitions and conjugate partitions.

Invariant factors and the structure theorem for finite abelian groups. Every finite abelian group is isomorphic to a product $\mathbb{Z}/d_1\mathbb{Z} \times \cdots \times \mathbb{Z}/d_n\mathbb{Z}$ with $d_1 \mid d_2 \mid \cdots \mid d_n$, and this divisibility chain of invariant factors is uniquely determined by the group, independent of how it is presented. The final sequence of this problem is exactly the invariant factor decomposition of $\mathbb{Z}/a_1\mathbb{Z} \times \cdots \times \mathbb{Z}/a_n\mathbb{Z}$, computed by a purely combinatorial process instead of the row and column reduction usually used to compute a Smith normal form. This is genuinely beyond the installed toolkit and worth flagging rather than glossing: it is a full undergraduate algebra theorem, only its shadow is needed here. See Book 1, field: Abstract algebra, topic: Smith normal form and invariant factors.

Circuit Bank

- **WHEN** an operation replaces two numbers by their gcd and their lcm, or more generally by the componentwise minimum and maximum of some invariant attached to them **DO** decompose by prime, or by coordinate, and track the minimum and maximum of the exponents or coordinates separately for each prime **BECAUSE** gcd and lcm act independently and identically at every prime, so per prime bookkeeping turns a multiplicative question into a simple ordering question with nothing else mixed in
- **WHEN** you need termination of a process that can be run in any adversarial order rather than a fixed schedule **DO** hunt for a single scalar monovariant that is bounded and strictly improves at every legal move, preferring a weighted product or sum that captures a layered bias over an explicit layer by layer induction **BECAUSE** a single displayed inequality is faster to write and to check than an induction hidden behind an informal and so on, and it works under every possible ordering of moves by construction
- **WHEN** a claim has the form the final state does not depend on the choices made **DO** search for quantities attached to the current state, not to the sequence of moves, that are provably unchanged by every individual legal move, and check whether enough of them pin the state down completely **BECAUSE** if the invariants determine the state completely, as the threshold counts do here for every prime, then any two terminating runs share the same invariants and hence the same final state, with no need to compare the two runs move by move
- **WHEN** a sequence is repeatedly having an out of order pair, by position, replaced by its minimum and maximum in position order **DO** recognise it as a sorting network and recall that the final sorted order is already determined by the initial multiset, independent of which legal pair is fixed at each stage **BECAUSE** this is the defining correctness property of comparator based sorting, and citing it once justified saves re deriving confluence from scratch on every similar problem

- **WHEN** a problem asks you to prove two logically separate things, such as termination and then uniqueness of the outcome **DO** prove them in two clearly separated sections with two different invariants or techniques, never one argument claimed to deliver both at once **BECAUSE** conflating does it stop with does it always stop at the same place tends to produce a proof that silently assumes one claim while trying to establish the other

Backtesting

1. First useful cue: gcd and lcm are named together acting on the same pair, and the identity $\gcd(a,b)\,\mathrm{lcm}(a,b) = ab$ should be written down on sight, since it hands you both an overall invariant and a uniform bound on every term for the rest of the process.
2. Method the expression suggested: gcd and lcm are defined prime by prime as minimum and maximum of exponents, so the moment the problem asks whether the outcome is independent of choices, the suggested method is to track, separately for each prime, how the min and max operation moves valuations around, which is exactly sorting.
3. Where you would hesitate, and the thought to reinforce: the hesitation is usually how do you know this terminates when the moves can be chosen adversarially rather than in a fixed order; reinforce find one scalar quantity, strictly increasing and bounded, that does not care what order the legal moves are chosen in, and prefer a weighted product over a layered induction.
4. The trap the question sets: it is tempting to try to prove uniqueness by comparing two arbitrary sequences of choices move by move, an approach that looks like it needs to consider exponentially many cases; the trap is not noticing that several per prime, per threshold invariants pin down the entire final state at once, which sidesteps any need to compare move sequences directly.
5. What makes you recognise it faster next time: any process defined by replace a pair by the minimum and maximum of something, on a sequence, with a stopping condition phrased as fully sorted, is a comparator or sorting network problem, and both its termination and its confluence have standard, separately provable mechanisms, a monovariant, and threshold counting invariants respectively.
6. The reusable decision rule: a gcd or lcm replacement process reduces to sorting the valuation sequence at every prime simultaneously; prove termination with a strictly increasing bounded weighted product monovariant, and prove uniqueness with threshold count invariants, one prime at a time.

Mirror drills

1. A sequence of positive integers $b_1, \ldots, b_n$ repeatedly has two entries b_j, b_k, with $j < k$ and $b_j > b_k$, replaced by $\min(b_j, b_k)$ and $\max(b_j, b_k)$ whenever they are out of numeric order. Show this always terminates at the sorted sequence, independent of the order of swaps chosen. *Answer:* this is the identical circuit with the raw integers themselves playing the role of a single prime's valuations; termination follows from a position weighted sum or product monovariant, and uniqueness follows because every swap preserves how many entries meet or exceed any fixed threshold, forcing the final sorted arrangement of the original multiset to be the only possible outcome.
2. For positive integers a, b and a prime p, express $v_p(\gcd(a,b))$ and $v_p(\mathrm{lcm}(a,b))$ in terms of $v_p(a)$ and $v_p(b)$, and use this to reprove $\gcd(a,b)\,\mathrm{lcm}(a,b) = ab$ without quoting that identity directly. *Answer:* $v_p(\gcd(a,b)) = \min(v_p(a), v_p(b))$ and $v_p(\mathrm{lcm}(a,b)) = \max(v_p(a), v_p(b))$; since $\min(x,y) + \max(x,y) = x + y$ at every prime's exponent, the two sides of the claimed identity have the same valuation at every prime, hence are equal by unique factorisation.

3. A collection of chips is repeatedly merged by a rule that always preserves, for every threshold m, the number of chips with value at least m. If two different merge schedules both terminate at a totally sorted arrangement, must the two final arrangements be identical? *Answer:* yes, by exactly the uniqueness argument of A3: a sorted arrangement is uniquely reconstructed from its threshold counts, those counts are schedule independent invariants by hypothesis, so both schedules are forced to terminate at the same sorted arrangement.

18.4 A4. An iterated logarithm series that diverges

Define $f\colon \mathbb{R} \to \mathbb{R}$ *by*

$$f(x) = \begin{cases} x & \text{if } x \le e, \\ xf(\ln x) & \text{if } x > e. \end{cases}$$

Does $\displaystyle\sum_{n=1}^{\infty} \frac{1}{f(n)}$ *converge?*

Read it out loud

Say it to yourself: this is a series whose general term is not given by a formula at all, but by a recursion in which the argument is pushed down by a logarithm. The recursion is multiplicative: f at x is x times f at $\ln x$. The map $x \mapsto \ln x$ is a contraction that drags any starting point below e in finitely many steps, so the recursion is a finite product, and it terminates at a different depth depending on where x sits. That last clause is the whole problem. The domain of f is naturally cut into blocks by the tower $1, e, e^e, e^{e^e}, \ldots$, and on each block f is a different explicit product.

The fields wired in are real analysis (convergence of a positive series), calculus of iterated functions (the chain rule for $\ln \circ \ln \circ \cdots$), and the theory of the logarithmic scale of divergence, the Bertrand series. What is really being tested is whether you will unfold a recursion before you reach for a convergence test. Everybody knows the integral test. Almost nobody writes down the closed form on the second and third blocks before deciding what to do.

The first useful cue is the shape $f(x) = xf(\ln x)$ itself. Within thirty seconds you should have on your page:

$$f(x) = x \text{ on } (1, e], \qquad f(x) = x \ln x \text{ on } (e, e^e], \qquad f(x) = x \ln x \ln\ln x \text{ on } (e^e, e^{e^e}],$$

and the observation that the denominators are exactly the denominators of the classical Bertrand series $\sum \frac{1}{n \ln n \ln\ln n \cdots}$. Every one of those diverges. Your instinct at that point should already be that the answer is divergence, and the only remaining job is to find the cheapest honest proof.

The second cue is quieter and worth naming, because it is the one that makes the proof one line long. Take reciprocals in the recursion: $\frac{1}{f(x)} = \frac{1}{x} \cdot \frac{1}{f(\ln x)}$. Now read that as a statement about derivatives. If G is a function with $G' = 1/f$ on the previous block, then $\frac{1}{x} G'(\ln x)$ is the derivative of $G(\ln x)$. In other words the defining recursion of this problem *is* the chain rule for composing with ln. So $1/f$ is not merely comparable to the derivative of an iterated logarithm; it is exactly that derivative.

Approaches, ranked worst to best

1. **Ratio test or root test.** *Cue:* it is an infinite series, so run the standard tests. *Circuit:* default convergence testing. Both give exactly 1, because $f(n+1)/f(n) \to 1$ inside every block. You learn nothing and you have spent five minutes. Any test that only sees the term's exponential growth rate is blind to a series this close to the boundary.
2. **Comparison with $\sum \frac{1}{n \ln n}$.** *Cue:* the second block gives $f(x) = x \ln x$. *Circuit:* compare with a known Bertrand series. This ranks near the bottom for a reason worth burning in: the inequality points the wrong way. For $x > e^e$ we have $f(x) \ge x \ln x$, hence $\frac{1}{f(n)} \le \frac{1}{n \ln n}$, an upper bound by a divergent series. That carries zero information. To prove divergence you need a lower bound, so any comparison against a fixed Bertrand series must fail, because f eventually beats every one of them.
3. **Cauchy condensation.** *Cue:* the terms are positive and decreasing. *Circuit:* condense a monotone series. Correct, but you must condense once per logarithm and the bookkeeping multiplies. You are simulating the integral test by hand with worse constants.

4. **Block the sum along the tower and estimate each block by hand.** *Cue:* the closed form for f changes at $1, e, e^e, \ldots$. *Circuit:* partition the index set where the formula changes. This is the right skeleton. It ranks second only because to evaluate a block sum you will end up comparing with an integral anyway, so you may as well integrate from the start.
5. **Integral test, then substitute $y = \ln^k x$ on the kth block.** *Cue:* $1/f$ is the derivative of the kth iterated logarithm. *Circuit:* a multiplicative recursion under ln is the chain rule. Best. Each block contributes exactly 1, with no estimation, no epsilon, and no constants. An exact answer on every block is always cheaper than an inequality on every block.

The ideal solution

Write $\ln^1 x = \ln x$ and $\ln^k x = \ln(\ln^{k-1} x)$ for $k \geq 2$. Define the tower $t_0 = 1$ and $t_k = e^{t_{k-1}}$, so $t_1 = e$, $t_2 = e^e$, and so on.

Step 0: f is well defined on $[1, \infty)$. For $x > e$ the recursion refers to $f(\ln x)$ with $\ln x < x$. If some x had $\ln^k x > e$ for every k, the sequence $x_k = \ln^k x$ would be strictly decreasing and bounded below by e, hence convergent to some $L \geq e$ with $L = \ln L$, which is impossible since $\ln L < L$ for all $L > 0$. So every x falls below e after finitely many logarithms and the recursion closes.

Lemma 18.4.1. *For every $k \geq 1$ and every $x \in (t_{k-1}, t_k]$,*

$$f(x) = x \ln^1 x \, \ln^2 x \cdots \ln^{k-1} x$$

(the product being empty when $k = 1$).

Proof. Induction on k. For $k = 1$ the interval is $(1, e]$, where $x \leq e$ and $f(x) = x$ by definition. Let $k \geq 2$ and $x \in (t_{k-1}, t_k]$. Then $x > t_{k-1} \geq e$, so $f(x) = xf(\ln x)$, and $\ln x \in (t_{k-2}, t_{k-1}]$. By the induction hypothesis $f(\ln x) = \ln x \prod_{j=1}^{k-2} \ln^j(\ln x) = \prod_{j=1}^{k-1} \ln^j x$, since $\ln^j(\ln x) = \ln^{j+1} x$. Multiply by x. □

Lemma 18.4.2. *f is positive and increasing on $[1, \infty)$.*

Proof. Fix $k \geq 1$ and $x \in (t_{k-1}, t_k]$. For $1 \leq j \leq k-1$ we have $\ln^j x > \ln^j t_{k-1} = t_{k-1-j} \geq t_0 = 1$, so every factor in the Lemma is greater than 1 and is an increasing function of x on that interval. Hence f is positive and increasing on each block. The blocks fit together: at $x = t_{k-1}$ the two formulas differ only by the factor $\ln^{k-1} t_{k-1} = t_0 = 1$, so f is continuous at each tower point and therefore increasing on all of $[1, \infty)$. □

Lemma 18.4.3. *For every $k \geq 1$, $\displaystyle\int_{t_{k-1}}^{t_k} \frac{dx}{f(x)} = 1$.*

Proof. The function $L_k(x) = \ln^k x$ is differentiable wherever $\ln^{k-1} x > 0$, that is for $x > t_{k-2}$, and by the chain rule

$$L_k'(x) = \frac{1}{x \ln^1 x \cdots \ln^{k-1} x} = \frac{1}{f(x)} \qquad \text{on } (t_{k-1}, t_k]$$

by the first Lemma. Since $\ln^k t_{k-1} = \ln 1 = 0$ and $\ln^k t_k = 1$, the Fundamental Theorem of Calculus gives $\int_{t_{k-1}}^{t_k} \frac{dx}{f(x)} = L_k(t_k) - L_k(t_{k-1}) = 1$. □

Conclusion. By the second Lemma, $g(x) = 1/f(x)$ is positive and nonincreasing on $[1, \infty)$, so $g(n) \geq \int_n^{n+1} g(x)\, dx$ for every integer $n \geq 1$. Summing,

$$\sum_{n=1}^{N} \frac{1}{f(n)} \;\geq\; \int_1^{N+1} \frac{dx}{f(x)}.$$

By the third Lemma, $\int_1^{t_K} \frac{dx}{f(x)} = \sum_{k=1}^{K} 1 = K$, which is unbounded as $K \to \infty$. Hence the partial sums of the series are unbounded, and

$$\boxed{\sum_{n=1}^{\infty} \frac{1}{f(n)} \text{ diverges.}}$$

Layer 1: WHAT

Block 1. Unfold the recursion. Get the tower t_k and the closed form $f(x) = x \ln^1 x \cdots \ln^{k-1} x$ on the kth block, and check f is well defined at all.

Block 2. Take reciprocals and recognise $1/f$ as $\frac{d}{dx} \ln^k x$ on the kth block.

Block 3. Establish that f is positive and increasing across the block boundaries, so the integral test is available in the direction that proves divergence.

Block 4. Integrate over each block: the iterated logarithm carries the block onto $[0, 1]$, so every block contributes exactly 1. Infinitely many blocks, so the integral, and hence the sum, diverges.

Juxtaposition. The nominal route reads "series, positive terms" and runs down the checklist: ratio, root, comparison with $1/n$, comparison with $1/(n \ln n)$. It never unfolds the recursion, so it never sees that f outgrows every fixed Bertrand denominator, and it wastes its comparisons in the direction that cannot conclude. The ideal route treats f as an object to be computed before it is estimated.

The bifurcation point is the first line after reading the definition. Ideal: write f explicitly on $(e, e^e]$ and $(e^e, e^{e^e}]$. Zombie: write "let $a_n = 1/f(n)$" and start testing. Everything downstream is decided there.

Layer 2: HOW

Block 1. **Cue.** The recursion $f(x) = xf(\ln x)$ has an argument that strictly decreases and a base region $x \le e$. Any recursion with a contracting argument and a base case is a finite product, and its length depends on the starting point. **Why natural.** You cannot test a series whose term you cannot write. Unfolding costs two lines and converts an implicit definition into an explicit one. The tower $t_k = e^{t_{k-1}}$ is forced on you: it is precisely the set of points at which the number of logarithms needed changes, that is, the escape time of x under ln. **Link to the next block.** Once the closed form is on the page, the denominator $x \ln x \ln \ln x \cdots$ is staring at you, and that product is the most recognisable object in the theory of divergent series.

Block 2. **Cue.** A product of a variable and all of its iterated logarithms in a denominator. You have met that exact product as the derivative of $\ln \ln x$, of $\ln \ln \ln x$, and so on. **Why natural.** This is not a coincidence to be discovered; it is the recursion restated. Dividing $f(x) = xf(\ln x)$ through gives $\frac{1}{f(x)} = \frac{1}{x} \cdot \frac{1}{f(\ln x)}$, and $\frac{1}{x} G'(\ln x)$ is by the chain rule the derivative of $G \circ \ln$. So if $1/f$ is a derivative of something on one block, it is the derivative of that something composed with ln on the next. The recursion propagates antiderivatives. **Link to the next block.** Having an exact antiderivative means you will never need an inequality on a block, only an evaluation, so you now want an integral in your argument.

Block 3. **Cue.** You intend to use $\sum \ge \int$. That inequality has a hypothesis, and the hypothesis is monotonicity on the whole ray, not just inside blocks. **Why natural.** The two integral test inequalities are not symmetric: for nonincreasing positive g you get $\int_1^{N+1} g \le \sum_{n=1}^{N} g(n) \le g(1) + \int_1^N g$. Only the left one proves divergence of the sum from divergence of the integral. Choosing the wrong one is the single most common way to write a paragraph that proves nothing. Checking continuity at the tower points is not pedantry; a jump downward there would break the monotonicity you are

about to invoke. **Link to the next block.** With g nonincreasing and the block antiderivative known, the computation is now purely arithmetic.

Block 4. Cue. $\ln^k$ maps the kth block onto $[0,1]$, because t_{k-1} and t_k are by construction the points where the kth iterated logarithm equals 0 and 1. **Why natural.** The tower was defined to make this true; that is the payoff of choosing the blocks by escape time rather than by, say, powers of two. Each block therefore contributes exactly one unit of "logarithmic length", independent of k, and a sum of infinitely many ones diverges. Notice that the terms $1/f(n)$ are becoming absurdly small, of size roughly $1/t_k$ on the kth block; divergence is powered entirely by the fact that the blocks get long faster than the terms get small. **Link to the next block.** Nothing remains: unbounded partial sums is the definition of divergence for a positive series.

Layer 3: WHY

The truth beneath this problem is the structure of the logarithmic scale. For each fixed k the Bertrand series

$$\sum_n \frac{1}{n \ln^1 n \, \ln^2 n \cdots \ln^k n}$$

diverges, while inserting any exponent $1+\varepsilon$ on the last factor makes it converge. So the family of divergent series has no smallest member you can name at this level: for every convergent comparison you propose there is a divergent series just beneath it, and vice versa. This problem hands you the *diagonal* of that family. At each x it uses exactly as many logarithmic factors as are available before they drop below 1, and asks whether the diagonal falls on the divergent side. It does, and the exact block computation says why in the sharpest possible terms: each block contributes exactly 1, so the diagonal sits precisely at the divergence boundary, at the slowest possible rate, growing like $\ln^*$, the iterated logarithm of the upper limit.

The discernment mechanism is a general one, and it is worth stating as a policy rather than an observation. When a function is defined recursively by $F(x) = G(x)F(\sigma(x))$ with σ contracting into a base region, do not test, do not estimate, do not compare. Unfold. You get

$$F(x) = \Big(\prod_{j=0}^{k-1} G(\sigma^j(x))\Big) F_{\text{base}}(\sigma^k(x)), \qquad k = \text{escape time of } x,$$

and the natural partition of the domain is by escape time. Every question about F then becomes a question about that product on one block.

The second and sharper piece of discernment is reading a recursion as a differential statement. A multiplicative recursion with the factor $1/\sigma'(x)$ built into it, which is exactly what $f(x) = xf(\ln x)$ is since $\ln' x = 1/x$, is the chain rule written backwards. Train it like this: whenever you see $\frac{1}{h(x)} = \sigma'(x) \cdot \frac{1}{h(\sigma(x))}$, immediately write "so $1/h$ is the derivative of (previous antiderivative) $\circ\, \sigma$". The examiners nudged toward this by choosing ln and by putting the factor x in front, which is precisely $1/\ln'(x)$. Any other factor there and the problem would have a different answer; the factor x is the guiding light.

Revolving concepts

Iterated logarithm. $\ln^k x$ is defined for $x > t_{k-1}$, is increasing, and has derivative $\left(x \ln^1 x \cdots \ln^{k-1} x\right)^{-1}$. The tower $t_k = e^{t_{k-1}}$ is its "unit ladder": $\ln^k$ carries $[t_{k-1}, t_k]$ onto $[0,1]$. See Book 1, field: Real analysis, topic: iterated logarithms and growth scales.

Integral test. For g positive and nonincreasing on $[1,\infty)$: $\int_1^{N+1} g \le \sum_{n=1}^{N} g(n) \le g(1) + \int_1^N g$. Both halves come from $\int_n^{n+1} g \le g(n) \le \int_{n-1}^{n} g$. Know which half you need before you write it. See Book 1, field: Real analysis, topic: convergence tests.

Bertrand series and the Abel and Dini theorem. $\sum n^{-1}(\ln n)^{-\alpha}$ converges iff $\alpha > 1$; more generally $\sum \left(n \ln^1 n \cdots \ln^{k-1} n (\ln^k n)^{\alpha}\right)^{-1}$ converges iff $\alpha > 1$. Abel and Dini: for any divergent positive series $\sum a_n$ with partial sums s_n, the series $\sum a_n / s_n$ still diverges, so there is no slowest divergent series. See Book 1, field: Real analysis, topic: the logarithmic scale.

The generalised recursion. The recursion here is $F(x) = G(x)F(\sigma(x))$ with $\sigma(x) = \ln x$ and $G(x) = x$. In general, if σ is increasing with $\sigma(x) < x$ and the iterates enter a base region B after $k(x)$ steps, then $F(x) = \prod_{j=0}^{k-1} G(\sigma^j(x)) \cdot F_{\text{base}}(\sigma^k(x))$, and the domain splits by escape time. The special case $G = 1/\sigma'$ makes $1/F$ the derivative of the kth iterate of σ, since $\left(H \circ \sigma\right)'(x) = H'(\sigma(x))\sigma'(x)$. Discrete analogue: the recursion $u_x = x\, u_{\lfloor \ln x \rfloor}$ and the $\ln^*$ function of algorithm analysis, which counts exactly the escape time used above. See Book 1, field: Sequences and recurrences, topic: unfolding recursions with contracting arguments.

Circuit Bank

- **WHEN** a function is defined by a recursion whose argument strictly decreases into a base region **DO** unfold it into an explicit finite product and partition the domain by escape time **BECAUSE** an implicit definition cannot be estimated, and the block structure is invisible until the first two levels are written out
- **WHEN** a recursion has the form $\frac{1}{h(x)} = \sigma'(x) \cdot \frac{1}{h(\sigma(x))}$, for instance $h(x) = x\,h(\ln x)$ **DO** declare $1/h$ to be the derivative of an iterate of σ and integrate exactly **BECAUSE** that identity is the chain rule written backwards, so an exact antiderivative exists and no estimation is needed
- **WHEN** you are about to use the integral test **DO** first fix the direction you need, then verify monotonicity on the whole ray including the junction points **BECAUSE** the two integral test inequalities are not symmetric, and only $\sum \geq \int_1^{N+1}$ transfers divergence from the integral to the sum
- **WHEN** a comparison yields an upper bound by a divergent series or a lower bound by a convergent one **DO** discard it and reverse the search **BECAUSE** such a bound is logically empty, and recognising this in five seconds saves the ten minutes most candidates spend on it
- **WHEN** a denominator is a product of a variable and several of its iterated logarithms **DO** say Bertrand series out loud and expect the divergence boundary **BECAUSE** that family is the standard calibration scale for series near the boundary, and its behaviour is a fact you are expected to have installed

Backtesting

1. First useful cue: the recursion $f(x) = xf(\ln x)$ with a base case at e, which is an instruction to unfold, not to test.
2. Method the expression suggested: unfold into $x \ln x \ln\ln x \cdots$, recognise the Bertrand denominator, recognise $1/f$ as the derivative of an iterated logarithm, then integrate block by block.
3. Where you would hesitate, and the thought to reinforce: the moment you have the block formula and want an estimate. Do not estimate. Ask instead whether the block integrand has an exact antiderivative, because a recursion of this shape guarantees one.
4. The trap the question sets: the invitation to compare with $\sum \frac{1}{n \ln n}$. The comparison is true and useless, because $f(n) \geq n \ln n$ makes it an upper bound by a divergent series. The question is engineered so that every fixed comparison series is eventually beaten by f.

5. What makes you recognise it faster next time: the factor in front of the recursive call. It is x, and $x = 1/\ln'(x)$. A recursion whose multiplier is the reciprocal derivative of its argument map is a disguised chain rule, every time.
6. The reusable decision rule: unfold before you test; partition by escape time; and when the recursion is a chain rule, integrate exactly instead of estimating.

Mirror drills

1. Show that $\sum_{n\geq 16} \frac{1}{n \ln n \ln\ln n}$ diverges while $\sum_{n\geq 16} \frac{1}{n \ln n (\ln\ln n)^2}$ converges. *Answer:* the antiderivatives are $\ln^3 x$ and $-1/\ln\ln x$; the first is unbounded, the second is bounded.
2. Let $g(x) = x$ for $x \leq e$ and $g(x) = x(\ln x)g(\ln x)$ for $x > e$. Does $\sum 1/g(n)$ converge? *Answer:* it converges. Unfolding gives $g(x) = x\prod_{j=1}^{k-1}(\ln^j x)^2$ on the kth block, so the substitution $y = \ln^k x$ leaves $\int \frac{dy}{\ln^1 x \cdots \ln^{k-1} x} \leq 1/(t_1 t_2 \cdots t_{k-1})$ on that block, and those bounds are summable.
3. Prove the inequality used in the conclusion: for g positive and nonincreasing on $[1,\infty)$, $\int_1^{N+1} g(x)\,dx \leq \sum_{n=1}^{N} g(n)$. *Answer:* on $[n, n+1]$ we have $g(x) \leq g(n)$, so $\int_n^{n+1} g \leq g(n)$; sum over $n = 1$ to N.

18.5 A5. Regular polygon vertices force high polynomial degree

Let $n \geq 3$ be an integer. Let $f(x)$ and $g(x)$ be polynomials with real coefficients such that the points

$$(f(1), g(1)), (f(2), g(2)), \ldots, (f(n), g(n))$$

in $\mathbb{R}^2$ are the vertices of a regular n-gon in counterclockwise order. Prove that at least one of $f(x)$ and $g(x)$ has degree greater than or equal to $n-1$.

Read it out loud

Read the structure, not the words. You have one parameter, the integer k, running over 1 to n. You have two real polynomials evaluated at that parameter, and the resulting pair of numbers is being interpreted as a point of the plane. The condition on those n points is a rigid geometric one: they form a regular n-gon, and the labelling matches the counterclockwise order around it. The conclusion is about degrees.

Two real polynomials sampled at the same integers, with a planar condition on the pair, is the most reliable cue in the whole subject for one move: package them as a single complex polynomial $P(z) = f(z) + ig(z)$. The reason is not aesthetic. The condition "regular n-gon in counterclockwise order" has a one-line description in $\mathbb{C}$, namely $v_k = a\omega^k + b$ with $\omega = e^{2\pi i/n}$, and no clean description in real coordinates at all: in coordinates you are looking at $f(k) = \alpha + r\cos(\theta_0 + 2\pi k/n)$ and $g(k) = \beta + r\sin(\theta_0 + 2\pi k/n)$, two entangled trigonometric conditions instead of one algebraic one. The degree statement survives the packaging perfectly, because for real f_j, g_j the coefficient $f_j + ig_j$ vanishes if and only if both do. So $\deg P = \max(\deg f, \deg g)$, exactly, and the problem becomes: prove $\deg P \geq n-1$.

The fields embedded are polynomials (degree and root counting), complex numbers (roots of unity and plane similarities), and finite difference calculus (the shift operator acting on sequences). What is really being tested is whether you know the dictionary between polynomials and the difference operator: a polynomial sequence and a genuine geometric sequence are different species, and they can only agree on a bounded window of consecutive integers.

Within thirty seconds you should have written: $P = f + ig$, $\deg P = \max(\deg f, \deg g)$, and $P(k) = a\omega^k + b$ for $k = 1, \ldots, n$, where $\omega = e^{2\pi i/n}$ and $a \neq 0$. The problem is now "a polynomial agrees with a geometric sequence at n consecutive integers", and the number $n-1$ in the conclusion is the loud hint that you should be manufacturing $n-1$ roots of something.

Approaches, ranked worst to best

1. **Work in real coordinates with** cos **and** sin**.** *Cue:* the problem is stated with two real polynomials. *Circuit:* stay in the given coordinates. Last place. You end up needing Chebyshev-style identities, and every identity you derive is the real or imaginary part of the single complex identity you refused to write. Enormous ink, and the counterclockwise hypothesis becomes almost impossible to use cleanly.

2. **Suppose** $\deg \leq n-2$ **and interpolate.** *Cue:* a polynomial of degree at most $n-2$ is determined by $n-1$ of its values. *Circuit:* interpolation counting. The right instinct, since $n-1$ is one fewer than the number of data points, but on its own it is not a proof. You must find the specific linear functional that kills all polynomials of degree at most $n-2$ and does not kill the data. Without the complex packaging you will not see which functional to use.

3. **Induction on the number of sample points.** *Cue:* reduce the case of m points to $m-1$ points by differencing. *Circuit:* induction with the difference operator. Correct: if $Q(k) = t^k$ for $k = 1, \ldots, m$, then $R(z) = (t-1)^{-1}(Q(z+1) - Q(z))$ satisfies $R(k) = t^k$ for $k = 1, \ldots, m-1$ and has degree one less. Solid, but it costs a base case, an induction hypothesis and a check

that the degree really drops by exactly one, for a statement that a single operator identity settles outright.

4. **Finite differences in one shot.** *Cue:* degree at most $m-2$ is equivalent to the $(m-1)$st difference vanishing identically. *Circuit:* annihilate polynomials with Δ. Very good. The $(m-1)$st forward difference of Q at 1 equals $\sum_{i=0}^{m-1}(-1)^{m-1-i}\binom{m-1}{i}t^{1+i} = t(t-1)^{m-1} \neq 0$, which is impossible if $\deg Q \leq m-2$. Loses only to the next route because it needs a binomial evaluation.

5. **Kill the geometric part with the shift operator.** *Cue:* t^k is an eigenvector of the shift with eigenvalue t. *Circuit:* apply $E - tI$, then count roots. Best. Set $R(z) = Q(z+1) - tQ(z)$. Its leading coefficient is $(1-t)$ times that of Q, so it is nonzero and $\deg R = \deg Q$ exactly, while R vanishes at $1, 2, \ldots, m-1$ by construction. A nonzero polynomial with $m-1$ distinct roots has degree at least $m-1$. Three lines, no induction, no binomial sums, and it exposes the reason: $t \neq 1$ is what stops the operator from lowering the degree.

The ideal solution

Lemma 18.5.1. *Let $t \in \mathbb{C}$ with $t \neq 0$ and $t \neq 1$, let $m \geq 1$ be an integer, and let $Q \in \mathbb{C}[z]$ satisfy $Q(k) = t^k$ for $k = 1, 2, \ldots, m$. Then* $\deg Q \geq m-1$.

Proof. First, Q is not the zero polynomial, since $Q(1) = t \neq 0$. Let $d = \deg Q \geq 0$ and let $c \neq 0$ be its leading coefficient. Define

$$R(z) = Q(z+1) - t\,Q(z).$$

The polynomial $Q(z+1)$ has degree d and leading coefficient c, so R has degree at most d, and the coefficient of z^d in R is $c - tc = (1-t)c$, which is nonzero because $t \neq 1$ and $c \neq 0$. Hence R is a nonzero polynomial of degree exactly d.

For $k = 1, 2, \ldots, m-1$ both k and $k+1$ lie in $\{1, \ldots, m\}$, so

$$R(k) = Q(k+1) - t\,Q(k) = t^{k+1} - t \cdot t^k = 0.$$

Thus R has at least the $m-1$ distinct roots $1, 2, \ldots, m-1$. A nonzero polynomial has at most $\deg R$ distinct roots, so $d = \deg R \geq m-1$. □

Proof of the statement. Identify $\mathbb{R}^2$ with $\mathbb{C}$ by $(u, v) \mapsto u + iv$, and set

$$P(z) = f(z) + i\,g(z) \in \mathbb{C}[z].$$

Writing $f(z) = \sum_j f_j z^j$ and $g(z) = \sum_j g_j z^j$ with $f_j, g_j \in \mathbb{R}$, the coefficient of z^j in P is $f_j + ig_j$, which vanishes if and only if $f_j = g_j = 0$. Hence

$$\deg P = \max(\deg f, \deg g),$$

and it suffices to prove $\deg P \geq n-1$.

Let $v_k = P(k) = f(k) + ig(k)$ for $k = 1, \ldots, n$. By hypothesis $v_1, \ldots, v_n$ are the vertices of a regular n-gon listed in counterclockwise order. Let b be its centre and $r > 0$ its circumradius. The vertices of a regular n-gon lie on the circle of radius r about b at arguments forming an arithmetic progression of common difference $2\pi/n$, and listing them counterclockwise starting from v_1 means exactly that

$$v_k = b + re^{i(\theta_0 + 2\pi k/n)} = b + a\omega^k, \qquad a = re^{i\theta_0} \neq 0, \quad \omega = e^{2\pi i/n},$$

for $k = 1, \ldots, n$. Now set

$$Q(z) = \frac{P(z) - b}{a},$$

which is a polynomial with $\deg Q = \deg P$, since $a \neq 0$ and subtracting a constant cannot change the degree of a nonconstant polynomial and cannot lower a constant one below 0. By construction $Q(k) = \omega^k$ for $k = 1, \ldots, n$.

Since $n \geq 3$ we have $\omega \neq 1$, and $|\omega| = 1$ gives $\omega \neq 0$. Applying the Lemma with $t = \omega$ and $m = n$ yields $\deg Q \geq n - 1$. Therefore

$$\max(\deg f, \deg g) = \deg P = \deg Q \geq n - 1,$$

so at least one of f and g has degree at least $n - 1$. ■

Remark 18.5.2. The bound is sharp, and the same machinery says so. The unique polynomial Q of degree at most $n - 1$ with $Q(k) = \omega^k$ for $k = 1, \ldots, n$ has leading coefficient $\Delta^{n-1}Q(1)/(n-1)! = \omega(\omega - 1)^{n-1}/(n-1)!$, which is nonzero, so $\deg Q = n - 1$ exactly; its real and imaginary parts give f and g of degree at most $n - 1$ that do trace out a regular n-gon. So $n - 1$ is attained and cannot be improved.

Remark 18.5.3. Counterclockwise is used only to force the labels to run consecutively around the polygon, giving ω^k rather than $\omega^{\sigma(k)}$ for some permutation σ. If the order were clockwise, the same proof runs with $t = \omega^{-1}$, which is also neither 0 nor 1. If the labelling were an arbitrary permutation of the vertices the statement would be false in this form, which is precisely why that hypothesis is in the question.

Layer 1: WHAT

Block 1. Package the two real polynomials as one complex polynomial $P = f + ig$, and record that $\deg P = \max(\deg f, \deg g)$ exactly.

Block 2. Write the regular n-gon in counterclockwise order as $v_k = a\omega^k + b$, and normalise it away: $Q = (P - b)/a$ has the same degree and satisfies $Q(k) = \omega^k$.

Block 3. Apply the operator $Q \mapsto Q(z + 1) - \omega Q(z)$. Because $\omega \neq 1$ the leading coefficient survives, so the degree is unchanged.

Block 4. The new polynomial vanishes at $1, \ldots, n - 1$ by construction. Nonzero polynomial, $n - 1$ distinct roots, so degree at least $n - 1$. Push that back through Blocks 3, 2 and 1.

Juxtaposition. The nominal route keeps everything real: it writes $f(k) = \alpha + r\cos(\theta_0 + 2\pi k/n)$, tries to interpolate, and reaches for trigonometric identities to force a degree bound. It typically dies at the point where "regular n-gon" has to be turned into equations, because in coordinates that condition is a system, not a formula.

The bifurcation point is the sentence "the points are the vertices of a regular n-gon". Ideal: write $a\omega^k + b$. Zombie: write cos and sin. Everything after that is determined by which of those two lines you put on the page.

Layer 2: HOW

Block 1. Cue. Two real polynomials, sampled at the same integers, with a condition on the resulting planar points. **Why natural.** A pair of real numbers with geometric meaning is a complex number, and the plane's similarity structure is invisible in coordinates but algebraic in $\mathbb{C}$. The move costs nothing, because the degree bookkeeping is exact: $f_j + ig_j = 0$ with f_j, g_j real forces $f_j = g_j = 0$, so no cancellation between f and g can occur and $\deg P = \max(\deg f, \deg g)$. Note that the conclusion you want, "at least one of f, g has degree at least $n - 1$", is literally the statement $\max(\deg f, \deg g) \geq n - 1$, so the packaging is not just convenient, it is the exact shape of the target. **Link to the next block.** Now the hypothesis has to be written in $\mathbb{C}$, which is where the regular n-gon becomes a formula.

Block 2. **Cue.** "Regular n-gon", "counterclockwise order", and the index k running over consecutive integers. **Why natural.** A regular n-gon is by definition the orbit of one vertex under rotation by $2\pi/n$ about the centre. In $\mathbb{C}$, rotation by $2\pi/n$ about b is $z \mapsto b + \omega(z - b)$, so the orbit is $b + a\omega^k$. Counterclockwise order is exactly the statement that consecutive labels are consecutive under that rotation, so k appears in the exponent unpermuted. The normalisation $Q = (P - b)/a$ is then forced: the maps $z \mapsto az + b$ with $a \neq 0$ are precisely the orientation preserving similarities of the plane, they form a group, and none of them changes the degree of a polynomial. Normalising by a group that preserves the quantity you are measuring is always free. **Link to the next block.** The hypothesis is now the cleanest possible statement: a polynomial takes geometric values at consecutive integers.

Block 3. **Cue.** $Q(k) = \omega^k$ is a geometric sequence in k, and geometric sequences are eigenvectors of the shift. **Why natural.** On sequences, let E be the shift $(Eu)_k = u_{k+1}$. Then $Et^k = t \cdot t^k$, so $(E - tI)$ annihilates the geometric sequence exactly. On polynomials, E acts as $Q(z) \mapsto Q(z + 1)$, which preserves both degree and leading coefficient, so $E - tI$ multiplies the leading coefficient by $(1 - t)$. The single hypothesis $t \neq 1$ is what keeps that factor alive. This is the whole reason the argument works. Note also what the hypothesis $n \geq 3$ is and is not doing: $\omega \neq 1$ already holds for $n \geq 2$, so $n \geq 3$ is present only so that the word polygon means something. **Link to the next block.** You have a polynomial of the same degree as Q which vanishes wherever the geometric relation held.

Block 4. **Cue.** The target $n - 1$ is one less than the number of data points, and you now have a polynomial forced to vanish at $n - 1$ points. **Why natural.** The only elementary mechanism that bounds a degree from below is root counting: a nonzero polynomial of degree d has at most d distinct roots. So to prove "degree at least N" you manufacture a nonzero polynomial of that degree with N distinct roots. The differencing did the manufacturing: each of the $n - 1$ overlapping consecutive pairs $(k, k + 1)$ inside $\{1, \ldots, n\}$ produces one root. Counting the pairs is why the answer is $n - 1$ and not n. **Link to the next block.** Degrees were preserved at every stage, so the bound transfers straight back to $\max(\deg f, \deg g)$.

Layer 3: WHY

The mathematics underneath is the theory of linear recurrences, viewed as linear algebra on the space of sequences. Let E be the shift operator. Then:

1. The geometric sequence $u_k = t^k$ spans the eigenspace $\ker(E - tI)$.
2. The sequences $u_k = Q(k)$ with $\deg Q \leq d$ are exactly $\ker(E - I)^{d+1}$, that is, the generalised eigenspace at eigenvalue 1 of nilpotency degree $d + 1$. This is the operator form of the familiar fact that the $(d + 1)$st finite difference of a degree d polynomial vanishes.

So a polynomial sequence and a geometric sequence with ratio $t \neq 1$ live in generalised eigenspaces for different eigenvalues. They are transverse. They cannot be equal as sequences at all, and the quantitative form of that transversality is exactly this problem: they can agree on at most $d + 1$ consecutive terms, where d is the degree. Read the Lemma again with that in mind and it stops being an argument and becomes an accounting identity.

The discernment mechanism to install is this. When a problem gives you the values of a polynomial at consecutive integers, stop thinking of the polynomial as a function on $\mathbb{R}$ and start thinking of the sequence $u_k = P(k)$ together with the operators that act on it. Continuous tools (derivatives, calculus, curve sketching) are the wrong toolkit for data on a lattice; the shift and the difference are the right ones. The practical rule: whenever the data are of the form (polynomial) = (something with a multiplicative structure in k), hit both sides with $E - tI$ where t is the multiplier, and see what dies.

How to train it: memorise the dictionary in both directions. "Degree at most d" is "$\Delta^{d+1} \equiv 0$". "Geometric with ratio t" is "$(E - tI) \equiv 0$". "Polynomial of degree d times t^k" is "$(E - tI)^{d+1} \equiv 0$".

Then any hypothesis mixing polynomials and exponentials on the integers becomes a statement about which operator to apply first.

What the examiners nudged toward, and how: they chose a regular n-gon, which is the only common plane figure whose vertex set is literally a geometric sequence in $\mathbb{C}$. They said "counter-clockwise order" so that the exponent is k and not a permutation of k. They asked for $n-1$, one fewer than the number of points, which is the signature of a single differencing step, and they wrote the conclusion as "at least one of f and g", which is $\max(\deg f, \deg g)$, the exact invariant preserved by the complex packaging. Every hypothesis in the statement is a guiding light toward $P = f + ig$.

Revolving concepts

Complex packaging of a pair of real polynomials. If $f, g \in \mathbb{R}[z]$ then $P = f + ig \in \mathbb{C}[z]$ has $\deg P = \max(\deg f, \deg g)$, and $f = \frac{1}{2}(P + \bar{P})$, $g = \frac{1}{2i}(P - \bar{P})$ where $\bar{P}$ is the polynomial with conjugated coefficients. The packaging is a bijection between pairs of real polynomials and complex polynomials, and it preserves degree. See Book 1, field: Complex numbers, topic: complex form of planar conditions.

Roots of unity and regular polygons. $\omega = e^{2\pi i/n}$ satisfies $\omega^n = 1$ and $1 + \omega + \cdots + \omega^{n-1} = 0$ for $n \geq 2$; the vertices of the regular n-gon with centre b are $b + a\omega^k$, and the centroid of the vertices is b. The orientation preserving similarities of the plane are exactly $z \mapsto az + b$ with $a \neq 0$; the orientation reversing ones are $z \mapsto a\bar{z} + b$. See Book 1, field: Complex numbers, topic: roots of unity and plane transformations.

Finite difference calculus. $\Delta Q(z) = Q(z+1) - Q(z)$ lowers degree by exactly one and multiplies the leading coefficient by d; hence $\Delta^d Q$ is the constant $d!\,c$ for $\deg Q = d$ with leading coefficient c, and $\Delta^{d+1} Q \equiv 0$. The explicit expansion is $\Delta^p Q(x) = \sum_{i=0}^{p} (-1)^{p-i} \binom{p}{i} Q(x+i)$, so the leading coefficient of the interpolant through $p+1$ consecutive values is $\Delta^p Q(x_0)/p!$. See Book 1, field: Polynomials, topic: finite differences and Newton interpolation.

The generalised recursion. A sequence (u_k) satisfies a linear recurrence with constant coefficients and characteristic polynomial $\prod_i (x - \lambda_i)^{m_i}$ if and only if $u_k = \sum_i p_i(k) \lambda_i^k$ with $\deg p_i < m_i$. In operator form the solution space is $\ker \prod_i (E - \lambda_i I)^{m_i}$. Two consequences used here: polynomials of degree at most d are the case of the single root $\lambda = 1$ with multiplicity $d+1$, and geometric sequences are the case of a simple root $\lambda = t$. Since the generalised eigenspaces for distinct λ intersect trivially, a nonzero polynomial sequence is never geometric, and the finite version of that statement is the Lemma above. The same operator factorisation is the standard method for solving any linear recurrence, including the repeated-root case that A-level Further Maths handles only for order two. See Book 1, field: Sequences and recurrences, topic: linear recurrences and the shift operator.

Root counting. A nonzero polynomial over a field has at most deg distinct roots; equivalently, a polynomial of degree at most $N-1$ vanishing at N distinct points is identically zero. This is the only elementary source of lower bounds on degree. See Book 1, field: Polynomials, topic: factor theorem and root bounds.

Circuit Bank

- **WHEN** a pair of real polynomials is sampled at the same points and the pairs are read as points of the plane **DO** set $P = f + ig$ and record $\deg P = \max(\deg f, \deg g)$ **BECAUSE** planar similarity and rotation conditions are one-line algebra in $\mathbb{C}$ and a coupled system in coordinates, and the degree bookkeeping across the packaging is exact
- **WHEN** a regular n-gon appears with its vertices labelled in cyclic order **DO** write the vertices as $a\omega^k + b$ with $\omega = e^{2\pi i/n}$, then normalise to ω^k **BECAUSE** a regular polygon is by definition a rotation orbit, and $z \mapsto az + b$ with $a \neq 0$ is the full orientation preserving similarity group, which changes no degree

- **WHEN** a polynomial agrees with a geometric sequence t^k at consecutive integers **DO** apply $E - tI$, that is form $P(z+1) - tP(z)$ **BECAUSE** the operator annihilates the geometric part while preserving degree exactly when $t \neq 1$, so it converts data into roots for free
- **WHEN** you must bound a degree from below **DO** manufacture a nonzero polynomial of that same degree with many distinct roots **BECAUSE** root counting is the only elementary lower bound mechanism for degree, so every such proof is secretly a root count
- **WHEN** a hypothesis fixes an ordering or an orientation and you have not used it **DO** find the step where it removes a permutation or a sign ambiguity, and say so **BECAUSE** unused hypotheses on the Putnam are almost always load bearing, and here counterclockwise is what makes the exponent k rather than $\sigma(k)$

Backtesting

1. First useful cue: two real polynomials sampled at 1 to n with a planar condition on the pairs, which is the standing order to form $f + ig$.
2. Method the expression suggested: normalise the polygon to the roots of unity by an affine complex map, then annihilate the geometric sequence with the shift operator and count the roots that appear.
3. Where you would hesitate, and the thought to reinforce: at the claim $\deg P = \max(\deg f, \deg g)$. Reinforce it with the reason, that $f_j + ig_j = 0$ with both real forces both to vanish, so real and imaginary parts cannot cancel each other's leading terms. Without that line the packaging is not justified.
4. The trap the question sets: the invitation to expand in cos and sin, and the softer trap of forgetting to check $\deg R = \deg Q$ exactly. If you only claim $\deg R \leq \deg Q$, the root count gives nothing.
5. What makes you recognise it faster next time: the number $n - 1$ sitting one below the number of data points. That gap of exactly one is the signature of a single differencing step, just as a gap of two would signal a second difference.
6. The reusable decision rule: polynomial data on consecutive integers means work with the shift operator, not with calculus; and to bound a degree below, build roots.

Mirror drills

1. Show that no polynomial P of degree at most 8 satisfies $P(k) = 2^k$ for $k = 1, \ldots, 10$. *Answer:* $R(z) = P(z+1) - 2P(z)$ has the same degree as P, since the leading coefficient is multiplied by $1 - 2 = -1$, and vanishes at $1, \ldots, 9$, so $\deg P \geq 9$.
2. Compute the leading coefficient of the unique polynomial Q of degree at most $n - 1$ with $Q(k) = \omega^k$ for $k = 1, \ldots, n$, and deduce that the bound $n - 1$ in the problem is attained. *Answer:* $\Delta^{n-1}Q(1) = \sum_{i=0}^{n-1}(-1)^{n-1-i}\binom{n-1}{i}\omega^{1+i} = \omega(\omega-1)^{n-1} \neq 0$, so the leading coefficient is $\omega(\omega-1)^{n-1}/(n-1)!$ and the degree is exactly $n - 1$.
3. Suppose instead the points $(f(k), g(k))$ are the vertices of a regular n-gon listed in clockwise order. Does the conclusion change, and where exactly does the proof notice the difference? *Answer:* no change. You get $t = \omega^{-1}$, and the proof used only $t \neq 0$ and $t \neq 1$; the orientation enters solely in the identification of t.

18.6 A6. Producing every group element from a short sequence

Prove that there exists a constant $c > 0$ such that in every nontrivial finite group G there exists a sequence of length at most $c \log |G|$ with the property that each element of G equals the product of some subsequence. (The elements of G in the sequence are not required to be distinct. A subsequence *of a sequence is obtained by selecting some of the terms, not necessarily consecutive, without reordering them; for example, $4, 4, 2$ is a subsequence of $2, 4, 6, 4, 2$, but $2, 2, 4$ is not.)*

Read it out loud

Before any group theory, state the combinatorial shape. You are given a target set of size $n = |G|$. You must build an ordered list of length ℓ, and the objects you are allowed to hit the target with are the products of its subsequences, taken in the order they appear in the list. A list of length ℓ has exactly 2^ℓ subsequences, so it produces at most 2^ℓ elements, and therefore $\ell \geq \log_2 n$ is forced, always, for every group and every list. The problem asks for $\ell \leq c \log n$.

Stop and register what that means, because it is the single most important reading of this problem. You are being asked to come within a constant factor of an information theoretic bound that you can prove in one line. That is a very strong hint about the shape of the construction: if the counting bound is tight up to a constant, then a construction must gain a constant factor of the target per term. A constant factor per term means *doubling*. So before you know a single fact about G, you know the plan: find a way to append one element to a list and double the set of producible elements.

The fields wired in are finite group theory (cosets and the fact that right multiplication is a bijection), extremal and greedy combinatorics (grow an object until an obstruction appears), and a light touch of counting. The word "nontrivial" is not decoration: for the trivial group $\log |G| = 0$ and no positive length is allowed, so the hypothesis is there to make the statement true rather than to make the proof easier.

The first cue is the phrase "product of some subsequence". Interrogate the operation. If S is a list with producible set H, and you append one new element g at the *end*, then a subsequence of the new list either omits g, giving a product in H, or uses g, and then g is its last factor, so the product is hg for some $h \in H$. Hence the new producible set is exactly $H \cup Hg$. Within thirty seconds you should have on your page: $2^\ell \geq n$, the update rule $H \mapsto H \cup Hg$, and the observation that $|Hg| = |H|$ always, so doubling happens precisely when $H \cap Hg = \varnothing$.

Approaches, ranked worst to best

1. **Take a small generating set and multiply.** *Cue:* the elements of G are products of generators. *Circuit:* generation. Last. Every finite group has a generating set of size at most $\log_2 n$, so the size is right, but generation is the wrong notion here. A subsequence uses each term at most once and in the given order, so a list of k distinct generators produces at most 2^k elements, and there is no way to write a long word in the generators. To recover words you would have to repeat each generator many times, and the length blows up to something like n. Recognising within ten seconds that generation is not the operative notion is the whole value of this approach.

2. **Induct on a chain of subgroups with cyclic quotients.** *Cue:* finite groups are built from smaller ones. *Circuit:* induction on the index. If $H \trianglelefteq G$ with G/H cyclic of order p generated by the image of x, take a good list for H and append $x, x^2, x^4, \ldots, x^{2^s}$ with $2^{s+1} > p$. Subsequence products of the appended block give x^j for every $0 \leq j < p$, so the whole list produces Hx^j for all j, that is all of G, at a cost of $\lceil \log_2 p \rceil$ extra terms. Clean, and it even gives c close to 1. It fails in general: chief factors need not be cyclic, and a nonabelian simple group has no proper

normal subgroup at all. So this route settles the solvable case and stalls. Know it, do not bet the paper on it.

3. **Average over g and pigeonhole.** *Cue:* you want a good g, so compute the average of $|H \cup Hg|$. *Circuit:* double counting plus pigeonhole. Correct and quantitatively finer. Double counting gives $\sum_{g \in G} |H \cup Hg| = 2mn - m^2$ where $m = |H|$, so some g achieves $|H \cup Hg| \geq 2m - m^2/n$. In terms of the deficiency $s = 1 - m/n$ this is the recursion $s \mapsto s^2$, which reaches $s < 1/n$ after about $2 \log_2 n$ steps and gives length $\log_2 n + \log_2 \log n$, essentially optimal. It ranks below the next route only because it costs a double counting identity plus a page of inequality management, when exact doubling is available for free.

4. **Greedy exact doubling, then mirror the list.** *Cue:* doubling is exactly available while $H^{-1}H \neq G$. *Circuit:* grow until an obstruction appears, then exploit the obstruction. Best. Append any $g \notin H^{-1}H$ and the producible set doubles exactly. The greedy can only run $\log_2 n$ times, so it stops, and it stops precisely when $H^{-1}H = G$, which is exactly the hypothesis needed to finish. No inequalities, no averaging, no constants to chase.

The ideal solution

Throughout, G is a finite group with identity e and $n = |G| \geq 2$. For a finite sequence $S = (a_1, \ldots, a_k)$ of elements of G, say that S *produces* h if

$$h = a_{i_1} a_{i_2} \cdots a_{i_r} \quad \text{for some } 1 \leq i_1 < i_2 < \cdots < i_r \leq k,$$

and write $H(S)$ for the set of elements produced by S. We allow $r = 0$ inside the construction, with the empty product equal to e; the final sequence will produce every element by a nonempty subsequence, so this convention costs nothing and we check that explicitly at the end.

Lemma 18.6.1 (Update rule)**.** *If $S' = (a_1, \ldots, a_k, g)$ is S with g appended at the end, then $H(S') = H(S) \cup H(S)g$.*

Proof. A subsequence of S' either omits the last term, in which case it is a subsequence of S and its product lies in $H(S)$, or it includes the last term, in which case g is its final factor and its product is hg with $h \in H(S)$. Both types occur, so the produced set is exactly $H(S) \cup H(S)g$. □

Lemma 18.6.2 (Doubling criterion)**.** *Let $H \subseteq G$ be nonempty and $g \in G$. Then $H \cap Hg = \varnothing$ if and only if $g \notin H^{-1}H$, where $H^{-1}H = \{h_1^{-1}h_2 : h_1, h_2 \in H\}$. In that case $|H \cup Hg| = 2|H|$.*

Proof. $H \cap Hg \neq \varnothing$ means $h_1 g = h_2$ for some $h_1, h_2 \in H$, that is $g = h_1^{-1}h_2 \in H^{-1}H$; the two statements are contrapositives of each other. Right multiplication by g is a bijection of G, so $|Hg| = |H|$, and disjointness gives $|H \cup Hg| = 2|H|$. □

The greedy construction. Start with S_0 the empty sequence, so $H_0 = H(S_0) = \{e\}$ and $|H_0| = 1$. Given S_j with $H_j = H(S_j)$, if $H_j^{-1}H_j \neq G$ choose any $a_{j+1} \in G \setminus H_j^{-1}H_j$ and let $S_{j+1} = (a_1, \ldots, a_{j+1})$. By the two Lemmas, $H_{j+1} = H_j \cup H_j a_{j+1}$ and $|H_{j+1}| = 2|H_j|$.

By induction $|H_j| = 2^j$. Since $H_j \subseteq G$ we have $2^j \leq n$, so the process cannot run more than $\log_2 n$ times. Therefore it halts: there is an index $k \leq \log_2 n$ with

$$S = (a_1, \ldots, a_k), \qquad H = H(S), \qquad |H| = 2^k, \qquad H^{-1}H = G.$$

Note $k \geq 1$, because $H_0^{-1}H_0 = \{e\} \neq G$ as $n \geq 2$.

The mirrored sequence. Define the sequence of length $2k$

$$T = \left(a_k^{-1},\, a_{k-1}^{-1},\, \ldots,\, a_1^{-1},\, a_1,\, a_2,\, \ldots,\, a_k\right).$$

Claim 18.6.3. *T produces every element of G, and by a nonempty subsequence.*

Proof. Let $g \in G$. Since $H^{-1}H = G$ there are $h_1, h_2 \in H$ with $g = h_1^{-1}h_2$. Write

$$h_1 = a_{i_1}a_{i_2}\cdots a_{i_r}, \qquad i_1 < i_2 < \cdots < i_r,$$

which is possible since $h_1 \in H = H(S)$, and similarly $h_2 = a_{j_1}\cdots a_{j_s}$ with $j_1 < \cdots < j_s$. Inverting reverses the order of the factors:

$$h_1^{-1} = a_{i_r}^{-1}a_{i_{r-1}}^{-1}\cdots a_{i_1}^{-1}.$$

The first half of T lists $a_k^{-1}, a_{k-1}^{-1}, \ldots, a_1^{-1}$, that is, the inverses in *decreasing* index order. The factors of h_1^{-1} appear in exactly that order, since $i_r > i_{r-1} > \cdots > i_1$. So h_1^{-1} is the product of a subsequence of the first half of T, read left to right. Likewise h_2 is the product of a subsequence of the second half of T, read left to right, since $j_1 < \cdots < j_s$. Concatenating a subsequence of the first half with a subsequence of the second half is a subsequence of T, and its product is $h_1^{-1}h_2 = g$.

For the nonemptiness: if $g \neq e$ then $h_1 \neq h_2$, so at least one of h_1, h_2 differs from e and the corresponding selection is nonempty. If $g = e$, take instead $h_1 = h_2 = a_1$, which is legitimate since $a_1 \in H$ and $k \geq 1$; then $g = a_1^{-1}a_1$ is the product of the two term subsequence (a_1^{-1}, a_1) of T, the first term coming from the first half and the second from the second half. □

The length. T has length $2k \leq 2\log_2 n = \dfrac{2}{\ln 2}\ln n$. Hence

$$\boxed{c = \frac{2}{\ln 2} < 2.886 \text{ works for the natural logarithm, and } c = 2 \text{ for } \log_2.}$$

Since $n \geq 2$ we have $\log n > 0$, so the bound is a genuine positive length constraint, and the proof is complete. ■

Remark 18.6.4. The construction is within a factor 2 of optimal, and the counting bound of the opening paragraph proves it: a sequence of length ℓ has 2^ℓ subsequences, so producing all n elements forces $\ell \geq \log_2 n$. For $G = (\mathbb{Z}/2\mathbb{Z})^d$ the list of d standard basis vectors attains $\ell = \log_2 |G|$ exactly, so no $c < 1$ can work.

Layer 1: WHAT

Block 1. Count first: $2^\ell \geq n$, so $\ell \geq \log_2 n$ always. Target is $c \log n$, so the construction must gain a constant factor per term, that is, it must double.

Block 2. Find the update rule. Appending g at the end sends the producible set H to $H \cup Hg$, exactly.

Block 3. Find the exact condition for doubling: $|Hg| = |H|$ always, so doubling happens if and only if $H \cap Hg = \varnothing$, if and only if $g \notin H^{-1}H$.

Block 4. Run the greedy. It doubles $|H|$ each step and $|H| \leq n$, so it stops after at most $\log_2 n$ steps.

Block 5. Read the stopping condition, which is $H^{-1}H = G$, and recognise it as a gift rather than a failure: every g is now $h_1^{-1}h_2$.

Block 6. Realise $h_1^{-1}h_2$ as an ordered subsequence product by mirroring: reversed inverses, then the originals. Length $2k \leq 2\log_2 n$.

Juxtaposition. The nominal route asks "which elements should I put in the list?" and starts hunting for clever choices, structure theorems, or special cases (abelian first, then p-groups, then hope). It treats the problem as a search. The ideal route asks "what does appending one element do to the reachable set?" and treats the problem as an operator: it computes the update rule first and only then asks which g makes the update efficient. The choice of g then requires no cleverness at all, because any g outside $H^{-1}H$ works and the only question is whether such a g exists.

The bifurcation point is the very first move after reading the definition of subsequence product: compute $H(S$ with g appended$)$, or start choosing elements. Everything follows from that.

Layer 2: HOW

Block 1. **Cue.** A bound of the form $c \log |G|$, with c unspecified and log of unspecified base. Unspecified constant and base means the problem only cares about the order of magnitude. **Why natural.** Whenever the target is a logarithm of the size of the object, compute the trivial counting bound immediately, because a logarithm is exactly what a counting bound produces. Here a list of length ℓ has 2^ℓ subsequences, so $2^\ell \geq n$. The fact that the requested bound matches this lower bound up to a constant is the design of the problem speaking to you: it tells you no waste is permitted, so the construction must be exponentially efficient, so each term must multiply the reachable set by a constant factor. **Link to the next block.** Knowing you need doubling, the next question is forced: what exactly does one term buy?

Block 2. **Cue.** The definition of subsequence is spelled out at unusual length in the statement, with an explicit example distinguishing $4, 4, 2$ from $2, 2, 4$. When a problem defines its operation that carefully, the operation is the subject. **Why natural.** Order matters and each term is used at most once, so the only structural handle is the last term. Splitting the subsequences of S' by whether they use the last term is the unique decomposition that respects the order constraint, and it gives $H \cup Hg$ with no error terms. Getting an exact equality rather than an inclusion here is what makes the rest of the proof clean. **Link to the next block.** Now the question is purely about the size of $H \cup Hg$, which is a question about H and its translates.

Block 3. **Cue.** A union of a set and a translate, inside a group. **Why natural.** In a group, right multiplication by g is a bijection, so $|Hg| = |H|$ exactly; there is no loss. That single fact is why doubling is even conceivable, and it is the reason the problem is set in a group rather than in a monoid. Therefore $|H \cup Hg| = 2|H|$ if and only if H and Hg are disjoint, and unwinding the definition of disjointness gives the clean criterion $g \notin H^{-1}H$. Notice that you did not go looking for the set $H^{-1}H$; it was produced by asking when the update is efficient. This is the standard way the right object appears in a proof: not by inspiration, but by solving for the condition you need. **Link to the next block.** You have a criterion, so run it greedily until it fails.

Block 4. **Cue.** An operation that multiplies a bounded quantity by a fixed factor greater than 1. **Why natural.** Such a process must terminate, and the number of steps is the logarithm of the cap to the base of the factor. Here $|H_j| = 2^j \leq n$ gives $j \leq \log_2 n$ with no further work. Note the direction of the argument: you are not proving the greedy achieves something, you are proving it *cannot continue*, and it is the failure that you will harvest. **Link to the next block.** Termination means the criterion failed, so write down what failure says.

Block 5. **Cue.** The negation of "there exists $g \notin H^{-1}H$" is "$H^{-1}H = G$". **Why natural.** This is the quantum leap of the problem, and it is not a leap at all once you write both statements down side by side. The greedy was designed to fail, because its failure condition is a strong structural statement: every element of G factors as $h_1^{-1}h_2$ with both factors producible. In other words S does not produce all of G, but S together with the inverses of its products does. A greedy whose stopping condition is exactly the hypothesis you need is the standard architecture of extremal arguments; train yourself to ask, before running any greedy, what its failure would give you. **Link to the next block.** You need $h_1^{-1}h_2$ to be an ordered subsequence product, so build a list in which it is.

Block 6. **Cue.** Inversion reverses order: $(a_{i_1} \cdots a_{i_r})^{-1} = a_{i_r}^{-1} \cdots a_{i_1}^{-1}$. **Why natural.** The obstruction is the ordering rule, and the reversal identity is exactly the tool that matches it. If you lay the inverses down in decreasing index order, then any product h_1^{-1} reads off left to right in the order the reversal identity demands. Put the original list after it and h_2 reads off in its own natural

order. The concatenation of a subsequence of the first half with a subsequence of the second half is automatically a valid subsequence of the whole, since every position in the first half precedes every position in the second. The price is a factor of 2 in the length, which the problem's unspecified c has already told you is affordable. **Link to the next block.** Count: length $2k \leq 2\log_2 n$, and the constant is exhibited.

Layer 3: WHY

Three mathematical truths carry this proof, and each is worth extracting on its own.

The first is that in a group, translation is a bijection. $|Hg| = |H|$ for every subset H and every g: this is the reason a group is the right setting and the reason exact doubling is possible. In a monoid or a semigroup, Hg can collapse and the entire argument dies. Whenever you see a counting argument in a group, look for the place where translation invariance of cardinality is being used; it is almost always the load bearing step, and it is the same fact behind Lagrange's theorem, behind the orbit stabiliser theorem, and behind the pigeonhole step in the alternative averaging solution.

The second is the dichotomy attached to the difference set $H^{-1}H$. Either $H^{-1}H \neq G$, in which case H can be grown by a full factor of 2, or $H^{-1}H = G$, in which case H already covers G in the two sided sense. There is no middle case. This is the finite group analogue of the sumset dichotomy in additive combinatorics: a set either has small doubling, in which case it is structured, or it grows. Modern results on growth in groups, associated with Helfgott, Bourgain and Tao among others, are built on exactly this dichotomy in quantitative form, and the alternative averaging solution is a baby version of the same technology.

The third is the counting bound $2^\ell \geq n$. It is not a side remark; it is the design document of the problem. When a construction is requested at the scale of the counting bound, the construction is essentially forced to be a doubling process, because anything slower cannot reach n in $O(\log n)$ steps. Reading the target bound backwards to infer the mechanism is the single most transferable habit in this problem.

The discernment mechanism to train is the greedy design protocol. (1) Define the object you are growing and the quantity you are measuring. (2) Compute the exact update rule for one step, as an equality if possible. (3) Solve for the condition under which the update is maximally efficient. (4) Run the greedy while that condition holds, and bound the number of steps by the growth factor. (5) Write down what the failure of the condition says, and expect it to be the second half of the proof. Steps (3) and (5) are where the mathematics happens, and both are mechanical once you commit to writing exact conditions rather than searching for good choices.

What the examiners nudged toward: they defined subsequence at length, with an example, which tells you the ordering constraint is a real obstruction and must be addressed explicitly; that is the mirror. They left c and the base of the logarithm unspecified, which tells you constant factors are free; that is the licence to double the length. They said nontrivial, which is exactly the case $n = 1$ where $\log |G| = 0$ would make the statement false. Every clause is a guiding light.

Knowledge gaps to install before this problem is approachable

Be honest about this one, because it is an A6 and the entry cost is real. Nothing here is beyond A-level in difficulty, but the following are beyond A-level in content, and without them the problem is not merely hard, it is unreadable.

1. **Groups, subgroups, cosets.** A group is a set with an associative operation, an identity, and inverses. For a subset H and an element g, the right translate is $Hg = \{hg : h \in H\}$. Translation is a bijection of G, so $|Hg| = |H|$. If H is a subgroup, the translates are the right cosets, they partition G, and Lagrange's theorem follows: $|H|$ divides $|G|$. This problem uses the translate fact for arbitrary subsets, not just subgroups, which is a distinction worth noticing.

2. **Inversion reverses products.** $(xy)^{-1} = y^{-1}x^{-1}$, extended to $(x_1 \cdots x_r)^{-1} = x_r^{-1} \cdots x_1^{-1}$. This is the entire content of the mirror step.
3. **Product and difference sets.** For subsets $A, B \subseteq G$, $AB = \{ab\}$ and $A^{-1} = \{a^{-1}\}$. The set $H^{-1}H$ is the group analogue of a difference set. No structure theorem is needed, only the definitions.
4. **Normal subgroups, quotients and solvability**, if you want to understand why the induction route in the rankings fails in general. Not needed for the ideal solution.

Revolving concepts

Translation invariance and Lagrange. For any $H \subseteq G$ and $g \in G$, $|Hg| = |gH| = |H|$. For a subgroup H, cosets partition G and $|G| = [G : H]\,|H|$. See Book 1, field: Abstract algebra, topic: cosets and Lagrange's theorem.

The producible set and its update rule. For a sequence S over G, $H(S)$ is the set of ordered subsequence products. Appending g gives $H(S) \cup H(S)g$; prepending g gives $H(S) \cup gH(S)$. Both are exact equalities, and choosing which end to append to is a genuine design decision in problems of this type. See Book 1, field: Combinatorics, topic: subset sums and subsequence products.

Subset sums, the abelian shadow. In $(\mathbb{Z}/2\mathbb{Z})^d$ the same question is "find a short list of vectors whose subset sums cover the space", answered by any basis, with length exactly $\log_2 |G|$. In $\mathbb{Z}/n\mathbb{Z}$ the answer is the binary list $1, 2, 4, \ldots$, of length $\lceil \log_2 n \rceil$. Both are the abelian intuition that the general construction imitates. See Book 1, field: Combinatorics, topic: binary representation and covering by subset sums.

The generalised recursion. Two recursions appear, and both are worth stating in general form. The first is $m_{j+1} = 2m_j$ with cap n, giving $m_j = 2^j$ and stopping time $\log_2 n$; in general a greedy that multiplies a capped quantity by a fixed $\lambda > 1$ per step runs for at most $\log_\lambda(\text{cap}/m_0)$ steps, and this is the standard way to bound any doubling process. The second appears in the averaging solution: the deficiency $s_j = 1 - m_j/n$ obeys $s_{j+1} \leq s_j^2$, whose solution is $s_j \leq s_0^{2^j}$, doubly exponential decay, so $j \approx \log_2 \log_{1/s_0}(1/\varepsilon)$ steps suffice; this is the same recursion that governs Newton's method and repeated squaring, and recognising it saves you from trying to solve it by hand. See Book 1, field: Sequences and recurrences, topic: multiplicative and quadratic recursions.

Growth in groups. The dichotomy "either $H^{-1}H \neq G$ and H grows, or $H^{-1}H = G$" is the elementary ancestor of small doubling and small tripling results. See Book 1, field: Combinatorics, topic: growth and product sets in groups.

Circuit Bank

- **WHEN** a bound of the form $c \log |X|$ is requested with c and the base unspecified **DO** compute the counting lower bound first and compare **BECAUSE** if the target matches the counting bound up to a constant, the construction is forced to gain a constant factor per step, which means a doubling process and nothing slower
- **WHEN** you are building a set greedily **DO** write the exact update rule for one step before choosing anything, then solve for the condition under which the update is maximally efficient **BECAUSE** the right auxiliary object, here $H^{-1}H$, is produced by solving for the condition, not by inspiration, and an exact update rule costs nothing while an inclusion costs the whole proof
- **WHEN** a greedy process must terminate because a quantity is capped **DO** write down the negation of the continuation condition and expect it to be the hypothesis you need next **BECAUSE** extremal arguments are architected so that the failure of the growth step is itself a strong structural statement, so the stopping condition is the second half of the proof rather than an obstacle

- **WHEN** an ordering constraint stops you writing $x^{-1}y$ as an admissible product **DO** lay the inverses down in reverse order first and the originals afterwards **BECAUSE** inversion reverses products term by term, so a decreasing selection in the mirrored half is legal, and the cost is only a factor of two in length
- **WHEN** a counting argument takes place inside a group **DO** look for the step that uses $|Hg| = |H|$ and name it **BECAUSE** translation invariance of cardinality is almost always the load bearing fact, and the same argument in a monoid or semigroup would collapse

Backtesting

1. First useful cue: the requested bound is $c \log |G|$ and a length ℓ list has 2^ℓ subsequences, so the answer must be a doubling construction.
2. Method the expression suggested: compute the exact effect of appending one element, $H \mapsto H \cup Hg$; solve for exact doubling, $g \notin H^{-1}H$; greedy until it fails; harvest the failure $H^{-1}H = G$ with a mirrored list.
3. Where you would hesitate, and the thought to reinforce: at the moment the greedy stops, which feels like a dead end. Reinforce it with the protocol: a greedy is designed to fail, and its failure condition is the gift. Write the negation down before deciding you are stuck.
4. The trap the question sets: reading "product of some subsequence" as generation. Subsequences use each term at most once and in order, so a generating set is worthless by itself, and any approach based on words in generators will produce lengths of order $|G|$.
5. What makes you recognise it faster next time: the pairing of an information theoretic target with an ordered selection rule. That pairing has appeared before in covering codes, binary representations and subset sum constructions, and its answer is always doubling plus a device to handle the ordering.
6. The reusable decision rule: compute the update rule, solve for maximal efficiency, run the greedy, then use the stopping condition as a theorem.

Mirror drills

1. Prove that every finite group G has a generating set of size at most $\log_2 |G|$. *Answer:* greedily add any element outside the subgroup generated so far; the subgroup strictly grows, so by Lagrange its order at least doubles at each step, and the order is capped by $|G|$.
2. Show that the constant c cannot be taken smaller than 1 when log means $\log_2$. *Answer:* a list of length ℓ has 2^ℓ subsequences, so $2^\ell \geq |G|$; and in $(\mathbb{Z}/2\mathbb{Z})^d$ the d standard basis vectors achieve $\ell = d = \log_2 |G|$ exactly, so the bound is attained.
3. In $\mathbb{Z}/n\mathbb{Z}$ exhibit a list of length $\lceil \log_2 n \rceil$ whose subsequence sums are all residues, and say why the mirror step of the ideal solution is unnecessary here. *Answer:* take $1, 2, 4, \ldots, 2^{\lceil \log_2 n \rceil - 1}$; binary representation gives every value in $\{0, \ldots, n-1\}$. No mirror is needed because the group is abelian and the subset sums already form the full difference set, so the greedy never needs an inverse.

18.7 B1. rational chords force a rational centre

Let C be a circle in $\mathbb{R}^2$ whose centre is not a rational point. What is the maximum number of rational points that can lie on C? (A rational point is a point both of whose coordinates are rational numbers.)

Read it out loud

Say the sentence back to yourself in order: a circle, an irrational centre, then a count of rational points on the boundary. The command term is "maximum number", which always splits into two separate jobs: an upper bound, and a construction that meets it. The guiding light is the phrase "whose centre is not a rational point": the question is not really asking you to study circles, it is asking what an irrational centre can force about the points that sit on that circle. That phrasing is the cue to run the argument in reverse, asking not how many rational points fit, but what having several rational points would force onto the centre.

The field embedded here is elementary Euclidean geometry, but the mechanism doing the actual work is field arithmetic: the rational numbers are closed under addition, subtraction, multiplication, and division by anything nonzero. Any point built from rational data using only those four operations is again rational. A circle's defining property, equidistance from the centre, translates directly into perpendicular bisectors, and a perpendicular bisector of a rational segment is built from nothing but a midpoint (an average) and a rotated direction vector (a coordinate swap and a sign change). Both stay inside the rationals. Within thirty seconds you should have written: if three rational points lie on the circle, the centre lies on two perpendicular bisectors, both rational lines, so the centre is rational. That sentence, once written, is the whole problem; everything else is bookkeeping to make it rigorous.

Do not reach for the circle's algebraic equation $(x-a)^2+(y-b)^2=r^2$. It is correct but it drags in the radius, a genuinely new unknown you never need to touch. The moment a question ties a centre's rationality to points on the circle, the radius is irrelevant scaffolding: strip it away and work with distances pairwise, which is exactly what a perpendicular bisector already encodes.

Approaches, ranked worst to best

1. **numeric guessing.** *Cue:* trying explicit rational triples and checking whether a circle through them can have an irrational centre. *Circuit:* pattern spotting, not proof.: this only produces a conjectured answer of 2. It never closes the upper bound, since you cannot enumerate every rational triple, and it supplies no mechanism for the construction half.

2. **general circle equation.** *Cue:* writing $(x-a)^2+(y-b)^2=r^2$, or the equivalent 4×4 determinant, through three unknown points. *Circuit:* brute elimination of a, b, r.: fully rigorous, and in fact Kedlaya's own alternate remark, but it costs more ink: you carry the radius as a live unknown throughout, or expand a 4×4 determinant correctly under time pressure, either of which invites an arithmetic slip the leaner route never risks.

3. **perpendicular bisector routing.** *Cue:* "centre is not a rational point" tied to a count of points equidistant from it. *Circuit:* rational field closure under midpoint, rotation, and a nonsingular 2×2 linear solve.: the ideal route. It never introduces the radius, needs only two of the three hypothetical points at a time, and every step is a named field operation, so the rationality of the centre is visibly forced rather than argued about.

The ideal solution

The answer is $\boxed{2}$.

Upper bound: at most two. Suppose, for contradiction, that three rational points $P = (a, b)$, $Q = (c, d)$, $R = (e, f)$ all lie on a circle C with centre $O = (g, h)$. A line meets a circle in at most two points, so P, Q, R are pairwise distinct and noncollinear.

Because O is equidistant from P and Q, it lies on the perpendicular bisector of segment PQ. That bisector consists of every point (x, y) satisfying

$$(c - a)\left(x - \tfrac{a+c}{2}\right) + (d - b)\left(y - \tfrac{b+d}{2}\right) = 0,$$

a line $A_1x + B_1y = C_1$ with $A_1 = c - a$, $B_1 = d - b$, and C_1 built from rational sums and products of a, b, c, d; hence A_1, B_1, C_1 are all rational. The same construction on Q and R gives a second rational line $A_2x + B_2y = C_2$ through O.

Since P, Q, R are noncollinear, the vectors $(c - a, d - b)$ and $(e - c, f - d)$ are linearly independent. Rotating a vector by a quarter turn is an invertible linear map, so the corresponding normal vectors (A_1, B_1) and (A_2, B_2) are independent too, which means $A_1B_2 - A_2B_1 \neq 0$. The two rational lines therefore meet in exactly one point, and by Cramer's rule that point is

$$g = \frac{C_1B_2 - C_2B_1}{A_1B_2 - A_2B_1}, \qquad h = \frac{A_1C_2 - A_2C_1}{A_1B_2 - A_2B_1}.$$

Both coordinates are ratios of rational numbers with a nonzero rational denominator, so $O = (g, h)$ is rational. This contradicts the hypothesis that the centre of C is irrational. Hence no circle with an irrational centre carries three rational points.

Construction: two is achieved. Fix the two rational points $(0, 0)$ and $(1, 0)$. For any real t, the circle centred at $\left(\frac{1}{2}, t\right)$ with radius $\sqrt{\frac{1}{4} + t^2}$ passes through both, since each is at that exact distance from $\left(\frac{1}{2}, t\right)$. Choosing t irrational, say $t = 1$, gives a circle with centre $\left(\frac{1}{2}, 1\right)$, which is not a rational point, carrying two rational points on it.

Combining the bound and the construction, the maximum number of rational points on a circle whose centre is not rational is exactly 2.

Layer 1: WHAT

Block 1: read "equidistant from an irrational centre" as the true content of the problem, and translate it into perpendicular bisectors rather than the circle's algebraic equation. Block 2: show a perpendicular bisector of a rational segment is a rational line, since its coefficients come from a midpoint and a rotated direction vector, both field operations that keep rational inputs rational. Block 3: intersect two such rational lines, using noncollinearity of the three hypothetical points to guarantee the lines are not parallel, and read off a rational intersection point by Cramer's rule. Block 4: the contradiction closes the upper bound; supply the two point construction with an irrational centre to show the bound is attained.

The nominal route bifurcates from the ideal one immediately after "suppose three rational points lie on the circle": the zombie writer reaches for $(x - a)^2 + (y - b)^2 = r^2$, substitutes three points, and grinds through three simultaneous quadratics, or a 4×4 determinant, to isolate a and b, carrying the unnecessary unknown r the entire way. The ideal writer instead asks what a circle is, definitionally, and reaches for the perpendicular bisector, which never mentions r at all. That single choice, at the very first line of working, is the bifurcation point.

Layer 2: HOW

Block 1. Cue. "centre is not a rational point" set against "how many rational points lie on the circle". **Why natural.** A circle is defined as the locus equidistant from its centre; equidistance between two named points is precisely the perpendicular bisector construction, so any argument connecting the centre's rationality to points on the circle should be built from bisectors of chords, which need only

two points at a time, rather than the full circle equation, which needs all three points and the radius simultaneously. **Link to the next block.** Committing to bisectors means you now need the purely algebraic fact that a bisector of a rational segment has rational coefficients.

Block 2. Cue. midpoint and direction vector of a segment between two rational points. **Why natural.** the rational numbers are closed under addition, subtraction, multiplication, and division by a nonzero element; a midpoint is an average of rational coordinates, hence rational, and a direction vector rotated a quarter turn is obtained by swapping the two coordinates and negating one, an operation that never leaves the rationals. Every coefficient of the bisector's line equation is a finite combination of such operations on rational inputs, so the whole equation is rational. **Link to the next block.** With two rational bisector lines available, from P, Q and from Q, R, the remaining question is a 2×2 linear algebra one: do they meet, and where.

Block 3. Cue. two linear equations, two unknowns, and the noncollinearity of P, Q, R. **Why natural.** P, Q, R lie on a genuine circle, and a line meets a circle in at most two points, so the three are automatically noncollinear; that forces the chord directions PQ and QR to be linearly independent, and a quarter turn rotation, being an invertible linear map, carries that independence over to the two bisector normal vectors. Two lines with independent normals meet at exactly one point, and Cramer's rule writes that point as a ratio of rational determinants over a nonzero rational determinant, hence rational. **Link to the next block.** That rational point is forced to be the centre, since both bisectors pass through it by definition, contradicting an irrational centre; the last job is to check the bound of two is achievable.

Block 4. Cue. the word "maximum" in the question. **Why natural.** "maximum" is a claim of equality, not merely an inequality; an upper bound argument alone only proves "at most", so the problem is not finished until a circle with an irrational centre carrying two rational points is exhibited explicitly. **Link to the next block.** none, this closes the problem.

Layer 3: WHY

The phenomenon underneath this problem has nothing to do with circles specifically. The rational numbers form a field, closed under the four operations except division by zero, and any point in the plane describable purely by midpoints, differences, quarter turn rotations, and the solution of a nonsingular linear system with rational coefficients, must itself be rational, with no reference to geometry required. A circle happens to give you a natural source of such a description, through the equidistance property, since equidistance from two points is exactly a perpendicular bisector, and a bisector of a rational segment is one of those purely field theoretic objects.

The discernment mechanism to train is this: whenever a problem asks you to prove that some derived point, a centre, an intersection, a foot of a perpendicular, inherits rationality (or integrality, or membership of some other closed algebraic system) from given data, search for the smallest set of field operations that produces that point. If you can write the point down using only those operations, the rationality is automatic and you never need the full geometric picture, including quantities like a radius the target point does not actually depend on. Examiners nudge you toward this by phrasing the hypothesis on the centre rather than on the points ("centre is not a rational point"), an invitation to argue by contrapositive: assume enough rational points and force the centre.

Revolving concepts

Rational point and rational line. A point is rational if both coordinates lie in $\mathbb{Q}$; a line is rational if it can be written $ax + by = c$ with $a, b, c \in \mathbb{Q}$. Two distinct rational points determine a rational line, and two nonparallel rational lines meet at a rational point, by Cramer's rule on a 2×2 system with

rational, nonzero determinant coefficients. This is genuinely a statement about any field K in place of $\mathbb{Q}$: two K-points determine a K-line, and two nonparallel K-lines meet at a K-point. See Book 1, field: Geometry, topic: affine geometry over a field; also field: Linear algebra, topic: Cramer's rule for 2×2 systems.

Perpendicular bisector as the centre's locus. The centre of any circle through two given points lies on the perpendicular bisector of the segment joining them, since the centre is by definition equidistant from both. See Book 1, field: Geometry, topic: loci of equidistant points.

The general circle through three points. The equation of the circle through (x_1, y_1), (x_2, y_2), (x_3, y_3) can be written as a 4×4 determinant in $x^2 + y^2$, x, y, 1, giving $a(x^2 + y^2) + dx + ey + f = 0$ with centre $(-d/2a, -e/2a)$; rational input points give rational a, d, e, f, a second, heavier proof of the same fact. See Book 1, field: Matrices and determinants, topic: determinant formula for a conic through given points.

Generalisation to higher dimensions. The same bisector argument shows that at most n rational points can lie on an $(n-1)$-dimensional sphere in $\mathbb{R}^n$ whose centre is irrational: n rational points give $n-1$ independent rational bisector hyperplanes, which pin down the centre only once you have n of them, i.e. $n+1$ points. Setting $n = 2$ recovers the ceiling of 2 for a circle. See Book 1, field: Geometry, topic: spheres and hyperplane bisectors in $\mathbb{R}^n$.

Circuit Bank

- **WHEN** a problem ties rationality (or integrality) of a derived geometric point, a centre, an intersection, a foot of a perpendicular, to rationality of the given points **DO** search for a description of that point using only midpoints, differences and the solution of a nonsingular linear system with rational coefficients **BECAUSE** those operations never leave the field the given data lives in, so the derived point is rational for free, with no case work on the geometric picture needed
- **WHEN** a circle problem states a constraint on the centre and asks about points on the circle **DO** route through perpendicular bisectors of chords rather than the circle's algebraic equation **BECAUSE** a bisector uses only two points and never introduces the radius as an extra unknown, the minimum amount of algebra the question actually requires
- **WHEN** the question asks for a "maximum number" **DO** treat it as two separate deliverables: an upper bound argument, then an explicit construction attaining it **BECAUSE** "maximum" asserts equality, and an upper bound alone only proves "at most", never "exactly"
- **WHEN** you need to certify two chord directions are linearly independent **DO** invoke that a genuine circle meets a line in at most two points, so any three points on it are automatically noncollinear **BECAUSE** this removes the need for a separate non-degeneracy check on the three points

Backtesting

1. First useful cue: "centre is not a rational point" set against "maximum number of rational points", inviting the contrapositive: assume enough rational points and force the centre to be rational.
2. Method the expression suggested: equidistance from the centre routes directly to perpendicular bisectors of chords, not to the circle's algebraic equation.
3. Where you would hesitate, and the thought to reinforce: whether the two bisector lines are guaranteed to meet; reinforce with "three points on a genuine circle are automatically noncollinear, so their chord directions are independent, and a quarter turn rotation preserves that independence".

4. The trap the question sets: reaching for $(x-a)^2+(y-b)^2=r^2$ and solving for a, b, r together, dragging in the radius, an unknown the target point never depends on.
5. What makes you recognise it faster next time: whenever the proof target is "this derived point lies in the same field as the given data", check first whether it is built from midpoints, differences, and one linear solve.
6. The reusable decision rule: when the rationality of a derived point is the target, express that point purely through field operations on the given rational data, never through a full geometric equation carrying an extra unknown you do not need.

Mirror drills

1. Show that if three rational points lie on a circle, the square of its radius is also rational. *Answer:* the centre is rational by the argument above, so the squared radius, the squared distance from that centre to any one of the three rational points, is a sum of squares of rational differences, hence rational.
2. A parabola has no distinguished centre point equidistant from all of its points. Why does that mean the bisector circuit above cannot be used to bound the number of rational points on a parabola? *Answer:* the circuit is special to loci defined by equidistance from a single centre; a parabola carries no such centre, so there is no perpendicular bisector to route the argument through, and no contradiction of the same shape can be built.
3. Three rational points lie on a sphere in $\mathbb{R}^3$ whose centre is irrational. What is the true ceiling on rational points on such a sphere, and why does it differ from the circle's answer of 2? *Answer:* the ceiling is 3: two rational bisector planes from three points generically meet in a line, not a point, in $\mathbb{R}^3$, so a fourth rational point, giving three independent bisector planes, is needed before the centre is forced rational; the ceiling in $\mathbb{R}^n$ is always n.

18.8 B2. guess the closed form, then induct

Let $F_0(x) = \ln x$. *For* $n \geq 0$ *and* $x > 0$, *let* $F_{n+1}(x) = \int_0^x F_n(t)\,dt$. *Evaluate*

$$\lim_{n\to\infty} \frac{n!\,F_n(1)}{\ln n}.$$

Read it out loud

This is a recursively defined sequence of functions, each the antiderivative of the previous one, taken from 0: $F_0 = \ln x$, F_1 its integral from 0, F_2 the integral of that, and so on. The command term is "evaluate", not "find" or "prove": you are not asked to characterise F_n in general, only to extract a single numeric limit built from $F_n(1)$. That is itself a cue: whenever a problem defines an n-fold iterated operator and then asks only for the value at one fixed point, times a normalising factor, the intended route is almost always to find a closed form for $F_n(x)$ and read off the asymptotics, rather than to analyse $F_n(1)$ directly as n grows through some limiting trick.

The fields embedded are calculus, the Fundamental Theorem of Calculus and repeated integration, alongside the asymptotics of the harmonic numbers. The presence of $n!$ in the numerator, next to a limit the question asserts exists and is finite, is itself informative: $F_n(1)$ must decay roughly like $1/n!$ for the product $n!\,F_n(1)$ to stay controlled, a strong hint that $F_n(x)$ carries an $x^n/n!$ factor built in from n-fold integration. The $\ln n$ in the denominator similarly hints that whatever multiplies $x^n/n!$ grows like $\ln n$, and the most natural quantity that grows like $\ln n$ while being built from n discrete steps is the harmonic number $H_n = \sum_{k=1}^{n} 1/k$.

The first useful move, within the first minute, is to compute $F_1(x)$ explicitly: $\int_0^x \ln t\,dt = x\ln x - x$, a standard integral. Laying that next to the guess "$F_n(x)$ should look like $(\ln x - a_n)x^n/n!$ for some sequence a_n" already matches at $n = 1$ with $a_1 = 1 = H_1$. That match is the entire content of the problem: once you have the ansatz and one confirmed base case, the rest is a mechanical induction using the Fundamental Theorem of Calculus, followed by a well known bound on harmonic numbers.

Approaches, ranked worst to best

1. **direct estimation.** *Cue:* "evaluate a limit" read as an invitation to bound $F_n(1)$ recursively without ever writing a closed form. *Circuit:* ad hoc integral bounding, no real circuit.: ranks worst since every step needs a fresh, uncertain estimate on a function you have not pinned down, with no guarantee the bounds are tight enough to identify the exact value -1 rather than merely show boundedness.
2. **grind and pattern spot.** *Cue:* computing F_1, F_2, F_3 explicitly by repeated integration by parts and eyeballing the pattern. *Circuit:* pattern recognition from small cases.: genuinely useful as the discovery phase, and exactly how you should find the ansatz, but stopping here leaves the claim unproven for general n; it needs the formal induction that the ideal route supplies.
3. **ansatz plus induction.** *Cue:* an operator applied n times to a fixed seed, asked about only at one point. *Circuit:* guess a closed form from the first case, confirm it for all n by induction via the Fundamental Theorem of Calculus, then apply the harmonic number asymptotic.: the ideal route. It produces the exact closed form of $F_n(1)$ with a short, fully justified induction, after which the target limit is one line.

The ideal solution

Claim. For every $n \geq 1$ and $x > 0$, $F_n(x) = (\ln x - H_n)\dfrac{x^n}{n!}$, where $H_n = \sum_{k=1}^{n} \dfrac{1}{k}$, extended continuously by $F_n(0) = 0$.

Base case $n = 1$**.** Integrating by parts, $\int \ln t\, dt = t \ln t - t + C$, and $\lim_{t\to 0^+}(t \ln t - t) = 0$, so

$$F_1(x) = \int_0^x \ln t\, dt = x \ln x - x = (\ln x - 1)x,$$

matching the claim with $H_1 = 1$.

Inductive step. Suppose the claim holds for some $n \geq 1$, with F_n continuous on $(0, \infty)$ and $F_n(x) \to 0$ as $x \to 0^+$. Set

$$G(x) = (\ln x - H_{n+1}) \frac{x^{n+1}}{(n+1)!}, \qquad H_{n+1} = H_n + \frac{1}{n+1}.$$

Differentiating,

$$G'(x) = \frac{1}{x} \cdot \frac{x^{n+1}}{(n+1)!} + (\ln x - H_{n+1}) \cdot \frac{x^n}{n!} = \frac{x^n}{n!}\left[\frac{1}{n+1} + \ln x - H_{n+1}\right] = \frac{x^n}{n!}\big[\ln x - H_n\big] = F_n(x),$$

using $H_{n+1} - \frac{1}{n+1} = H_n$. Also $G(x) \to 0$ as $x \to 0^+$, since $x^{n+1} \ln x \to 0$ and $x^{n+1} \to 0$.

Both F_{n+1} and G are continuous on $(0, \infty)$ with the same derivative F_n there, so their difference has zero derivative on the connected interval $(0, \infty)$ and is constant; that constant is forced to 0 by the shared limit 0 as $x \to 0^+$. Hence $F_{n+1} = G$ on $(0, \infty)$, which is exactly the claim for $n + 1$. This completes the induction.

Evaluating the limit. By the claim, $F_n(1) = (\ln 1 - H_n)/n! = -H_n/n!$, so $n!\, F_n(1) = -H_n$ and

$$\lim_{n\to\infty} \frac{n!\, F_n(1)}{\ln n} = -\lim_{n\to\infty} \frac{H_n}{\ln n}.$$

Since $1/x$ is decreasing, for $k \geq 2$, $\int_k^{k+1} \frac{dx}{x} \leq \frac{1}{k} \leq \int_{k-1}^{k} \frac{dx}{x}$. Summing over $k = 2, \ldots, n$ gives

$$\ln(n+1) - \ln 2 \leq H_n - 1 \leq \ln n,$$

so $\ln(n+1) - \ln 2 + 1 \leq H_n \leq 1 + \ln n$. Dividing by $\ln n$ and letting $n \to \infty$, both bounds tend to 1, so $H_n / \ln n \to 1$ by the squeeze theorem.

Hence the required limit is $\boxed{-1}$.

Layer 1: WHAT

Block 1: recognise an n-fold operator applied to a fixed seed, asked about only at one point with a normalising factor, and route to finding a closed form, not to direct asymptotic estimation. Block 2: compute F_1 explicitly by a standard integral, matching the guessed ansatz $(\ln x - a_n)x^n/n!$. Block 3: prove the ansatz for all n by induction via the Fundamental Theorem of Calculus, differentiating the proposed F_{n+1}, matching the previous ansatz, and pinning the constant with the boundary limit at $x = 0^+$. Block 4: evaluate at $x = 1$ to get $F_n(1) = -H_n/n!$ in closed form, reducing the whole limit to $H_n/\ln n$. Block 5: apply the standard integral comparison squeeze for harmonic numbers to conclude $H_n/\ln n \to 1$, giving the answer -1.

The nominal route bifurcates immediately after computing $F_1(x) = x \ln x - x$: the zombie writer moves on to bound $F_2, F_3, \ldots$ one at a time with fresh inequalities, hoping a pattern of bounds emerges. The ideal writer instead proposes the general ansatz $(\ln x - a_n)x^n/n!$ at once and commits to proving it for every n in a single induction. That single choice, right after the first computation, is the bifurcation point.

Layer 2: HOW

Block 1. **Cue.** $n!$ sitting next to $F_n(1)$ in the same limit as $\ln n$, immediately after a definition built by n-fold integration. **Why natural.** a limit built from $n!$ times the n-th iterate value, asked to be evaluated, hence finite, signals $F_n(x)$ must carry an $x^n/n!$ factor, or $n!\,F_n(1)$ could not stay controlled; the $\ln n$ in the denominator signals whatever remains should grow like a harmonic sum, the canonical n-step-built quantity with logarithmic growth. The productive move is to conjecture a closed form of exactly that shape rather than estimate $F_n(1)$ term by term. **Link to the next block.** finding the precise closed form needs at least one explicit computation to calibrate it.

Block 2. **Cue.** $F_1(x) = \int_0^x \ln t\,dt$, a standard integral you already know. **Why natural.** computing the first iterate explicitly is the cheapest way to calibrate an ansatz; matching $(\ln x - a_1)x/1!$ against $x\ln x - x$ forces $a_1 = 1$, which is also H_1, the clue that a_n should be the n-th harmonic number rather than some other logarithm adjacent sequence. **Link to the next block.** with a calibrated ansatz for $n = 1$ you need a mechanism propagating it to every n, exactly what the defining recursion supplies via the Fundamental Theorem of Calculus.

Block 3. **Cue.** the recursive definition $F_{n+1}(x) = \int_0^x F_n(t)\,dt$ itself. **Why natural.** the Fundamental Theorem of Calculus converts "F_{n+1} is defined as an integral of F_n" into "$F'_{n+1} = F_n$ plus a boundary condition at 0", a differential equation with an initial condition, the natural tool for confirming a guessed closed form: differentiate the candidate for F_{n+1}, check it equals the already trusted formula for F_n, and match the one remaining degree of freedom using the value at the singular endpoint $x = 0$, where $x^k \ln x \to 0$ rescues you from the blow up of $\ln x$ itself. **Link to the next block.** with the closed form nailed down for every n, the actual question, a numeric limit, needs only the single value $x = 1$.

Block 4. **Cue.** the specific evaluation point $x = 1$ named in the question. **Why natural.** plugging in $x = 1$ kills the $\ln x$ term entirely, collapsing the two term closed form to the one term $-H_n/n!$, and the $n!$ in the question's numerator exists precisely to cancel the $n!$ in that denominator, a confirmation that the derived formula matches the problem's own normalising constants. **Link to the next block.** what remains is a single classical asymptotic fact about H_n.

Block 5. **Cue.** the ratio $H_n/\ln n$. **Why natural.** the harmonic numbers are sandwiched between consecutive integrals of $1/x$ by monotonicity of $1/x$, a standard integral test comparison, giving $H_n = \ln n + O(1)$ and hence $H_n/\ln n \to 1$, with no need for the sharper Euler-Mascheroni constant. **Link to the next block.** none, this closes the problem, the answer -1 picking up its sign from the ansatz's $-H_n$.

Layer 3: WHY

The underlying truth is that repeated application of a linear operator, here "integrate from 0", to a function decomposing into a log part and a polynomial part preserves that decomposition, since integration is linear and $\int x^n \ln x\,dx$ and $\int x^n\,dx$ both stay inside the span of $\{x^{n+1}\ln x,\ x^{n+1}\}$ after one integration by parts. The correct discernment mechanism whenever an n-fold iterated linear operator appears, integration, differentiation, a linear recurrence, a matrix power, is: identify the smallest finite dimensional family of functions or vectors the operator maps into itself, guess the coefficients from one or two small cases, and confirm by induction using the operator's own defining property, the Fundamental Theorem of Calculus for an integral operator, the recurrence itself for a sequence, an eigen decomposition for a matrix.

The examiners nudged you here by choosing $F_0 = \ln x$ specifically, not a polynomial, not e^x, a seed whose repeated antiderivatives are famous for staying inside the two dimensional family

$\{x^n \ln x,\ x^n\}$, and by asking for a ratio built exactly from the two natural scales in that family: $n!$ from the $x^n/n!$ coefficient that n-fold integration of a bounded function always produces, $\ln n$ from the harmonic number coefficient that using $\ln x$ as the seed always produces.

Revolving concepts

Repeated antiderivative of $\ln x$. $F_0 = \ln x$, $F_{n+1} = \int_0^x F_n$, gives the closed form $F_n(x) = (\ln x - H_n)x^n/n!$; the family $\{x^n \ln x,\ x^n\}$ is preserved by integration from 0. See Book 1, field: Calculus and integrals, topic: repeated integration by parts and reduction formulae.

Harmonic numbers and their logarithmic growth. $H_n = \sum_{k=1}^{n} 1/k$ satisfies $\ln(n+1) \le H_n \le 1 + \ln n$, proved by sandwiching $1/k$ between consecutive integrals of $1/x$; hence $H_n/\ln n \to 1$, and more precisely $H_n = \ln n + \gamma + o(1)$ for the Euler-Mascheroni constant γ, though only the coarser bound is needed here. See Book 1, field: Sequences and recurrences, topic: harmonic number asymptotics via the integral test.

Pinning a constant of integration at a singular endpoint. Two functions continuous on $(0,\infty)$, differentiable with equal derivatives there, and sharing a limit as $x \to 0^+$, are identical on $(0,\infty)$: their difference has zero derivative on a connected interval, hence is constant, and the shared limit forces that constant to 0. See Book 1, field: Real analysis, topic: uniqueness of an antiderivative via the mean value theorem.

Recursion generalisation. Any sequence of functions $F_{n+1} = T[F_n]$ for a linear operator T can be attacked by guessing a closed form ansatz from the first one or two terms, then confirming by induction that the ansatz for F_{n+1} satisfies T's own defining identity when applied to the ansatz for F_n, matching any remaining constant at a convenient boundary value. This is the standard playbook for any "apply an operator n times" Putnam problem: iterated derivatives with a Leibniz rule closed form, iterated finite differences, and linear recurrences solved by an ansatz spanned by the characteristic roots. See Book 1, field: Sequences and recurrences, topic: ansatz plus induction for linear iterated operators.

Circuit Bank

- **WHEN** a problem defines a sequence of functions by repeated integration, or differentiation, of a fixed seed and asks for the value at one point **DO** guess a closed form ansatz from the first explicit computation and prove it for all n by induction via the Fundamental Theorem of Calculus **BECAUSE** repeated application of a linear operator to a function inside a small closed family stays inside that family, so one calibration plus one inductive step pins down every term at once
- **WHEN** a limit involves $n!$ in the numerator alongside the n-th term of a sequence built by n-fold integration **DO** expect the sequence's closed form to carry a matching $x^n/n!$ factor and let the two cancel **BECAUSE** n-fold integration of a function that does not grow factorially always produces exactly that $1/n!$ scale
- **WHEN** you need to pin the constant of integration for an antiderivative defined via a definite integral from a fixed lower limit **DO** use the value, or limit, of both sides at that lower limit rather than an arbitrary point **BECAUSE** the defining integral automatically vanishes there, giving a free, exact data point instead of an unknown constant to solve for
- **WHEN** a limit reduces to a sum resembling $1 + \frac{1}{2} + \cdots + \frac{1}{n}$ divided by $\ln n$ **DO** reach immediately for the integral test comparison sandwiching the harmonic sum between consecutive integrals of $1/x$ **BECAUSE** this gives $H_n = \ln n + O(1)$ in two lines with no deeper machinery needed

Backtesting

1. First useful cue: $n!$ sitting next to $F_n(1)$ in the same limit as $\ln n$, immediately after a definition built by n-fold integration.
2. Method the expression suggested: guess a closed form $(\ln x - a_n)x^n/n!$, calibrated by computing F_1 explicitly.
3. Where you would hesitate, and the thought to reinforce: whether the constant of integration in the inductive step is really pinned down; reinforce with "match both sides at the lower limit of the defining integral, where the defining integral is automatically zero".
4. The trap the question sets: trying to estimate $F_n(1)$ via ad hoc bounds one iteration at a time instead of committing to an exact closed form, which either stalls or silently reconstructs the same formula with far more work.
5. What makes you recognise it faster next time: any "operator applied n times to a fixed seed, evaluate at one point, normalised by $n!$ or a similar scale" problem should trigger closed form ansatz plus induction before any estimation is attempted.
6. The reusable decision rule: when a recursively defined sequence of functions is built by a linear operator from a simple seed, find the finite dimensional family the operator preserves, calibrate on the first case, and induct via the operator's own defining identity.

Mirror drills

1. Let $G_0(x) = e^x$ and $G_{n+1}(x) = \int_0^x G_n(t)\,dt$. Find a closed form for $G_n(x)$. *Answer:* $G_n(x) = e^x - \sum_{k=0}^{n-1} x^k/k!$, the tail of the exponential series after subtracting its first n Taylor terms; found the same way, calibrate on $G_1(x) = e^x - 1$, guess the tail ansatz, confirm by induction via the Fundamental Theorem of Calculus.
2. Before computing anything, explain why the mere appearance of $n!\,F_n(1)$ as an evaluable quantity already predicts that F_n's closed form must contain an $x^n/n!$ factor. *Answer:* for $n!\,F_n(1)$ to stay controlled as $n \to \infty$, $F_n(1)$ itself must shrink at a rate comparable to $1/n!$, and the only natural way n-fold integration produces a $1/n!$ scale is through the $x^n/n!$ term arising from integrating a degree $n-1$ monomial exactly n times.
3. Evaluate $\lim_{n\to\infty} \dfrac{1 + \frac{1}{2} + \cdots + \frac{1}{n}}{\ln(n+1)}$. *Answer:* 1, by the same integral test squeeze used above, since $\ln(n+1)$ and $\ln n$ are asymptotically equivalent.

18.9 B3. pair up coordinates, bound each pair

What is the largest possible radius of a circle contained in a four dimensional hypercube of side length 1*?*

Read it out loud

Strip away the fear of "four dimensional": a circle is still a one parameter family of points $v_1 \cos\theta + v_2 \sin\theta$ traced about its centre, for two orthogonal vectors v_1, v_2 of equal length r, no matter what the ambient dimension is. That parametrisation is the entire content of the word "circle" and is the correct starting point regardless of dimension. "Contained in a hypercube" translates coordinate by coordinate into a bound on each coordinate function, once the hypercube is centred at the origin, which costs nothing since both the hypercube and the circle are shapes, unaffected by where you choose to place your axes. So the whole question becomes: how large can r be while every coordinate of $v_1 \cos\theta + v_2 \sin\theta$ stays inside the hypercube's range, for every θ at once.

The guiding light is "contained in", a per coordinate, for all θ constraint, not a single point constraint. The natural tool for "what is the maximum over θ of $a\cos\theta + b\sin\theta$" is the amplitude formula $\sqrt{a^2+b^2}$, an identity most people meet purely as a trigonometric rewriting trick but rarely recognise as a norm bound in disguise. Applying it once per coordinate converts a continuum of containment constraints, one for every θ, into finitely many algebraic constraints, one per coordinate, exactly the reduction turning a seemingly continuous, four dimensional geometry problem into a finite sum of squares optimisation.

There is a second, quieter idea hiding before any of that: whether the circle's centre can be assumed to sit at the hypercube's own centre at all. It can, for free, because both a circle and a hypercube are symmetric under reflection through their own centre, and that symmetry alone forces the recentred circle back inside the hypercube. Once that is granted, the whole difficulty of the problem lives entirely in the coordinate by coordinate amplitude bound and the arithmetic that follows it, not in any hard piece of four dimensional visualisation.

Approaches, ranked worst to best

1. **coupled optimisation.** *Cue:* "largest circle contained in a region" read as a joint calculus problem over the centre's position and the circle's orientation together. *Circuit:* brute multivariable optimisation, no real circuit.: ranks worst because it conflates two logically separate freedoms, where the centre sits and how the circle is oriented once centred, into one large coupled optimisation, when the centre can be fixed for free by a short symmetry lemma.
2. **low dimension analogy.** *Cue:* noticing the largest circle in a unit square or a unit cube face has radius $1/2$ and guessing the pattern continues. *Circuit:* pattern matching across dimensions, not proof.: a useful sanity check, and it correctly flags that a flat, coordinate plane circle is only a candidate, not necessarily optimal, but by itself it produces no bound and no rigorous maximum.
3. **recentre then bound per coordinate.** *Cue:* a "for all θ" containment condition on a linear combination of $\cos\theta$ and $\sin\theta$. *Circuit:* free recentring via central symmetry, then the amplitude identity applied coordinate by coordinate.: the ideal route. It splits the problem into two independent, individually easy steps, a symmetry lemma and a sum of squares bound, and produces a fully rigorous bound plus a matching construction in a handful of lines.

The ideal solution

It is convenient to solve the rescaled problem for a hypercube of side length 2, namely $H = [-1,1]^4$, and divide the resulting radius by 2 at the end; this trades the awkward bound $1/2$ per coordinate

for the cleaner bound 1, at the cost of one final division.

Recentring the circle for free. Let C be a circle of radius r contained in H, with centre P. Since C is a circle centred at P, it is invariant under the point reflection $\rho_P(x) = 2P - x$. Because $C \subseteq H$, applying ρ_P to both sides gives $C = \rho_P(C) \subseteq \rho_P(H)$, so $C \subseteq H \cap \rho_P(H)$. In coordinate i, H occupies $[-1, 1]$ and $\rho_P(H)$ occupies $[2P_i - 1, 2P_i + 1]$; these two length 2 intervals intersect in an interval centred at P_i with half width $1 - |P_i| \leq 1$ (the reflection $x \mapsto 2P_i - x$ swaps the two intervals and fixes only P_i, forcing the intersection to be symmetric about P_i, and the intersection cannot extend past 1 on either raw interval, giving half width exactly $1 - |P_i|$). Consequently $C - P$, the translate of C to be centred at the origin, lies inside $[-1, 1]^4 = H$ as well. So there is no loss of generality in assuming P is the origin O.

Reducing containment to a per coordinate bound. Write the recentred circle as $\{v_1 \cos\theta + v_2 \sin\theta : 0 \leq \theta < 2\pi\}$, where $v_1, v_2 \in \mathbb{R}^4$ are orthogonal with $|v_1| = |v_2| = r$. Containment in H means that for every coordinate i and every θ,

$$|v_{1i} \cos\theta + v_{2i} \sin\theta| \leq 1.$$

By the amplitude identity, $v_{1i} \cos\theta + v_{2i} \sin\theta = \sqrt{v_{1i}^2 + v_{2i}^2} \cos(\theta - \varphi_i)$ for a suitable phase φ_i, whose maximum over θ is exactly $\sqrt{v_{1i}^2 + v_{2i}^2}$. So the bound holds for every θ if and only if

$$v_{1i}^2 + v_{2i}^2 \leq 1 \qquad (i = 1, 2, 3, 4).$$

Bounding the radius. Since $v_1 \perp v_2$ and $|v_1| = |v_2| = r$,

$$2r^2 = |v_1|^2 + |v_2|^2 = \sum_{i=1}^{4} (v_{1i}^2 + v_{2i}^2) \leq \sum_{i=1}^{4} 1 = 4,$$

so $r \leq \sqrt{2}$.

Achieving equality. Take $v_1 = (1, 1, 0, 0)$ and $v_2 = (0, 0, 1, 1)$. Then $v_1 \cdot v_2 = 0$, $|v_1| = |v_2| = \sqrt{2}$, and coordinate by coordinate, $v_{1i}^2 + v_{2i}^2$ equals 1 for every $i = 1, 2, 3, 4$, so the circle traced by $v_1 \cos\theta + v_2 \sin\theta$ lies in H and has radius $\sqrt{2}$. This matches the bound, so the maximum radius for the side length 2 hypercube is exactly $\sqrt{2}$.

Undoing the rescaling. A hypercube of side length 1 is a hypercube of side length 2 scaled down by a factor of $\frac{1}{2}$, and scaling multiplies every length, including the radius of an inscribed circle, by the same factor. Hence the largest radius for side length 1 is $\frac{1}{2}\sqrt{2} = \boxed{\frac{\sqrt{2}}{2}}$.

Layer 1: WHAT

Block 1: recognise "circle" as the parametrisation $P + v_1 \cos\theta + v_2 \sin\theta$ with $v_1 \perp v_2$, a description valid in any dimension, and recognise "contained in the hypercube" as a per coordinate, for all θ constraint rather than a picture to visualise directly. Block 2: recentre the circle at the hypercube's own centre for free, via a short symmetry lemma, removing the centre's location from the optimisation before any inequality is written. Block 3: convert the for all θ containment constraint into a finite algebraic constraint per coordinate, using the amplitude identity for $a \cos\theta + b \sin\theta$. Block 4: sum the per coordinate bounds to get $2r^2 \leq 4$, the universal bound $r \leq \sqrt{2}$ for the rescaled hypercube. Block 5: exhibit an explicit orthogonal pair achieving equality, and undo the side length rescaling to answer the original question.

The nominal route bifurcates right after reading "circle contained in a four dimensional hypercube": the zombie writer tries to visualise, or directly optimise, over both the centre's position and the circle's orientation as one coupled multivariable problem. The ideal writer's very first move is the symmetry observation that the centre can be fixed at the hypercube's own centre without loss of generality, decoupling the problem into a pure "best orientation through a fixed point" question. That decoupling, before any inequality is written, is the bifurcation point.

Layer 2: HOW

Block 1. **Cue.** "circle" together with "contained in", a shape defined parametrically meeting a region defined by many linear constraints. **Why natural.** any circle of radius r, wherever it sits and however it is tilted, is exactly $\{P + v_1\cos\theta + v_2\sin\theta\}$ for its centre P and an orthogonal pair v_1, v_2 with $|v_1| = |v_2| = r$ spanning its plane; writing this down immediately turns a geometric containment question into a statement that must hold for every θ, an infinite family of linear inequalities in the free parameters P, v_1, v_2. **Link to the next block.** an infinite family indexed by θ is unwieldy directly, so the productive next move is removing as many of the other free parameters, in particular P, as possible before dealing with the θ dependence.

Block 2. **Cue.** the hypercube is centrally symmetric about its own centre, and so is a circle about its own centre. **Why natural.** since a circle is invariant under a 180 degree rotation about its own centre P, if $C \subseteq H$ then reflecting through P gives $C = \rho_P(C) \subseteq \rho_P(H)$, so C lies in $H \cap \rho_P(H)$, and a short coordinate computation shows this intersection, translated so P becomes the origin, still fits inside H; this costs a few lines and removes the centre entirely from the optimisation at zero cost to the bound. **Link to the next block.** with P fixed at the hypercube's own centre, the only remaining freedom is the orientation, encoded by v_1 and v_2, and containment becomes purely about how $v_1\cos\theta + v_2\sin\theta$ behaves coordinate by coordinate.

Block 3. **Cue.** a linear combination $a\cos\theta + b\sin\theta$, required to stay bounded for every θ. **Why natural.** this is exactly the amplitude, or $R\cos(\theta - \varphi)$, identity from Further Pure trigonometry, restated as a norm: the maximum over θ of $a\cos\theta + b\sin\theta$ is $\sqrt{a^2 + b^2}$, so "bounded by 1 for all θ" is equivalent to the single algebraic inequality $\sqrt{a^2 + b^2} \leq 1$; applying this once per coordinate converts the continuum of constraints from block 1 into four ordinary inequalities. **Link to the next block.** four inequalities of the same shape, each bounding a sum of two squares by 1, are begging to be added together.

Block 4. **Cue.** four separate inequalities $v_{1i}^2 + v_{2i}^2 \leq 1$, and the fact that $|v_1|^2 + |v_2|^2 = 2r^2$ by orthogonality and equal length. **Why natural.** summing the four per coordinate inequalities gives $\sum_i (v_{1i}^2 + v_{2i}^2) \leq 4$, and the left side is exactly $|v_1|^2 + |v_2|^2$ by definition of the Euclidean norm, which equals $2r^2$ since v_1, v_2 are orthogonal with common length r; this single line of arithmetic is the entire quantitative content of the bound. **Link to the next block.** an inequality alone only proves an upper bound, so the last job is checking it is achieved.

Block 5. **Cue.** equality in $\sum_i (v_{1i}^2 + v_{2i}^2) \leq 4$ needs every one of the four coordinate inequalities to be tight simultaneously. **Why natural.** pairing up the four coordinates two at a time, putting all of v_1's length into the first pair and all of v_2's length into the second, is the natural way to make each per coordinate sum equal exactly 1 while keeping $v_1 \perp v_2$; the vectors $(1, 1, 0, 0)$ and $(0, 0, 1, 1)$ do exactly this. **Link to the next block.** none, this closes the problem after undoing the side length rescaling.

Layer 3: WHY

The underlying truth is that a constraint required to hold "for all θ" against a two term trigonometric expression is always secretly a single Euclidean norm bound: the amplitude identity is nothing but the statement that the vector (a, b) has length at most the bound, viewed through the rotating unit vector $(\cos\theta, \sin\theta)$. Once you see that, any shape defined by a two parameter rotation, a circle, the principal axes of an ellipse, a rotating vector in a plane, meeting a box defined by independent coordinate bounds, reduces coordinate by coordinate to that same norm inequality, and the resulting optimisation is a plain sum of squares bound rather than a genuine multivariable calculus problem.

The discernment mechanism to train: whenever a "for all θ" or "for all directions" containment condition appears, ask whether it can be rewritten as a fixed norm bound via the amplitude identity, in two real dimensions, or the more general fact that the maximum of a linear functional over a sphere is achieved in the direction of the functional itself, in any number of dimensions, which is Cauchy-Schwarz. What the examiners were nudging toward: the number 4 in "four dimensional hypercube" is not there to make you visualise a four dimensional picture, it is there so the sum of four coordinate bounds gives a clean total of 4 and hence a clean $r = \sqrt{2}$ before rescaling, the same way "regular n-gon" problems nudge you toward roots of unity rather than literal polygon drawing.

Revolving concepts

Amplitude identity as a hidden norm bound. $a\cos\theta + b\sin\theta = \sqrt{a^2+b^2}\cos(\theta-\varphi)$ for a suitable φ; consequently $|a\cos\theta + b\sin\theta| \le M$ for every θ if and only if $\sqrt{a^2+b^2} \le M$. See Book 1, field: Inequalities, topic: amplitude form as a norm bound in disguise.

Parametrisation of a circle in $\mathbb{R}^n$. $P + v_1\cos\theta + v_2\sin\theta$, with $v_1 \perp v_2$ and $|v_1| = |v_2| = r$: the dimension free way to describe a circle once you leave the plane. See Book 1, field: Geometry, topic: circles as two dimensional slices of $\mathbb{R}^n$.

Central symmetry recentring lemma. If a centrally symmetric shape, any circle, or more generally any convex body symmetric about its own centre such as a ball or an ellipse, lies inside a centrally symmetric region, a cube or more generally any box, translating both so their centres coincide keeps the containment, proved by reflecting through the shape's centre. See Book 1, field: Geometry, topic: central symmetry and recentring arguments in containment problems.

Generalisation to k dimensional balls in n dimensional hypercubes. The largest radius of a k dimensional ball inside an n dimensional hypercube of side length 1 is $\frac{1}{2}\sqrt{n/k}$, provable via the trace identity $\operatorname{trace}(MM^{\mathsf{T}}) = \operatorname{trace}(M^{\mathsf{T}}M)$ for the matrix of radius vectors, with equality achieved by an equal norm tight frame construction; $k = 2$, $n = 4$ recovers $\sqrt{2}/2$, and $k = 2$, $n = 2$ recovers the trivial square answer $1/2$. See Book 1, field: Linear algebra, topic: trace identities and orthogonal projections bounding embedded balls.

Circuit Bank

- **WHEN** a shape's containment in a box must hold for all θ against an expression of the form $a\cos\theta + b\sin\theta$ **DO** rewrite it as the single inequality $\sqrt{a^2+b^2} \le$ the bound **BECAUSE** the amplitude identity turns an infinite family of constraints indexed by θ into one algebraic inequality, for free
- **WHEN** a centrally symmetric shape, a circle, a ball, an ellipse, is contained in a centrally symmetric region and its centre's position is one of the unknowns **DO** fix the shape's centre at the region's own centre by a short reflection argument before optimising anything else **BECAUSE** this removes an entire block of free parameters from the optimisation at no cost to the bound
- **WHEN** a maximisation is stated in n independent coordinates each individually bounded **DO** sum the per coordinate bounds and relate the total to the quantity you actually want, here $2r^2$ via orthogonality and equal length **BECAUSE** independent coordinate bounds add, turning a geometric optimisation into ordinary arithmetic
- **WHEN** you need to certify a bound is achieved **DO** construct the extremal object by spreading the available budget as unevenly as the equality case demands, here giving each of v_1, v_2 its full length in a disjoint pair of coordinates **BECAUSE** equality in a sum of independent bounds is easiest to arrange by making each bound tight on a separate, non overlapping part of the data

Backtesting

1. First useful cue: "circle", a two parameter rotation, meeting "contained in a hypercube", coordinate wise box constraints, a for all θ condition against independent per coordinate caps.
2. Method the expression suggested: rewrite the circle as $P + v_1 \cos\theta + v_2 \sin\theta$ and turn each coordinate's for all θ constraint into the amplitude bound $\sqrt{v_{1i}^2 + v_{2i}^2} \leq 1$.
3. Where you would hesitate, and the thought to reinforce: whether the circle's centre can really be assumed to sit at the hypercube's own centre without loss of generality; reinforce with "a circle is symmetric under reflection through its own centre, and a cube is symmetric under reflection through its own centre, so intersecting the cube with its own reflection through the circle's centre shows the translate to the origin still fits".
4. The trap the question sets: trying to visualise or directly parametrise the optimal circle in four dimensions by geometric intuition alone, rather than reducing containment to algebra coordinate by coordinate.
5. What makes you recognise it faster next time: any "for all θ, a linear combination of $\cos\theta$ and $\sin\theta$ stays bounded" condition should immediately become a single norm inequality via the amplitude identity.
6. The reusable decision rule: split a containment optimisation into a free recentring step, using central symmetry, followed by a per coordinate algebraic bound, and only then sum the bounds using whatever identity, orthogonality, equal length, relates the summed quantity to the thing being optimised.

Mirror drills

1. What is the largest radius of a circle contained in a two dimensional square of side length 1? *Answer:* $1/2$, by the identical per coordinate reduction with only two coordinates: for the side length 2 square, $2r^2 = \sum_{i=1}^{2}(v_{1i}^2 + v_{2i}^2) \leq 2$, so $r \leq 1$, achieved by $v_1 = (1, 0)$, $v_2 = (0, 1)$; halving for side length 1 gives $1/2$.
2. What is the largest radius of a circle contained in a three dimensional cube of side length 1, and does the flat, inscribed in a face circle of radius $1/2$ actually win? *Answer:* no: the true maximum is $\sqrt{6}/4 \approx 0.612$, strictly larger than $1/2$. For the side length 2 cube, take $v_1 = (1, -\frac{1}{2}, -\frac{1}{2})$, $v_2 = (0, \frac{\sqrt{3}}{2}, -\frac{\sqrt{3}}{2})$; these are orthogonal, $|v_1| = |v_2| = \sqrt{3/2}$, and $v_{1i}^2 + v_{2i}^2 = 1$ in every one of the three coordinates simultaneously, so $r = \sqrt{3/2}$ is achieved, giving $\sqrt{3/2}/2 = \sqrt{6}/4$ for side length 1, beating the naive coordinate plane circle by tilting.
3. Using the general formula $\frac{1}{2}\sqrt{n/k}$ for the largest k dimensional ball in an n dimensional unit hypercube, confirm it reproduces the answer to the main problem. *Answer:* $k = 2$, $n = 4$ gives $\frac{1}{2}\sqrt{4/2} = \frac{1}{2}\sqrt{2} = \sqrt{2}/2$, matching exactly.

18.10 B4. Lifting a polynomial bijection modulo prime powers

Let p be a prime number. Let $h(x)$ be a polynomial with integer coefficients such that $h(0), h(1), \ldots, h(p^2-1)$ are distinct modulo p^2. Show that $h(0), h(1), \ldots, h(p^3-1)$ are distinct modulo p^3.

Read it out loud

Say the structure to yourself in words before you write a single symbol. An integer polynomial is being evaluated on a complete residue system, and the hypothesis is that it separates every pair of residues at level two. You are asked to show that it then separates every pair at level three. So this is not a question about h; it is a question about the ladder p, p^2, p^3 and about how a polynomial map behaves when you climb one rung of that ladder. The fields wired into it are elementary number theory (congruences, the factor theorem over $\mathbb{Z}$) and the local structure of the rings $\mathbb{Z}/p^k\mathbb{Z}$.

The first cue is the word *distinct* attached to the list $h(0), \ldots, h(p^2-1)$. That list has exactly p^2 entries and there are exactly p^2 residue classes modulo p^2, so "distinct" is the same statement as "h induces a bijection of $\mathbb{Z}/p^2\mathbb{Z}$". Within thirty seconds you should have written that translation down, because injectivity is what the hypothesis hands you and surjectivity is what you will want to use. A finite set is the only place where you get both for free, and the examiners chose p^2 inputs deliberately so that you would notice.

The second cue is that the exponent moves up by exactly one. When a modulus climbs from p^k to p^{k+1}, the extra information sits in the kernel of the reduction map $\mathbb{Z}/p^{k+1}\mathbb{Z} \to \mathbb{Z}/p^k\mathbb{Z}$, which is a cyclic group of order p generated by p^k. So the real question is: what does h do to that kernel? A polynomial evaluated at $a+t$ where t is small in the p-adic sense is governed by its linear term in t, and the coefficient of that linear term is $h'(a)$. That is the whole problem. The derivative is not imported from calculus as a decoration; it is the induced map on the kernel, and it is forced on you the moment you write the increment as a separate variable.

Approaches, ranked worst to best

1. **Exhaust the residues.** *Cue:* "distinct modulo p^3" reads like a finite check. *Circuit:* compute when stuck. You cannot check anything: h has unspecified degree and coefficients, and p is arbitrary. Its only value is to force you to say out loud that the hypothesis must become a structural statement about h.

2. **Expand h coefficient by coefficient.** *Cue:* h is a polynomial, so write $h(x) = \sum c_i x^i$ and bash. *Circuit:* binomial theorem on each monomial. This works, since $(x+yp^2)^i \equiv x^i + ix^{i-1}yp^2 \pmod{p^3}$ is exactly what you need, but you rediscover the same expansion twice and carry sums over i through every line. Identical mathematics, worse bookkeeping.

3. **Rewrite h in the binomial basis.** *Cue:* integer valued polynomials are $\mathbb{Z}$ combinations of $\binom{x}{i}$. *Circuit:* change of basis to make integrality visible. Writing $h(x) = \sum_i d_i \binom{x}{i}$ with $d_i \in \mathbb{Z}$ makes the integrality of the higher Taylor coefficients transparent, and it is the right basis for many integrality problems, but here it buys nothing over one Taylor identity and you must prove the basis change first.

4. **Quote the classification of polynomial permutations of $\mathbb{Z}/p^k\mathbb{Z}$.** *Cue:* the problem is a corollary of a named theorem. *Circuit:* recognise the standard result and cite it. For $k \geq 2$, h permutes $\mathbb{Z}/p^k\mathbb{Z}$ if and only if it permutes $\mathbb{Z}/p\mathbb{Z}$ and $h'(a) \not\equiv 0 \pmod{p}$ for every integer a; the condition is independent of k, which settles the problem instantly. But the proof of that criterion is precisely the argument below, so cite it as a remark, never as the argument.

5. **Hensel style lifting of solutions.** *Cue:* lifting information from p^2 to p^3 is root lifting. *Circuit:* Hensel's lemma with a simple root. Recast the claim as: for each residue c the congruence

$h(z) \equiv c \pmod{p^3}$ has at most one solution. That is the correct conceptual home, and $p \nmid h'$ is Hensel's simple root condition, but the write up keeps translating between "solve $h(z) = c$" and "the values are distinct".

6. **First order Taylor with an integer remainder, then fibre by fibre.** *Cue:* increment plus base point; the modulus is a prime power. *Circuit:* $P(a+t) = P(a) + tP'(a) + t^2 \cdot \text{integer}$. One identity, proved once, used twice. Increment $t = p$ converts the hypothesis into $p \nmid h'$; increment $t = yp^2$ makes the map on each fibre of $\mathbb{Z}/p^3\mathbb{Z} \to \mathbb{Z}/p^2\mathbb{Z}$ affine with slope $h'(x)$, and an affine map with unit slope on a cyclic group of order p is a bijection. This is the route to write.

The ideal solution

Two lemmas first, both about a general polynomial P with integer coefficients.

Lemma 18.10.1. *For $P \in \mathbb{Z}[x]$ and integers u, v we have $(u - v) \mid P(u) - P(v)$. Consequently, if $u \equiv v \pmod{m}$ then $P(u) \equiv P(v) \pmod{m}$.*

Proof. By linearity it suffices to treat $P(x) = x^i$ with $i \geq 1$, and $u^i - v^i = (u - v)(u^{i-1} + u^{i-2}v + \cdots + v^{i-1})$ with the second factor an integer. The constant term contributes 0. □

Lemma 18.10.2. *For $P \in \mathbb{Z}[x]$ and integers a, t there is an integer R (depending on P, a, t) with*

$$P(a+t) = P(a) + t\,P'(a) + t^2 R.$$

Proof. Again by linearity take $P(x) = x^m$. The binomial theorem gives

$$(a+t)^m = a^m + ma^{m-1}t + t^2 \sum_{i=2}^{m} \binom{m}{i} a^{m-i} t^{i-2},$$

and the displayed sum is an integer (it is empty when $m \leq 1$). Summing over the monomials of P with their integer coefficients gives the claim, since the formal derivative is linear and sends x^m to mx^{m-1}. □

Step 1: the hypothesis says $p \nmid h'(x)$ for every integer x. Fix x with $0 \leq x \leq p-1$. Then $x + p \leq 2p - 1 \leq p^2 - 1$, using $p \geq 2$, so both x and $x + p$ lie in $\{0, 1, \ldots, p^2 - 1\}$ and the hypothesis gives

$$h(x+p) \not\equiv h(x) \pmod{p^2}.$$

Lemma 2 with $t = p$ gives $h(x+p) = h(x) + p\,h'(x) + p^2 R$, so $h(x+p) \equiv h(x) + p\,h'(x) \pmod{p^2}$. Combining, $p\,h'(x) \not\equiv 0 \pmod{p^2}$, that is, $h'(x) \not\equiv 0 \pmod{p}$. Now $h' \in \mathbb{Z}[x]$, so by Lemma 1 the residue $h'(x) \bmod p$ depends only on $x \bmod p$. Since every integer is congruent modulo p to one of $0, 1, \ldots, p-1$, we conclude

$$h'(x) \not\equiv 0 \pmod{p} \qquad \text{for every integer } x.$$

Step 2: the shape of h on a fibre. Let $0 \leq x \leq p^2 - 1$ and $0 \leq y \leq p - 1$. Lemma 2 with $t = yp^2$ gives

$$h(x + yp^2) = h(x) + yp^2 h'(x) + y^2 p^4 R.$$

Since $p^3 \mid y^2 p^4$, this yields the two congruences

$$h(x + yp^2) \equiv h(x) + yp^2 h'(x) \pmod{p^3}, \qquad h(x + yp^2) \equiv h(x) \pmod{p^2}.$$

Step 3: injectivity modulo p^3. Every $z \in \{0, 1, \ldots, p^3 - 1\}$ is written uniquely as $z = x + yp^2$ with $0 \leq x \leq p^2 - 1$ and $0 \leq y \leq p - 1$ (divide z by p^2 with remainder). Suppose

$$h(x_1 + y_1 p^2) \equiv h(x_2 + y_2 p^2) \pmod{p^3}$$

for two such pairs. Reducing modulo p^2 and using the second congruence of Step 2 gives $h(x_1) \equiv h(x_2) \pmod{p^2}$, and since $x_1, x_2 \in \{0, \dots, p^2-1\}$ the hypothesis forces $x_1 = x_2 =: x$. Feeding this back into the first congruence of Step 2 gives

$$y_1 p^2 h'(x) \equiv y_2 p^2 h'(x) \pmod{p^3},$$

hence $p^3 \mid p^2(y_1 - y_2)h'(x)$, hence $p \mid (y_1 - y_2)h'(x)$. By Step 1 the prime p does not divide $h'(x)$, so Euclid's lemma gives $p \mid y_1 - y_2$; and $|y_1 - y_2| \le p - 1 < p$ forces $y_1 = y_2$. Therefore $z_1 = z_2$, so the p^3 numbers $h(0), h(1), \dots, h(p^3-1)$ are pairwise distinct modulo p^3. ■

Layer 1: WHAT

Block 1. Translate the hypothesis: h induces a bijection of $\mathbb{Z}/p^2\mathbb{Z}$, and the target statement is that h induces a bijection of $\mathbb{Z}/p^3\mathbb{Z}$.

Block 2. Build one tool: for integer polynomials, $P(a+t) = P(a) + tP'(a) + t^2 \cdot (\text{integer})$, proved once by the binomial theorem.

Block 3. Set $t = p$ and read the hypothesis through the tool: $h(x+p) \not\equiv h(x) \pmod{p^2}$ becomes $p \nmid h'(x)$.

Block 4. Propagate: h' mod p depends only on x mod p, so $p \nmid h'(x)$ for all integers x, not just for $x < p$.

Block 5. Set $t = yp^2$ in the same tool. The quadratic remainder now carries p^4 and dies modulo p^3, leaving an affine formula with slope $h'(x)$.

Block 6. Split $z = x + yp^2$ and separate coordinates: the x coordinate is pinned by the hypothesis at level two, the y coordinate is pinned by $p \nmid h'(x)$.

The nominal route starts by fixing two integers $z_1 \not\equiv z_2 \pmod{p^3}$ and trying to prove $h(z_1) \not\equiv h(z_2)$ directly, splitting into the case $z_1 \equiv z_2 \pmod{p^2}$ and the case not. That is not wrong, but it invites you to expand $h(z_1) - h(z_2)$ as a difference of two unrelated evaluations and to lose the base point. The bifurcation point is Block 2: the decision to stop treating x as the variable and instead treat the *increment* t as the variable, with the base point a frozen. Once the increment is the variable, the linear coefficient in it is $h'(a)$ and the derivative appears without being invented.

Layer 2: HOW

Block 1. **Cue.** The list $h(0), \dots, h(p^2-1)$ has exactly as many entries as there are residues modulo p^2, and the word is "distinct". **Why natural.** On a finite set of matched size, injective, surjective and bijective are the same word. The hypothesis is therefore not a list of inequalities but a single structural fact, and structural facts survive being pushed through maps whereas lists of inequalities do not. **Link to the next block.** Once you say "bijection of $\mathbb{Z}/p^2\mathbb{Z}$" you immediately want the corresponding statement for $\mathbb{Z}/p^3\mathbb{Z}$, so you look at the map connecting the two rings.

Block 2. **Cue.** A prime power modulus and a step of exactly one in the exponent; equivalently, inputs that differ by something divisible by a high power of p. **Why natural.** If z and a differ by t with t divisible by a large power of p, then t^2 is divisible by twice that power, so every term of the expansion beyond the linear one is invisible modulo the relevant power. The only expansion of a polynomial in powers of an increment is the Taylor expansion, and for an integer polynomial its coefficients $P^{(i)}(a)/i!$ are integers. Two of the three facts you need are already in the binomial theorem, so prove exactly the piece you need and no more. **Link to the next block.** You now have a machine with a free parameter t. The natural thing is to try the two values of t that the problem itself names: p and p^2.

Block 3. **Cue.** The hypothesis contains pairs of inputs that differ by exactly p, namely x and $x+p$ for $x < p$, and both are inside the range $\{0, \dots, p^2-1\}$ where the hypothesis lives. **Why natural.** The hypothesis is a statement about the whole range, but you only need it on the pairs where the tool has bite. Feeding $t = p$ makes the remainder divisible by p^2, so it vanishes modulo p^2, and the hypothesis converts with no loss into a statement about h'. Notice what you did not do: you did not use the hypothesis on all $\binom{p^2}{2}$ pairs. You used it on p pairs and threw the rest away, because the rest carry no information about the derivative. **Link to the next block.** You have $p \nmid h'(x)$ for $x < p$ and you need it for $x < p^2$, so you look for a periodicity statement.

Block 4. **Cue.** h' has integer coefficients. **Why natural.** An integer polynomial evaluated modulo m depends only on the input modulo m, because $(u-v)$ divides $P(u) - P(v)$. This is the single most reused fact in congruence problems and it must be quoted, not rediscovered. **Link to the next block.** The invariant $p \nmid h'$ is now global, so it can be applied at every base point in Step 2 without further work.

Block 5. **Cue.** You must reach modulus p^3, and the inputs $0, \dots, p^3-1$ naturally split by their residue modulo p^2. **Why natural.** The set $\{0, \dots, p^3-1\}$ fibres over $\{0, \dots, p^2-1\}$ with fibres of size p, and a point of the fibre over x is $x + yp^2$. Feed that increment into the tool: $t^2 = y^2p^4$ is divisible by p^3, so the remainder dies and the restriction of h to the fibre is the affine map $y \mapsto h(x) + yp^2h'(x)$. Affine maps on a cyclic group of order p are bijections exactly when the slope is a unit, and Step 1 says the slope is a unit. **Link to the next block.** Bijectivity on the base plus bijectivity on each fibre is bijectivity upstairs, so the two coordinates can be pinned one after the other.

Block 6. **Cue.** Two inputs with equal images; you want to force them equal. **Why natural.** Reduce the equality modulo p^2 first, because that projection kills the y coordinate entirely and leaves a statement to which the hypothesis applies verbatim. Only after $x_1 = x_2$ is fixed does the y coordinate become a clean linear congruence. Order matters: doing it the other way round leaves two unknowns in one congruence. **Link to the next block.** Nothing follows; the proof is complete, and the final line should say the count, p^3 distinct values, so the grader sees the conclusion in the form the problem asked for.

Layer 3: WHY

The mathematical truth underneath is that $\mathbb{Z}/p^3\mathbb{Z} \to \mathbb{Z}/p^2\mathbb{Z}$ is a surjective ring homomorphism whose kernel is $p^2\mathbb{Z}/p^3\mathbb{Z}$, a cyclic group of order p. Any integer polynomial descends along this map, so h on $\mathbb{Z}/p^3\mathbb{Z}$ sits over h on $\mathbb{Z}/p^2\mathbb{Z}$, and for a map of finite sets respecting a fibration, bijectivity is equivalent to bijectivity of the base map together with bijectivity of every fibre map. The base map is a bijection by hypothesis, and on the fibre over x Lemma 2 says h acts by multiplication by $h'(x)$. So h is a bijection modulo p^3 precisely when $h'(x)$ is a unit modulo p for every x. The derivative is the induced map on the kernel of a reduction map; that is why calculus notation appears in a problem with no limits in it.

The discernment mechanism: when a problem hands you data at one level of a filtration and asks for data at the next, identify the map between levels, identify its kernel, and compute the induced action on the kernel. That action is always a linearisation, and for polynomial maps the linearisation is the formal derivative. Train it by rehearsing the same picture in Hensel's lemma, in Newton's method (the same formula over $\mathbb{R}$ with the same slope condition), and in the structure of $1 + p\mathbb{Z}_p$.

The examiners nudged you twice: they chose the exponents 2 and 3 rather than 1 and 2, so the base case modulo p is handed to you, and they wrote the hypothesis as a list of p^2 values rather

than as "permutes the residues", so that the translation is yours to perform.

Revolving concepts

Complete residue system and the pigeonhole equivalence. A list of m integers that are pairwise distinct modulo m is a complete residue system modulo m. For any map of finite sets of equal size, injective, surjective and bijective coincide. See Book 1, field: Number theory, topic: complete residue systems.

The factor theorem over $\mathbb{Z}$. For $P \in \mathbb{Z}[x]$ and integers u, v, $(u - v) \mid P(u) - P(v)$. Corollaries used constantly: P modulo m is a well defined function on $\mathbb{Z}/m\mathbb{Z}$; if P has a root modulo m then it has one in $\{0, \ldots, m-1\}$; and the order of $P(a) \bmod p$ is unchanged when a is shifted by a multiple of p. See Book 1, field: Number theory, topic: polynomial congruences.

Formal derivative and integer Taylor coefficients. For $P \in \mathbb{Z}[x]$ the formal derivative P' is again in $\mathbb{Z}[x]$, the product and chain rules hold formally, and $P(a+t) = \sum_{i \geq 0} \frac{P^{(i)}(a)}{i!} t^i$ with every coefficient an integer. Those coefficients are the Hasse derivatives, and their integrality is equivalent to $\binom{x}{i}$ being an integer valued polynomial. You need only the first two terms plus an integer remainder, which the binomial theorem supplies directly. See Book 1, field: Polynomials, topic: formal derivative and Hasse derivatives.

Hensel's lemma. If $P \in \mathbb{Z}[x]$, $k \geq 1$, $P(a) \equiv 0 \pmod{p^k}$ and $p \nmid P'(a)$, then there is exactly one b modulo p^{k+1} with $b \equiv a \pmod{p^k}$ and $P(b) \equiv 0 \pmod{p^{k+1}}$: write $b = a + tp^k$, expand with Lemma 2, and solve $P(a)/p^k + tP'(a) \equiv 0 \pmod{p}$, uniquely soluble because $P'(a)$ is invertible modulo p. The present problem is the same computation with the root replaced by a general value. See Book 1, field: Number theory, topic: Hensel lifting.

Polynomial permutations of $\mathbb{Z}/p^k\mathbb{Z}$ (Kempner's criterion). For $k \geq 2$, $h \in \mathbb{Z}[x]$ permutes $\mathbb{Z}/p^k\mathbb{Z}$ if and only if h permutes $\mathbb{Z}/p\mathbb{Z}$ and $h'(a) \not\equiv 0 \pmod{p}$ for every integer a. The criterion does not mention k, so permuting for one $k \geq 2$ is the same as permuting for all; the problem is the case $k = 2 \Rightarrow k = 3$. See Book 1, field: Number theory, topic: polynomial permutations of finite rings.

The recursion, generalised. Let B_k be "h induces a bijection of $\mathbb{Z}/p^k\mathbb{Z}$". The argument proves $B_k \Rightarrow B_{k+1}$ for every $k \geq 2$ with the single invariant $p \nmid h'(a)$ for all a, extracted once from B_2 and never recomputed. The general pattern is a recursion over the levels of a filtration $R_{k+1} \twoheadrightarrow R_k$ with kernel K, in which h acts on K by its linearisation. The method for every such level to level recursion is identical: find the kernel, linearise, demand invertibility of the linearisation, and check that the invertibility condition is level independent so a single induction closes all levels. The same skeleton runs the lifting of solutions of $x^2 \equiv a \pmod{2^k}$, the Teichmuller lifts, and the p-adic logarithm.

Circuit Bank

- **WHEN** a polynomial with integer coefficients is evaluated at $0, 1, \ldots, m-1$ and you are told the values are distinct modulo m **DO** rewrite it at once as "h induces a bijection of $\mathbb{Z}/m\mathbb{Z}$" **BECAUSE** the counts match, so you gain surjectivity for free, and a bijection is a structural object you can push through ring maps while a list of inequalities is not
- **WHEN** a modulus climbs from p^k to p^{k+1}, or two inputs differ by a multiple of a high power of p **DO** freeze a base point a, call the difference t, and write $P(a+t) = P(a) + tP'(a) + t^2 \cdot (\text{integer})$ **BECAUSE** the square of the increment carries twice the p power, so every term past the linear one vanishes and the map on each fibre is affine with slope $P'(a)$
- **WHEN** you have proved a congruence statement about $P(x) \bmod p$ for x in some short range and need it for all x **DO** quote $(u - v) \mid P(u) - P(v)$ and conclude that $P \bmod p$ is a function of $x \bmod p$ **BECAUSE** an integer polynomial descends to every quotient ring, so any statement about it modulo p is automatically p periodic in the input

- **WHEN** a bijection is wanted on a set that fibres over another set **DO** prove the base map is a bijection, then prove each fibre map is a bijection, and order your equalities so that the projection is taken first **BECAUSE** projecting kills one coordinate entirely, leaving a one variable congruence instead of a two variable one, which is the difference between three lines and half a page
- **WHEN** an affine congruence $y \mapsto c + \lambda y$ is to be a bijection modulo p **DO** check only that $p \nmid \lambda$ **BECAUSE** multiplication by a unit permutes a cyclic group, and Euclid's lemma is exactly the statement that non zero residues modulo a prime are units

Backtesting

1. First useful cue: p^2 values, distinct modulo p^2. Equal counts on both sides means the hypothesis is "bijection of $\mathbb{Z}/p^2\mathbb{Z}$", and that is the form in which it can be used twice.
2. Method the expression suggested: an increment expansion $P(a+t) = P(a) + tP'(a) + t^2R$ with integer R, because the modulus is a prime power and the two natural increments, p and yp^2, are exactly the ones that kill the remainder.
3. Where you would hesitate, and the thought to reinforce: at the moment the derivative appears, since the problem has no calculus in it. Reinforce that h' here is the induced map on the kernel of $\mathbb{Z}/p^{k+1}\mathbb{Z} \to \mathbb{Z}/p^k\mathbb{Z}$, not a limit; the formal derivative of an integer polynomial is an algebraic object and it is the correct linearisation over any ring.
4. The trap the question sets: proving $p \nmid h'(x)$ only for $0 \le x \le p-1$ and then silently using it for $0 \le x \le p^2 - 1$ in Step 2. The gap is real and it is cheap to close with the factor theorem, but a grader who is counting will notice it missing.
5. What makes you recognise it faster next time: the phrase "prime power modulus, exponent increases by one" should fire the increment expansion before you have finished reading the sentence. Any problem in which p^k and p^{k+1} both appear is a linearisation problem.
6. The reusable decision rule: to lift a bijectivity, injectivity or solvability statement one level up a p adic ladder, linearise on the kernel and demand the slope be a unit. Extract the slope condition once at the lowest available level, then never recompute it.

Mirror drills

1. Show that if $h \in \mathbb{Z}[x]$ satisfies the hypothesis of the problem, then $h(0), h(1), \ldots, h(p^k - 1)$ are distinct modulo p^k for every $k \ge 1$. *Answer:* the invariant $p \nmid h'$ from Step 1 is independent of k; run Steps 2 and 3 with $t = yp^k$ to get the inductive step $B_k \Rightarrow B_{k+1}$ for $k \ge 2$, and for $k = 1$ note that a bijection modulo p^2 forces a bijection modulo p by counting the p elements in each fibre.
2. Let p be an odd prime. Show that $h(x) = x^2$ does not satisfy the hypothesis, and find every h of the form $x^2 + cx$ that does. *Answer:* $h'(x) = 2x$ vanishes modulo p at $x = 0$, so $h(0) \equiv h(p) \pmod{p^2}$; for $x^2 + cx$ we need $2x + c \not\equiv 0 \pmod{p}$ for all x, which is impossible for odd p, so no such h exists (for $p = 2$ the condition becomes c odd).
3. Prove Hensel's lemma in the simple root case: if $P \in \mathbb{Z}[x]$, $P(a) \equiv 0 \pmod{p^k}$ and $p \nmid P'(a)$, then there is exactly one b modulo p^{k+1} with $b \equiv a \pmod{p^k}$ and $P(b) \equiv 0 \pmod{p^{k+1}}$. *Answer:* put $b = a + tp^k$, expand with Lemma 2 so that the remainder carries p^{2k}, and solve the linear congruence $P(a)/p^k + tP'(a) \equiv 0 \pmod{p}$, unique because $P'(a)$ is invertible modulo p.

18.11 B5. Denominator preserving smooth maps are signed integer translations

Find all continuously differentiable functions $f : \mathbb{R} \to \mathbb{R}$ such that for every rational number q, the number $f(q)$ is rational and has the same denominator as q. (The denominator of a rational number q is the unique positive integer b such that $q = a/b$ for some integer a with $\gcd(a, b) = 1$.)

Read it out loud

Say the shape of it: a hypothesis that is purely arithmetic, imposed only on the rationals, together with a hypothesis that is purely analytic, imposed on all of $\mathbb{R}$. Nothing in the problem connects the two. Your entire job is to build the connector. The fields wired in are real analysis (the mean value theorem, continuity, connectedness) and elementary number theory (denominators, coprimality, lattices in $\mathbb{R}$).

The first cue is the phrase "the same denominator". That is a very rigid demand, and the honest first move is to notice that it is really two demands stacked on top of each other: the denominator of $f(q)$ *divides* the denominator of q, and no factor is lost. The divisibility half is the useful half, because "denominator divides m" is the same as "lies in $\frac{1}{m}\mathbb{Z}$", and $\frac{1}{m}\mathbb{Z}$ is a subgroup of $(\mathbb{R}, +)$. The set of rationals with denominator exactly b is not closed under subtraction; the lattice $\frac{1}{m}\mathbb{Z}$ is. Difference quotients subtract. So within thirty seconds you should have written

$$f\left(\tfrac{1}{m}\mathbb{Z}\right) \subseteq \tfrac{1}{m}\mathbb{Z} \qquad \text{for every positive integer } m,$$

because that is the version of the hypothesis a difference quotient can eat.

The second cue is "continuously differentiable" rather than "differentiable". The setters are telling you that the final step is a continuity argument on f', not on f. Once you know that f' takes integer values somewhere dense, continuity plus the fact that $\mathbb{Z}$ is closed and totally disconnected does everything else: a continuous function from a connected set into a discrete set is constant. So the target of the whole middle of the proof is the single sentence "f' takes integer values on a dense set".

Approaches, ranked worst to best

1. **Answer with examples only.** *Cue:* "find all" invites a list. *Circuit:* pattern match and stop. Writing $f(x) = \pm x + n$ with a verification is worth almost nothing on its own, because the entire content of the problem is that there is nothing else. It is still the correct first line of the write up; it is a catastrophic last line.

2. **Build f denominator by denominator.** *Cue:* the hypothesis is indexed by b, so induct on b. *Circuit:* induction on a discrete parameter. Pin f on the integers, then on the halves, then on the thirds. It dies immediately: continuity alone does not pin f on $\mathbb{Z}$, an uncountable set of continuous functions maps $\mathbb{Z}$ into $\mathbb{Z}$, and you never obtain any statement about irrational inputs, which is where "find all" actually lives.

3. **Treat it as a functional equation.** *Cue:* "find all f" is Cauchy shaped. *Circuit:* additivity, then $\mathbb{Q}$ linearity, then continuity. There is no additive hypothesis. The condition relates f to the arithmetic of its argument, not to f at other points, so no substitution generates a relation between $f(x + y)$, $f(x)$ and $f(y)$. This is the classic misfire: matching the words "find all continuous f" rather than the structure.

4. **Difference quotient at a fixed rational.** *Cue:* differentiability is a limit of quotients, so choose a sequence of rationals converging to q. *Circuit:* make the quotient an integer by design. Fix $q = a/b$ and set $q_j = q + \frac{1}{bj}$; when $b \mid j$ this is in lowest terms with denominator bj, so

$bj(f(q_j) - f(q))$ is an integer, and its limit $f'(q)$ is therefore an integer that the sequence attains for large j. Then squeeze $f'(q)$ to ± 1 by inspecting the denominator of $f(q_j)$. This works, it is the route the official solution takes, and it is entirely correct; it costs an extra coprimality lemma and an extra "a convergent integer sequence is eventually constant" lemma, and it forces the value ± 1 at every rational separately when one global argument would do.

5. **Lattice preservation plus the mean value theorem.** *Cue:* "denominator divides m" is "lies in $\frac{1}{m}\mathbb{Z}$"; two lattice points sit a distance $\frac{1}{m}$ apart. *Circuit:* turn a secant slope into a derivative value. For $t \in \frac{1}{m}\mathbb{Z}$ the numbers $f(t)$ and $f(t + \frac{1}{m})$ both lie in $\frac{1}{m}\mathbb{Z}$, so the secant slope over that step is an integer, and the mean value theorem converts it into a value of f'. Those points are dense as m grows, so f' is integer valued on a dense set, hence everywhere, hence constant. Now f is affine with integer slope, and the exactness clause tested at $q = 1/b$ forces the slope to be a unit. No coprimality lemma, no sequence lemma, and the arithmetic is used exactly twice. This is the route to write.

The ideal solution

The answer is

$$\boxed{f(x) = x + n \quad \text{and} \quad f(x) = -x + n, \qquad n \in \mathbb{Z}.}$$

These work. Let $q = a/b$ in lowest terms with $b \geq 1$, and let $n \in \mathbb{Z}$. Then $\pm q + n = (\pm a + nb)/b$ and $\gcd(\pm a + nb, b) = \gcd(\pm a, b) = 1$, so $\pm q + n$ is in lowest terms with denominator b. Both functions are continuously differentiable. So every member of the stated family satisfies the condition.

Now suppose f satisfies the condition; we show it lies in the family.

Lemma 18.11.1. *For every positive integer m, the set of rationals whose denominator divides m is exactly $\frac{1}{m}\mathbb{Z}$, and $f\left(\frac{1}{m}\mathbb{Z}\right) \subseteq \frac{1}{m}\mathbb{Z}$.*

Proof. If $q = a/b$ in lowest terms and $b \mid m$ then $q = a(m/b)/m \in \frac{1}{m}\mathbb{Z}$; conversely if $q = u/m$ then cancelling gives $q = (u/g)/(m/g)$ with $g = \gcd(u, m)$, in lowest terms, and m/g divides m. For the second statement, let $q \in \frac{1}{m}\mathbb{Z}$ and let b be its denominator, so $b \mid m$. By hypothesis $f(q)$ is rational with denominator b, so $b \mid m$ again, so $f(q) \in \frac{1}{m}\mathbb{Z}$. □

Step 1: f' takes integer values on a dense set. Fix a positive integer m and an element $t \in \frac{1}{m}\mathbb{Z}$. Both t and $t + \frac{1}{m}$ lie in $\frac{1}{m}\mathbb{Z}$, so by the Lemma both $f(t)$ and $f(t + \frac{1}{m})$ lie in $\frac{1}{m}\mathbb{Z}$, whence

$$m\left(f\left(t + \tfrac{1}{m}\right) - f(t)\right) \in \mathbb{Z}.$$

Since f is differentiable on $\mathbb{R}$ it is continuous on $[t, t + \frac{1}{m}]$ and differentiable on $(t, t + \frac{1}{m})$, so the mean value theorem supplies $\xi \in (t, t + \frac{1}{m})$ with

$$f'(\xi) = \frac{f(t + \frac{1}{m}) - f(t)}{\frac{1}{m}} = m\left(f\left(t + \tfrac{1}{m}\right) - f(t)\right) \in \mathbb{Z}.$$

Let $Z = \{x \in \mathbb{R} : f'(x) \in \mathbb{Z}\}$. We have just shown that Z meets the open interval $(t, t + \frac{1}{m})$ for every $m \geq 1$ and every $t \in \frac{1}{m}\mathbb{Z}$. Given any nonempty open interval I, choose m with $\frac{1}{m} < \frac{1}{2}\,\text{length}(I)$; the points of $\frac{1}{m}\mathbb{Z}$ are spaced $\frac{1}{m}$ apart, so some $t \in \frac{1}{m}\mathbb{Z}$ has $[t, t + \frac{1}{m}] \subseteq I$, and then $Z \cap I \neq \emptyset$. Hence Z is dense in $\mathbb{R}$.

Step 2: f' is a constant integer. The function f' is continuous by hypothesis, $\mathbb{Z}$ is a closed subset of $\mathbb{R}$, and $f'(Z) \subseteq \mathbb{Z}$ with Z dense. For any $x \in \mathbb{R}$ pick $x_i \in Z$ with $x_i \to x$; then $f'(x) = \lim_i f'(x_i)$ lies in $\mathbb{Z}$ because $\mathbb{Z}$ is closed. So $f'(\mathbb{R}) \subseteq \mathbb{Z}$. Now $\mathbb{R}$ is connected and f' is continuous, so $f'(\mathbb{R})$ is a connected subset of $\mathbb{Z}$, that is, a single point. (Equivalently: if f' took two distinct integer values it

would take a non integer value in between, by the intermediate value theorem.) Write $f'(x) = k$ for all x, with $k \in \mathbb{Z}$.

Step 3: identify f. From $f' \equiv k$ we get $f(x) = kx + n$ where $n = f(0)$. The number 0 has denominator 1, so $f(0)$ has denominator 1, that is, $n \in \mathbb{Z}$.

Step 4: the exactness clause forces $k = \pm 1$. Let $b \geq 1$ be any integer. The rational $1/b$ has denominator b, and

$$f\left(\tfrac{1}{b}\right) = \frac{k + nb}{b}.$$

For a fraction u/v with $v \geq 1$ the denominator is $v/\gcd(u, v)$, so the denominator of $f(1/b)$ is $b/\gcd(k + nb, b) = b/\gcd(k, b)$, using $k + nb \equiv k \pmod{b}$. The hypothesis says this equals b, so $\gcd(k, b) = 1$ for every positive integer b. Taking $b = 2$ rules out $k = 0$, since $\gcd(0, 2) = 2$. If $|k| \geq 2$, taking $b = |k|$ gives $\gcd(k, |k|) = |k| \geq 2$, a contradiction. Hence $k = \pm 1$.

Therefore $f(x) = x + n$ or $f(x) = -x + n$ with $n \in \mathbb{Z}$, and both were verified above. ■

Remark 18.11.2. The hypothesis "continuously differentiable" is used exactly once, in Step 2, to spread integrality of f' from a dense set to all of $\mathbb{R}$. If you only assume f differentiable, Darboux's theorem still gives f' the intermediate value property, which replaces the connectedness argument at the end but not the density argument in the middle; so the weakening is not free, and you should not claim it.

Layer 1: WHAT

Block 1. Write down the family $f(x) = \pm x + n$ and verify it, so that "find all" has an answer on the page before the hard half begins.

Block 2. Split the hypothesis: "denominator of $f(q)$ divides m whenever the denominator of q divides m" is the group theoretic half, $f(\frac{1}{m}\mathbb{Z}) \subseteq \frac{1}{m}\mathbb{Z}$; "no cancellation" is the rigidity half, saved for the very end.

Block 3. Two neighbouring lattice points are a distance $\frac{1}{m}$ apart and their images lie in the same lattice, so the secant slope over that step is an integer.

Block 4. The mean value theorem converts that integer secant slope into an actual value of f', at an unknown point inside a known short interval.

Block 5. Shrink the mesh: the set where f' is an integer meets every interval, so it is dense.

Block 6. Continuity of f' plus closedness of $\mathbb{Z}$ gives $f'(\mathbb{R}) \subseteq \mathbb{Z}$; connectedness of $\mathbb{R}$ collapses that to a single integer k, so $f(x) = kx + n$ with $n = f(0) \in \mathbb{Z}$.

Block 7. Reintroduce the rigidity half at the single test point $q = 1/b$: the denominator of $(k + nb)/b$ is $b/\gcd(k, b)$, so $\gcd(k, b) = 1$ for all b, so $k = \pm 1$.

The nominal route fixes a rational q, builds a sequence $q_j \to q$ of rationals with growing denominators, and grinds out $f'(q) = \pm 1$ one rational at a time, paying for a coprimality lemma about $\frac{aj+1}{bj}$ and for the observation that a convergent integer sequence is eventually constant. It reaches the same place. The bifurcation point is Block 2: whether you keep the hypothesis in its "exactly b" form, which is not stable under subtraction and therefore forces you to fight coprimality every time you form a difference, or weaken it at once to the lattice form, which is a subgroup and therefore free under subtraction. Weakening a hypothesis to make it structural, and paying the lost strength back once at the end, is the move.

Layer 2: HOW

Block 1. Cue. "Find all" with a condition that is obviously satisfied by something. **Why natural.** You cannot aim a uniqueness argument at an unknown target. Verifying the family first also tells you what the final constant must be constrained to, so Step 4 has a known destination. **Link to the next block.** Having the answer $\pm x + n$ tells you that the derivative is the object to pin down, since the family is exactly "derivative ± 1, intercept an integer".

Block 2. **Cue.** The word "denominator", which is a divisibility statement in disguise, sitting next to a differentiability hypothesis, which needs subtraction. **Why natural.** Difference quotients subtract two values of f. The set of rationals with denominator exactly b is not closed under subtraction ($\frac{1}{3}$ and $\frac{2}{3}$ both have denominator 3, their difference has denominator 3, but $\frac{1}{3}$ and $\frac{4}{3}$ differ by an integer). The set with denominator dividing m is exactly $\frac{1}{m}\mathbb{Z}$, a subgroup, so it is closed under subtraction by construction. Weaken the hypothesis to the closed version; you can always spend the strength you dropped at the end, at one convenient point. **Link to the next block.** A subgroup of $\mathbb{R}$ preserved by f has a mesh, and a mesh gives you a canonical increment to differentiate along.

Block 3. **Cue.** The lattice $\frac{1}{m}\mathbb{Z}$ has mesh $\frac{1}{m}$, and $\frac{1}{m}$ is exactly the reciprocal of the number multiplying the values. **Why natural.** If $f(t)$ and $f(t+\frac{1}{m})$ both lie in $\frac{1}{m}\mathbb{Z}$, their difference lies in $\frac{1}{m}\mathbb{Z}$ and dividing by $\frac{1}{m}$ lands in $\mathbb{Z}$. The increment and the lattice mesh are the same number, so the quotient is an integer with nothing to check. This is the whole bridge between the arithmetic and the analysis, and it is one line. **Link to the next block.** You now hold an integer that looks like a derivative but is only a secant slope, so you need a theorem that turns secant slopes into derivative values.

Block 4. **Cue.** A secant slope over a short interval, with f differentiable everywhere. **Why natural.** The mean value theorem is precisely the statement "every secant slope is attained by the derivative". You do not care where it is attained, only that it is attained somewhere inside a controlled interval, because the next step only needs density. **Link to the next block.** The interval has length $\frac{1}{m}$ and m is yours to choose, so the located points can be made to fall inside any prescribed interval.

Block 5. **Cue.** m is a free parameter and $\frac{1}{m} \to 0$. **Why natural.** Density is not a limit statement, it is a "meets every interval" statement, and the lattice $\frac{1}{m}\mathbb{Z}$ with fine mesh has a full step inside any given interval. Notice what you did not do: you did not try to compute $\lim_m$ of anything, because you do not need the value of f' at any named point, only its membership of $\mathbb{Z}$ on a dense set. **Link to the next block.** Membership of a closed set on a dense set is exactly the input that continuity upgrades.

Block 6. **Cue.** "Continuously differentiable" in the hypothesis; $\mathbb{Z}$ is closed and has no interval in it. **Why natural.** Continuity carries a dense set to a dense subset of the image, and a closed set absorbs limits, so $f'(\mathbb{R}) \subseteq \overline{\mathbb{Z}} = \mathbb{Z}$. Then a continuous map from the connected set $\mathbb{R}$ into $\mathbb{Z}$ must be constant, since a connected subset of $\mathbb{Z}$ is a point; the intermediate value theorem is the same statement in exam language. **Link to the next block.** A constant derivative integrates to an affine function, so f is now completely known up to two integers.

Block 7. **Cue.** You have not yet used "the same denominator", only "the denominator divides". **Why natural.** The lost strength has to be repaid, and it is cheapest to repay it at a single family of test points. Choosing $q = 1/b$ is optimal because its numerator is 1, so the greatest common divisor computation collapses to $\gcd(k, b)$ with nothing else in the way. Requiring $\gcd(k, b) = 1$ for every b says k is a unit of $\mathbb{Z}$. **Link to the next block.** Nothing follows; state both families and confirm the verification from Block 1 closes the "if and only if".

Layer 3: WHY

The mathematical truth underneath is that $\frac{1}{m}\mathbb{Z}$ is a discrete subgroup of $(\mathbb{R}, +)$ and that these subgroups, ordered by divisibility of m, refine to a dense set. A C^1 map preserving a discrete subgroup of mesh $\frac{1}{m}$ has all of its mesh step secant slopes in $\mathbb{Z}$, and the mean value theorem transfers that integrality from secants to the derivative itself. Because $\mathbb{Z}$ is closed and totally disconnected while $\mathbb{R}$ is connected, integrality of a continuous function forces constancy. So the

analysis does not determine the constant; it only proves that a constant exists. The arithmetic then determines which constant: multiplication by k preserves denominators exactly if and only if $\gcd(k, b) = 1$ for every b, that is, if and only if k is a unit of $\mathbb{Z}$.

That two part anatomy is the general shape of rigidity theorems: discreteness plus connectedness produces a constant, and a separate arithmetic condition cuts the constant down to a unit. The same skeleton runs elsewhere: a continuous homomorphism $\mathbb{R} \to \mathbb{R}$ carrying $\mathbb{Z}$ into $\mathbb{Z}$ is $x \mapsto kx$ with $k \in \mathbb{Z}$, a continuous self map of the circle $\mathbb{R}/\mathbb{Z}$ has an integer degree that cannot change under deformation, and a C^1 map of $\mathbb{R}^n$ carrying every $\frac{1}{m}\mathbb{Z}^n$ into itself is affine with matrix in $M_n(\mathbb{Z})$.

The discernment mechanism: when a hypothesis is arithmetic and pointwise but the conclusion is analytic and global, the connector is always a difference quotient, and the design question is which increment makes the quotient arithmetically clean. Do not pick the increment for analytic convenience; pick it so that the numerator and the denominator have the same arithmetic scale. Ask, before writing any limit, what the common denominator of the two values you are subtracting is, and whether your increment can be its reciprocal.

The setters nudged you twice. They defined "denominator" explicitly, a hint that the split between "divides" and "is exactly" is where the work is, and they wrote "continuously differentiable" rather than "differentiable", which tells you the endgame is a topological argument about f' rather than a further computation with f.

Revolving concepts

Denominator of a rational. For integers u and $v \geq 1$, the fraction u/v in lowest terms has denominator $v/\gcd(u, v)$. Two facts get used constantly: $u \equiv u' \pmod{v}$ implies $\gcd(u, v) = \gcd(u', v)$, and the denominator of a sum divides the least common multiple of the denominators. See Book 1, field: Number theory, topic: fractions and coprimality.

The lattice $\frac{1}{m}\mathbb{Z}$. It equals $\{q \in \mathbb{Q} : \text{denominator of } q \text{ divides } m\}$, is a subgroup of $(\mathbb{R}, +)$ of mesh $\frac{1}{m}$, and satisfies $\frac{1}{m}\mathbb{Z} \subseteq \frac{1}{jm}\mathbb{Z}$ for every $j \geq 1$. The union over all m is $\mathbb{Q}$. By contrast the set of rationals with denominator exactly m is not a group. See Book 1, field: Number theory, topic: lattices and discrete subgroups.

Discrete subgroups of $\mathbb{R}$. Every subgroup of $(\mathbb{R}, +)$ is either dense or equal to $\alpha\mathbb{Z}$ for a unique $\alpha \geq 0$. This dichotomy is the reason "preserves a discrete subgroup" is a rigid condition, and it is the standard tool behind equidistribution and three distance arguments. See Book 1, field: Real analysis, topic: subgroups of the reals.

Mean value theorem and Darboux's theorem. The mean value theorem says every secant slope of a differentiable function is attained as a derivative value; Darboux's theorem says the derivative of a differentiable function has the intermediate value property even when it is not continuous. The first is the bridge in Step 1; the second is what would replace Step 2's connectedness argument if the hypothesis were weakened, though the density argument would still need repair. See Book 1, field: Real analysis, topic: mean value theorems.

Continuous maps into discrete sets. If g is continuous on a connected set and g takes values in a set with no interior points and no interval, such as $\mathbb{Z}$, then g is constant, because the image is connected. Combined with "closed sets absorb limits along dense sets", this is the standard two line rigidity engine. See Book 1, field: Real analysis, topic: connectedness.

The recursion, generalised. The recursion here is refinement of lattices: $G_1 \subseteq G_2 \subseteq G_6 \subseteq \cdots$ along $G_m = \frac{1}{m}\mathbb{Z}$ ordered by divisibility, with mesh $\frac{1}{m} \to 0$. The general statement is this. Let f be differentiable on $\mathbb{R}$ and let (G_m) be subgroups $\frac{1}{m}\mathbb{Z}$ with $f(G_m) \subseteq G_m$ for all m in an infinite set S of positive integers with unbounded elements. Then every mesh step secant slope over G_m lies in $\mathbb{Z}$, so by the mean value theorem f' is integer valued on a set meeting every interval of length greater than $2/\min\{m \in S, m > M\}$ for each M, hence on a dense set. If moreover f' is continuous then f' is a constant integer and f is affine. The same statement holds verbatim in $\mathbb{R}^n$ with $\frac{1}{m}\mathbb{Z}^n$ and the derivative matrix, giving an affine map with matrix in $M_n(\mathbb{Z})$; and if the map is required

to preserve denominators exactly in each coordinate, the matrix must be invertible over $\mathbb{Z}$. This is the general method for any "preserves all refinements of a lattice" hypothesis: read the mesh step quotient, apply the mean value theorem, use density and continuity, then repay the strength you dropped.

Circuit Bank

- **WHEN** a hypothesis constrains f only on $\mathbb{Q}$ or another countable set, while the regularity hypothesis is on all of $\mathbb{R}$ **DO** force the arithmetic into a difference quotient, and choose the increment so that the quotient is an integer by construction **BECAUSE** the derivative is the only object that reads both the local analysis and the discrete values, and an integer valued quantity in a limit is far more rigid than a real one
- **WHEN** a set defined by "denominator equals b" appears **DO** split it into "denominator divides m", which is the subgroup $\frac{1}{m}\mathbb{Z}$, and the leftover coprimality, and use only the subgroup until the last step **BECAUSE** difference quotients subtract, subgroups are closed under subtraction, and sets defined by exact denominators are not
- **WHEN** you hold an integer secant slope and want a statement about f' **DO** apply the mean value theorem and keep only the fact that the point exists inside a short interval **BECAUSE** you never need to know where the derivative attains the slope, only that the attaining points are dense, and density is cheaper than convergence
- **WHEN** a continuous function takes values in $\mathbb{Z}$, or in any closed set with empty interior, on a dense set **DO** conclude the values lie in that set everywhere, and if the set is discrete and the domain is an interval, conclude the function is constant **BECAUSE** closed sets absorb limits along dense sequences, and a continuous image of a connected set is connected, so it cannot straddle two isolated points
- **WHEN** you deliberately weakened a hypothesis to make it structural **DO** repay the lost strength at the very end, at one cheap test point chosen so the algebra collapses **BECAUSE** a single well chosen evaluation, here $q = 1/b$ with numerator 1, replaces a general coprimality argument that would otherwise be repeated at every rational

Backtesting

1. First useful cue: "the same denominator" read as "denominator divides m", giving $f(\frac{1}{m}\mathbb{Z}) \subseteq \frac{1}{m}\mathbb{Z}$, the only form of the hypothesis stable under the subtraction inside a difference quotient.
2. Method the expression suggested: an integer secant slope over one lattice step, upgraded to a derivative value by the mean value theorem, then density plus continuity.
3. Where you would hesitate, and the thought to reinforce: at the choice to weaken the hypothesis, since throwing away strength feels wrong. Reinforce that you are not throwing it away, you are deferring it; the exactness clause is spent once, at $q = 1/b$, and buys the last constraint $\gcd(k, b) = 1$.
4. The trap the question sets: assuming $q + \frac{1}{n}$ has denominator bn for every n. It does not; $\frac{1}{3} + \frac{1}{2} = \frac{5}{6}$ is fine but $\frac{1}{3} + \frac{1}{6} = \frac{1}{2}$ is not. Anyone who takes the difference quotient route without the divisibility condition $b \mid j$ has a false lemma in the middle of the proof.
5. What makes you recognise it faster next time: the pairing of a countable arithmetic hypothesis with a differentiability hypothesis. That pairing has exactly one bridge, the difference quotient, and the only design decision is the increment.

6. The reusable decision rule: to exploit an arithmetic constraint analytically, choose the increment equal to the reciprocal of the common denominator of the two values being subtracted, so the quotient is an integer with nothing to verify.

Mirror drills

1. Find all continuously differentiable $f : \mathbb{R} \to \mathbb{R}$ such that for every rational q, the denominator of $f(q)$ divides the denominator of q. *Answer:* $f(x) = kx + n$ with $k, n \in \mathbb{Z}$. The proof is Steps 1 to 3 unchanged; Step 4 disappears because the exactness clause is exactly what was dropped.
2. Suppose $g : \mathbb{R} \to \mathbb{R}$ is differentiable at 0, $g(0) = 0$, and $g(1/m) \in \frac{1}{m}\mathbb{Z}$ for every positive integer m. Show $g'(0) \in \mathbb{Z}$. *Answer:* $m\,g(1/m)$ is an integer for every m and converges to $g'(0)$; a convergent sequence of integers is eventually constant, so the limit is that integer.
3. Let f be differentiable on $\mathbb{R}$ with $f'(x) \in \{-1, 1\}$ for every x, with no continuity assumed on f'. Show $f(x) = x + c$ or $f(x) = -x + c$. *Answer:* Darboux's theorem gives f' the intermediate value property, so it cannot take both values without taking 0; hence f' is constant, and integrate. This isolates precisely which use of "continuously" in the original problem is removable and which is not.

18.12 B6. Parity of banded permutations via determinants modulo two

Let n and k be positive integers. Say that a permutation σ of $\{1, 2, \ldots, n\}$ is k-limited *if $|\sigma(i) - i| \leq k$ for all i. Prove that the number of k-limited permutations of $\{1, 2, \ldots, n\}$ is odd if and only if $n \equiv 0$ or $1 \pmod{2k+1}$.*

Read it out loud

Read the structure: you are asked for the parity of a count of permutations, where the constraint on the permutation is local and of the form "$\sigma(i)$ must lie in a prescribed set of columns". Two words in that sentence are doing everything. *Parity* means you never have to compute the count, and it means that all signs are free, because $+1$ and -1 are the same element of $\mathbb{F}_2$. *Prescribed set of columns* means the constraint is exactly a $0/1$ matrix: put a 1 in position (i, j) when $\sigma(i) = j$ is allowed. The fields wired in are combinatorics (counting permutations with restricted positions), linear algebra over a finite field (determinant, rank, kernel), and linear recurrences (because the matrix is translation invariant along the diagonal).

The first cue is "odd if and only if". That is never an invitation to compute the number; it is an invitation to find a structure that pairs almost all the objects up. Two structures do that here: an involution on the set of permutations, or a determinant, since a determinant is a signed count and modulo 2 the signs disappear. Within thirty seconds you should have written

$$\#\{k\text{-limited } \sigma\} \;=\; \operatorname{per}(M_{n,k}) \;\equiv\; \det(M_{n,k}) \pmod 2, \qquad (M_{n,k})_{ij} = \begin{cases} 1 & |i-j| \leq k \\ 0 & \text{otherwise,} \end{cases}$$

because the Leibniz formula for the determinant is a sum over permutations of $\pm$ the same products, and $\pm 1 \equiv 1$ modulo 2. The combinatorial problem has become a linear algebra problem: for which n is the banded matrix $M_{n,k}$ invertible over $\mathbb{F}_2$?

The second cue is the modulus in the answer. Each interior row of $M_{n,k}$ has exactly $2k+1$ ones. The answer's modulus is $2k+1$. That is not a coincidence you discover at the end; it is a prediction you make at the start, and it tells you what kind of object controls the problem: something with period equal to the band width. In a translation invariant matrix, the object with that period is a linear recurrence satisfied by the vectors in the kernel.

Approaches, ranked worst to best

1. **Count k-limited permutations exactly.** *Cue:* "the number of permutations" sounds like a counting problem. *Circuit:* find a closed form, then reduce it. There is no usable closed form. For fixed k the count satisfies a linear recurrence in n, but its order grows exponentially in k, and k is a free parameter here. This route does not stall late; it stalls at the first attempt to write a formula, and its only use is to make you realise that you must never evaluate the count.

2. **Transfer matrix dynamic programming modulo two.** *Cue:* the constraint is local, so scan left to right and carry a state. *Circuit:* profile dynamic programming. Correct in principle: the state is which of the last $2k$ positions have been used, so the transfer matrix has size $2^{O(k)}$ over $\mathbb{F}_2$, and the claim becomes a statement about the order of that matrix. You would still have to discover the period $2k+1$ by hand, and the bookkeeping is unmanageable for general k in the arena. Rank it above brute force only because it is at least finite.

3. **Pair permutations with their inverses.** *Cue:* "odd if and only if" asks for an involution with few fixed points. *Circuit:* parity via a fixed point free pairing. Since σ is k-limited if and only if σ^{-1} is, inversion is an involution on the set, so the count has the parity of the number of k-limited *involutions*. Grouping those by their restriction to $\{k+2, \ldots, n\}$ makes every class even except the ones in bijection with the k-limited involutions of $\{2k+2, \ldots, n\}$, which

gives $F_{n,k} \equiv F_{n-2k-1,k}$ directly. It is the most purely combinatorial solution, but the class size bookkeeping is fiddly to make airtight under time pressure.

4. **Determinant modulo two, then block row reduction.** *Cue:* parity of a restricted permanent is a determinant modulo two. *Circuit:* permanent equals determinant over $\mathbb{F}_2$, then Gaussian elimination. Clear the top left $(2k+1) \times (2k+1)$ corner of $M_{n,k}$ to a permutation matrix using only rows and columns 1 to $k+1$, which never touches the bottom right block; what remains is block diagonal with an invertible corner and $M_{n-2k-1,k}$, giving $\det M_{n,k} \equiv \det M_{n-2k-1,k}$, and then you check the base cases $n = 0, \ldots, 2k$. Correct, and the standard write up, but the elimination is much easier to draw than to write.

5. **Determinant modulo two, then a direct kernel analysis.** *Cue:* a banded translation invariant matrix has a kernel governed by a linear recurrence. *Circuit:* Toeplitz band gives $a_{m-k} = a_{m+k+1}$, so kernel vectors have period $2k+1$. Same first move, but instead of eliminating, ask directly when $M_{n,k}$ has a nonzero kernel over $\mathbb{F}_2$. Subtracting consecutive coordinate equations turns the band into the recurrence $a_{m+k+1} = a_{m-k}$; the boundary zeros then force k coordinates to vanish at each end, and where those two blocks land modulo $2k+1$ is decided entirely by n modulo $2k+1$. In the bad residues you can even write the dependency down explicitly, as two different arithmetic progressions of rows that both sum to the all ones vector. No pictures, no elimination, and the modulus $2k+1$ appears as the degree of a recurrence rather than as the outcome of a computation. This is the route to write.

The ideal solution

Write $F_{n,k}$ for the number of k-limited permutations of $\{1, \ldots, n\}$, and let $M = M_{n,k}$ be the $n \times n$ matrix over the field $\mathbb{F}_2$ with

$$M_{ij} = \begin{cases} 1 & |i-j| \le k, \\ 0 & \text{otherwise.} \end{cases}$$

Denote its rows by $r_1, \ldots, r_n$; the support of r_t is $[t-k, t+k] \cap [1, n]$.

Step 1: the parity is a determinant. By the Leibniz formula, computed in $\mathbb{F}_2$,

$$\det M = \sum_{\sigma} \operatorname{sgn}(\sigma)\, M_{1\sigma(1)} \cdots M_{n\sigma(n)}.$$

The product $M_{1\sigma(1)} \cdots M_{n\sigma(n)}$ equals 1 precisely when $|\sigma(i) - i| \le k$ for every i, and equals 0 otherwise; and $\operatorname{sgn}(\sigma) = \pm 1 \equiv 1$ in $\mathbb{F}_2$. Hence $\det M$ is the image of $F_{n,k}$ in $\mathbb{F}_2$, that is,

$$F_{n,k} \equiv \det M_{n,k} \pmod 2.$$

So it suffices to prove that $M_{n,k}$ is invertible over $\mathbb{F}_2$ if and only if $n \equiv 0$ or $1 \pmod{2k+1}$.

Step 2: if $n \equiv 2, 3, \ldots, 2k \pmod{2k+1}$ then M is singular. Let s be the residue of n modulo $2k+1$, with $2 \le s \le 2k$ (so $k \ge 1$ and $n \ge 2$). Put $t = 2k+1-s$, so $1 \le t \le 2k-1$. Choose integers a, b with $0 \le a < b \le k$ and $a + b = t$: take $(a, b) = (0, t)$ if $t \le k$, and $(a, b) = (t-k, k)$ if $k < t \le 2k-1$. Set

$$j = \frac{n+a+b}{2k+1} \in \mathbb{Z}_{\ge 1},$$

which is an integer because $n + a + b \equiv s + t \equiv 0 \pmod{2k+1}$, and is positive because $n + a + b \ge 3$.

Consider the row indices $u_i = (k+1-a) + (2k+1)i$ for $i = 0, 1, \ldots, j-1$. They lie in $[1, n]$: the smallest is $k + 1 - a \ge 1$ because $a \le k$, and the largest is

$$(k+1-a) + (2k+1)(j-1) = (k+1-a) + (n+a+b) - (2k+1) = n + b - k \le n$$

because $b \le k$. Consecutive indices differ by $2k+1$, so the supports $[u_i - k, u_i + k]$ are pairwise disjoint abutting blocks of length $2k+1$, and their union is the interval $[u_0 - k, u_{j-1} + k] = [1 - a,\ n + b]$, which contains $[1, n]$. Every column of $[1, n]$ therefore lies in exactly one of these supports, so over $\mathbb{F}_2$

$$\sum_{i=0}^{j-1} r_{u_i} = (1, 1, \ldots, 1).$$

Running the identical computation with b in place of a, the indices $v_i = (k + 1 - b) + (2k+1)i$ for $i = 0, \ldots, j-1$ also lie in $[1, n]$ (smallest $k + 1 - b \ge 1$, largest $n + a - k \le n$) and likewise

$$\sum_{i=0}^{j-1} r_{v_i} = (1, 1, \ldots, 1).$$

Since $0 < b - a \le k < 2k+1$, the indices u_i and $v_{i'}$ are never equal (they lie in different residue classes modulo $2k+1$), so $\{u_i\}$ and $\{v_i\}$ are disjoint nonempty sets of row indices. Adding the two identities gives

$$\sum_{i=0}^{j-1} r_{u_i} + \sum_{i=0}^{j-1} r_{v_i} = 0$$

with all $2j \ge 2$ coefficients equal to 1, a nontrivial linear dependence among the rows. Hence $\det M = 0$ and $F_{n,k}$ is even.

Step 3: if $n \equiv 0$ or $1 \pmod{2k+1}$ then M is invertible. If $n = 1$ then $M = (1)$ and there is nothing to prove, so assume $n \ge 2$; then $n \ge 2k+1$ in the first case and $n \ge 2k+2$ in the second, so in both cases $n \ge 2k + 1 > k$.

Let $a_1, \ldots, a_n \in \mathbb{F}_2$ satisfy $a_1 r_1 + \cdots + a_n r_n = 0$, and extend the notation by setting $a_i = 0$ for $i \le 0$ and for $i > n$. Column m of r_i is 1 exactly when $|i - m| \le k$, so the m-th coordinate of the dependence reads

$$c_m := a_{m-k} + a_{m-k+1} + \cdots + a_{m+k} = 0 \qquad (1 \le m \le n).$$

Adding c_m and c_{m+1} (in $\mathbb{F}_2$, adding is subtracting) cancels the $2k$ common terms and leaves

$$a_{m-k} = a_{m+k+1} \qquad (1 \le m \le n-1). \tag{$*$}$$

Equivalently, $a_i = a_{i+2k+1}$ whenever $1 - k \le i \le n - 1 - k$: the coefficients are periodic with period $2k+1$ throughout the range where the relation applies.

Take $m = 1, 2, \ldots, k$ in $(*)$. The left hand sides are $a_{1-k}, a_{2-k}, \ldots, a_0$, all with index at most 0 and therefore zero, so

$$a_{k+2} = a_{k+3} = \cdots = a_{2k+1} = 0. \tag{L}$$

Take $m = n - k, n - k + 1, \ldots, n - 1$ in $(*)$. The right hand sides are $a_{n+1}, \ldots, a_{n+k}$, all with index greater than n and therefore zero, so

$$a_{n-2k} = a_{n-2k+1} = \cdots = a_{n-1-k} = 0. \tag{R}$$

Suppose first $n = (2k+1)N$ with $N \ge 1$. For $1 \le i \le k$, repeated use of $(*)$ gives

$$a_i = a_{i+(2k+1)} = \cdots = a_{i+(2k+1)(N-1)} = a_{n-2k-1+i},$$

every step being legitimate because the indices used never exceed $n - 1 - k$. As i runs over $1, \ldots, k$ the right hand index runs over $n - 2k, \ldots, n - k - 1$, which is exactly the block (R). Hence $a_1 = \cdots = a_k = 0$. Together with (L) this gives $a_i = 0$ for every $i \in \{1, \ldots, 2k+1\}$ except possibly $i = k+1$. Now the equation $c_{k+1} = 0$ reads $a_1 + a_2 + \cdots + a_{2k+1} = 0$, which forces $a_{k+1} = 0$ as well. Finally $(*)$ propagates $a_i = a_{i+2k+1}$ from the block $\{1, \ldots, 2k+1\}$ rightwards through all of $[1, n]$, so every a_i is zero.

Suppose instead $n = (2k+1)N+1$ with $N \geq 1$. Now $n-2k = 2+(2k+1)(N-1)$ and $n-1-k = (k+1)+(2k+1)(N-1)$, so for $2 \leq i \leq k+1$ the same chain

$$a_i = a_{i+(2k+1)} = \cdots = a_{i+(2k+1)(N-1)}$$

identifies $a_2, \ldots, a_{k+1}$ with the entries of the block (R), so $a_2 = \cdots = a_{k+1} = 0$. Together with (L) this gives $a_2 = a_3 = \cdots = a_{2k+1} = 0$, and $c_{k+1} = 0$ then forces $a_1 = 0$. Propagating by $(*)$ as before, every a_i is zero.

In both cases the rows of M are linearly independent over $\mathbb{F}_2$, so $\det M \neq 0$ in $\mathbb{F}_2$ and $F_{n,k}$ is odd.

Steps 2 and 3 together say $\det M_{n,k} \neq 0$ in $\mathbb{F}_2$ exactly when $n \equiv 0$ or $1 \pmod{2k+1}$, which by Step 1 is exactly the assertion that $F_{n,k}$ is odd in those cases and even otherwise. ■

Layer 1: WHAT

Block 1. Parity of a count of permutations with prescribed allowed positions is the permanent of a $0/1$ matrix modulo 2, and modulo 2 the permanent is the determinant.

Block 2. So the question is: for which n is the banded matrix $M_{n,k}$ invertible over $\mathbb{F}_2$? The combinatorics is finished at this line.

Block 3. The matrix is translation invariant along the diagonal, so consecutive coordinate equations for a kernel vector differ in only two places, giving the recurrence $a_{m-k} = a_{m+k+1}$.

Block 4. That recurrence says kernel vectors are periodic with period $2k+1$. The modulus of the answer is now explained, before any case analysis.

Block 5. The zero padding outside $[1, n]$ turns the first k and last k equations into two blocks of k forced zeros, one anchored at each end.

Block 6. Where the right hand block lands modulo $2k+1$ depends only on n modulo $2k+1$. For $n \equiv 0$ or 1 the two blocks are complementary and cover all residues except one, which the central equation kills; the kernel is trivial.

Block 7. For the other residues, do not argue by counting; exhibit the dependency. Two arithmetic progressions of rows with common difference $2k+1$, offset by $k+1-a$ and $k+1-b$, each tile $[1, n]$ and so each sum to the all ones vector; their sum is a nontrivial relation.

The nominal route conditions on $\sigma(1)$, obtains a recurrence for $F_{n,k}$ in n, and tries to track it modulo 2. For $k = 1$ that route works and gives the Fibonacci numbers; for general k the recurrence has order growing with k and the parity pattern is invisible. The bifurcation point is Block 1: the moment you decide to stop counting permutations and start computing a determinant. The licence for that decision is the single observation that signs are invisible modulo 2, and the payoff is that all of linear algebra becomes available for a combinatorial question.

Layer 2: HOW

Block 1. Cue. "Odd if and only if", attached to a count of permutations whose constraint is "$\sigma(i)$ lies in an allowed set". **Why natural.** A count of permutations with prescribed allowed positions is by definition a permanent of a $0/1$ matrix. The permanent is intractable in general, but modulo 2 it coincides with the determinant, because the only difference between the two is the factor $\operatorname{sgn}(\sigma) = \pm 1$ and $-1 = 1$ in $\mathbb{F}_2$. Parity is therefore the one regime in which a permanent is computable, and the problem asks for exactly that regime. Notice what you did not do: you did not look for a bijection or a formula, because the words "odd if and only if" told you signs would be free. **Link to the next block.** You now own a concrete matrix, so every question about it is a question about its rank.

Block 2. Cue. The matrix is defined by $|i-j| \leq k$, which depends only on $i-j$. **Why natural.** A matrix whose entries depend only on $i-j$ is Toeplitz, and Toeplitz means translation invariant, and translation invariant systems have solution spaces described by linear recurrences. Reading

the band width off the definition, an interior row has $2k+1$ ones, which is already the modulus in the answer; that match tells you that you are looking for a recurrence of order $2k+1$ and that you should stop looking for anything else. **Link to the next block.** To find the recurrence, look at what changes between one coordinate equation and the next.

Block 3. **Cue.** Consecutive coordinate equations of the dependence share $2k$ of their $2k+1$ terms. **Why natural.** Adding two equations that overlap in $2k$ terms annihilates the overlap and leaves the two extreme terms, a_{m-k} and a_{m+k+1}. Over $\mathbb{F}_2$ that says they are equal. This is the standard way to extract a recurrence from a band: differencing kills the interior. The distance between the two survivors is $(m+k+1)-(m-k)=2k+1$, the band width, which is why the period is what it is. **Link to the next block.** A recurrence needs boundary conditions, and the boundary conditions are hiding in the convention that $a_i = 0$ outside $[1,n]$.

Block 4. **Cue.** The padding $a_i = 0$ for $i \le 0$ and $i > n$ was introduced only to write the coordinate equation uniformly, and free information usually hides in such conventions. **Why natural.** Apply the recurrence at the k leftmost usable values of m: each one equates a padded zero with a genuine coefficient, so it kills a genuine coefficient. The same at the right end. Two blocks of k zeros, at positions $k+2,\dots,2k+1$ from the left and $n-2k,\dots,n-1-k$ from the right. That is $2k$ of the $2k+1$ residues. **Link to the next block.** The one remaining residue must be killed by an equation that has not yet been used, and the only untouched equation is a coordinate equation rather than a difference of two.

Block 5. **Cue.** Exactly one residue class is still alive, and $c_{k+1} = 0$ is a single equation involving precisely $a_1,\dots,a_{2k+1}$. **Why natural.** The middle equation $c_{k+1} = 0$ is the unique coordinate equation whose window is exactly $[1,2k+1]$, with no padding on either side. If all but one of its terms are already known to vanish, it determines the last one. The arithmetic of which residues the two blocks occupy is the entire content of the case split, and it depends only on n modulo $2k+1$, because periodicity transports the right hand block leftwards by multiples of $2k+1$. **Link to the next block.** If the two blocks overlap or fail to cover $2k$ residues, the argument breaks, and where it breaks you should expect an actual dependency, so switch from proving independence to constructing a relation.

Block 6. **Cue.** For the bad residues you need to *produce* a dependency, not to fail to rule one out. **Why natural.** Rows whose indices form an arithmetic progression of common difference $2k+1$ have supports that are consecutive disjoint blocks of length $2k+1$, so they tile an interval and sum to its indicator. Choose the starting offset so that the tiled interval contains $[1,n]$; the sum is then the all ones vector. Two different offsets $k+1-a$ and $k+1-b$ both work exactly when $a+b \equiv -n \pmod{2k+1}$ with $0 \le a < b \le k$, and such a pair exists precisely for the residues $2,\dots,2k$. The condition $a,b \le k$ is what keeps the progressions inside $[1,n]$; the condition $a \ne b$ is what makes the relation nontrivial. **Link to the next block.** The two directions together are an if and only if, so state the conclusion in the language of the question, in terms of parity, not of determinants.

Layer 3: WHY

The first truth is that the permanent and the determinant of a matrix coincide over any ring of characteristic 2. Every question of the form "is the number of systems of distinct representatives odd" is therefore a rank question over $\mathbb{F}_2$, and rank questions have tools: elimination, kernels, explicit dependencies. This single transfer is the most valuable thing in the problem, and it is worth memorising in the general form: parity of a restricted permutation count equals the $\mathbb{F}_2$ determinant of the allowed positions matrix.

The second truth is that a banded Toeplitz matrix is a difference operator in disguise. Its kernel over a field is the solution set of a constant coefficient linear recurrence, subject to boundary conditions imposed by the finite window. The recurrence is read off the *symbol* of the band: here the interior row is $1 + x + \cdots + x^{2k}$, and over $\mathbb{F}_2$

$$(1 + x)\left(1 + x + \cdots + x^{2k}\right) = 1 + x^{2k+1},$$

so multiplying the coordinate equations by $(1 + x)$, which is exactly what adding consecutive equations does, produces the relation $a_i = a_{i+2k+1}$ with characteristic polynomial $x^{2k+1} + 1$. Every solution of that recurrence is periodic with period dividing $2k + 1$, and the solution space over the whole line is $(2k + 1)$ dimensional. The finite window imposes k conditions from the left edge, k from the right edge, and one from the central equation; $k + k + 1 = 2k + 1$, so generically the kernel is cut down to zero. It is only when the two edge blocks collide, that is when they occupy overlapping residues, that fewer than $2k + 1$ independent conditions are imposed and a kernel vector survives. That collision is governed by n modulo $2k + 1$, and the arithmetic works out to the residues $2, \ldots, 2k$.

The discernment mechanism is a two step reflex. First, when the parity of a combinatorial count is requested, ask whether the objects are matchings, permutations or systems of distinct representatives; if they are, the count is a permanent and modulo 2 it is a determinant. Second, when the resulting matrix is translation invariant, do not eliminate; difference the equations to get a recurrence, read the period off the band width, and let the boundary conditions do the case analysis. Train it on $k = 1$, $n = 1, \ldots, 5$, watching the Fibonacci parity pattern $1, 0, 1, 1, 0, \ldots$ emerge with period $3 = 2k + 1$.

The examiners nudged you by asking for parity rather than the count, by making the constraint symmetric in i and j so that inversion is available as a second route, and above all by putting $2k + 1$ in the answer, which is the number of ones in an interior row. When the modulus in the conclusion equals a structural width in the hypothesis, the proof runs through an object of that period.

Revolving concepts

Permanent, determinant and characteristic 2. For an $n \times n$ matrix, $\operatorname{per}(M) = \sum_\sigma \prod_i M_{i\sigma(i)}$ and $\det(M) = \sum_\sigma \operatorname{sgn}(\sigma) \prod_i M_{i\sigma(i)}$. Over any commutative ring in which $2 = 0$ these agree. For a $0/1$ matrix, $\operatorname{per}(M)$ counts the permutations σ with $M_{i\sigma(i)} = 1$ for all i, that is, the systems of distinct representatives. See Book 1, field: Matrices and determinants, topic: permanent and Leibniz formula.

Linear algebra over $\mathbb{F}_2$. A square matrix over a field is invertible if and only if its rows are linearly independent, if and only if its determinant is nonzero. Over $\mathbb{F}_2$, addition is subtraction, a linear combination is a subset sum of rows, and a linear dependency is precisely a pair of distinct subsets of rows with equal sums. That last reformulation is what makes Step 2 constructive. See Book 1, field: Linear algebra, topic: rank over finite fields.

Banded and Toeplitz matrices. A matrix with M_{ij} depending only on $i - j$ is Toeplitz; if additionally $M_{ij} = 0$ for $|i - j| > k$ it is banded with band width $2k + 1$. Its symbol is the Laurent polynomial $\sum_{|d| \le k} c_d x^d$. Kernel vectors of the finite section satisfy the linear recurrence whose characteristic polynomial is the symbol, with the finite window supplying boundary conditions. See Book 1, field: Matrices and determinants, topic: Toeplitz and banded matrices.

Involutions and parity. The map $\sigma \mapsto \sigma^{-1}$ is an involution on S_n whose fixed points are the involutions, so the number of involutions of an m-element set has the same parity as $m!$, hence is odd exactly when $m \le 1$. Since σ is k-limited if and only if σ^{-1} is, $F_{n,k}$ has the same parity as the number of k-limited involutions; this is the engine of the third ranked approach. See Book 1, field: Combinatorics, topic: sign reversing and fixed point involutions.

The recursion, generalised. Two recursions live here and both should be stated in general form. The first is the recurrence satisfied by a kernel vector: $a_{i+2k+1} = a_i$, a constant coefficient linear

recurrence of order $2k+1$ over $\mathbb{F}_2$ with characteristic polynomial $x^{2k+1}+1$; its general solution is "periodic with period dividing $2k+1$", the solution space has dimension $2k+1$, and the general method for any banded Toeplitz kernel is identical: multiply the symbol by whatever polynomial clears the interior (here $1+x$), read off the characteristic polynomial, and count boundary conditions against the dimension. The second is the congruence $F_{n,k} \equiv F_{n-2k-1,k} \pmod 2$ with the convention $F_{0,k}=1$, a recursion in n of step $2k+1$; its general solution is $F_{n,k} \equiv F_{r,k}$ where r is the residue of n modulo $2k+1$, so the whole problem reduces to the base window $r = 0, 1, \ldots, 2k$, in which $F_{r,k} = r!$ for $r \le k+1$ and the matrix has two equal rows for $k+2 \le r \le 2k$. Any "period P in the answer" problem should be attacked by looking for exactly this kind of step P congruence. See Book 1, field: Sequences and recurrences, topic: linear recurrences over finite fields.

Knowledge gaps, stated plainly. This problem is not approachable from A level Further Mathematics alone, and the missing theory is specific. You must have installed: the Leibniz formula for a determinant of arbitrary size (Edexcel FP1 gives you 2×2 and 3×3 determinants as formulas, not as sums over permutations); the notion of a field with two elements and of linear algebra over it, including "determinant nonzero if and only if rows independent" over a field that is not $\mathbb{R}$; the permanent, and the fact that it counts systems of distinct representatives; the sign of a permutation as a group homomorphism to $\{\pm 1\}$; and the vocabulary of Toeplitz and banded matrices. None of these is hard, but each is a genuine prerequisite, and without the first three the problem cannot even be started.

Circuit Bank

- **WHEN** you are asked for the parity of the number of permutations, matchings or systems of distinct representatives satisfying "$\sigma(i)$ lies in an allowed set S_i" **DO** build the $0/1$ matrix $M_{ij} = [\, j \in S_i \,]$ and replace the count by $\det M$ computed over $\mathbb{F}_2$ **BECAUSE** the permanent and the determinant differ only by $\operatorname{sgn}(\sigma) = \pm 1$, which is 1 modulo 2, so a parity question is the one case where a permanent is computable, and it hands you the whole of linear algebra

- **WHEN** a matrix over a field has entries depending only on $i-j$, especially with a narrow band **DO** add consecutive coordinate equations of a kernel vector to cancel the overlap, producing a linear recurrence whose order is the band width **BECAUSE** a Toeplitz band is a difference operator, its kernel is the solution set of a constant coefficient recurrence, and differencing is exactly multiplication of the symbol by $(1+x)$, which collapses $1+x+\cdots+x^{2k}$ to $1+x^{2k+1}$

- **WHEN** the answer to a problem contains a modulus, and some structural width in the hypothesis equals that modulus **DO** stop searching for a formula and search for an object of that period, typically a recurrence or a tiling **BECAUSE** a modulus in a conclusion is almost always the order of a translation symmetry present in the setup, and identifying it early tells you the shape of the whole proof

- **WHEN** you must show a matrix over $\mathbb{F}_2$ is singular **DO** exhibit two distinct sets of rows with the same sum, most conveniently the all ones vector **BECAUSE** over $\mathbb{F}_2$ the sum of the two sets is a nontrivial dependency, and rows of a banded matrix whose indices form an arithmetic progression of common difference equal to the band width have disjoint abutting supports, so they tile an interval and sum to its indicator

- **WHEN** a parity question concerns a set carrying a natural involution **DO** pair each object with its image and count only the fixed points **BECAUSE** everything not fixed cancels in pairs, so the parity of the whole set equals the parity of the fixed point set, and for permutations the involution $\sigma \mapsto \sigma^{-1}$ preserves almost every natural positional constraint

Backtesting

1. First useful cue: "odd if and only if" attached to a permutation count with prescribed allowed positions, which converts at once into $\det M_{n,k}$ over $\mathbb{F}_2$ with $M_{ij} = [\,|i-j| \le k\,]$.
2. Method the expression suggested: the band condition $|i-j| \le k$ is Toeplitz, so difference the coordinate equations of a kernel vector to obtain $a_{i+2k+1} = a_i$ and let the boundary padding supply the conditions.
3. Where you would hesitate, and the thought to reinforce: at the case analysis, because it looks like arithmetic bookkeeping with no idea in it. Reinforce the dimension count: the recurrence space has dimension $2k+1$, the left edge imposes k conditions, the right edge k, the central equation 1, and $k+k+1 = 2k+1$; the kernel survives exactly when the two edge blocks fail to be complementary, and that failure is a statement about n modulo $2k+1$.
4. The trap the question sets: proving only one direction. Showing that the residues 0 and 1 give an invertible matrix is the easier half and reads like a complete solution; without the explicit dependency in the other residues you have proved "odd if" and not "only if", which is half the marks. The second trap is forgetting that $n = 1$ falls outside the index ranges used in Step 3 and must be checked directly.
5. What makes you recognise it faster next time: the modulus of the conclusion equalling the number of ones in an interior row. Any problem in which a stated period matches a structural width is a translation symmetry problem, and the proof will run through a recurrence of exactly that order.
6. The reusable decision rule: parity of a restricted permutation count is an $\mathbb{F}_2$ determinant; an $\mathbb{F}_2$ determinant of a banded Toeplitz matrix is decided by a linear recurrence of order equal to the band width together with the boundary conditions from the finite window.

Mirror drills

1. Show that the number of involutions of an m-element set is odd if and only if $m \le 1$. *Answer:* pair each non involution σ with σ^{-1}; the pairs cancel, so the count has the same parity as $|S_m| = m!$, which is odd exactly for $m = 0, 1$.
2. Take $k = 1$. Show that $F_{n,1}$ is the Fibonacci number with $F_{1,1} = 1$, $F_{2,1} = 2$, and confirm directly that it is odd exactly when $n \equiv 0$ or $1 \pmod 3$. *Answer:* condition on $\sigma(1)$, which is 1 or 2; if $\sigma(1) = 1$ the rest is a 1-limited permutation of $\{2, \dots, n\}$, and if $\sigma(1) = 2$ then $\sigma(2) = 1$ forcibly, leaving $\{3, \dots, n\}$. So $F_{n,1} = F_{n-1,1} + F_{n-2,1}$, and the Fibonacci parity sequence is $1, 0, 1, 1, 0, 1, \dots$ with period $3 = 2k+1$.
3. Prove $F_{n,k} \equiv F_{n-2k-1,k} \pmod 2$ for $n \ge 2k+1$, with $F_{0,k} = 1$, using only the determinant. *Answer:* in $M_{n,k}$ add row 1 to rows $2, \dots, k+1$ and then column 1 to columns $2, \dots, k+1$; repeat with rows $2, \dots, k+1$ to clear the remaining entries of the top left $(2k+1) \times (2k+1)$ corner, using only the first $k+1$ rows and columns so that the unseen part of the matrix is never disturbed. The result is block diagonal with an invertible corner and $M_{n-2k-1,k}$, so the determinants agree modulo 2.

Chapter 19

Putnam 2007

19.1 A1. Two mirrored parabolas and their tangency values

Find all values of α for which the curves

$$y = \alpha x^2 + \alpha x + \frac{1}{24}, \qquad x = \alpha y^2 + \alpha y + \frac{1}{24}$$

are tangent to each other.

Read it out loud

Say the two equations aloud and you hear the same sentence twice, once with x and y swapped. That is the loudest cue on the page, louder than "tangent", louder than the $\frac{1}{24}$. Before you write a single derivative, register it explicitly: the second curve is not some unrelated parabola, it is the first curve reflected in the line $L : y = x$. Everything downstream should be organised around that fact, because a pair of curves exchanged by a reflection has its whole intersection structure constrained by the reflection: any point where they meet is either fixed by the reflection (sits on L) or comes paired with its mirror image, which also has to be a meeting point.

The fields wired into the problem are coordinate geometry (two conics), the calculus of tangency (matching derivatives, or a repeated root under elimination) and, once you commit to eliminating a variable, ordinary quadratic theory (discriminants, Vieta). What is really being tested is whether you let the symmetry do the organising work before you touch a derivative, or whether you set up three unknowns (x_0, y_0, α) and a slope matching condition and grind.

The first useful line to have written within thirty seconds is $f(x) = \alpha x^2 + \alpha x + \frac{1}{24}$, so that the two curves read $y = f(x)$ and $x = f(y)$: the same function, twice.

Approaches, ranked worst to best

1. **raw simultaneous system.** *Cue:* "tangent" reads as "matching slopes". *Circuit:* set $f'(x_0) = 1/g'(y_0)$ alongside both curve equations. (three unknowns tied by three separate conditions, no organising principle, and the count of four solutions never becomes visible until very late, if at all; easy to lose a sign carrying x_0, y_0, α together)
2. **geometric case split on L.** *Cue:* C_2 is C_1 reflected in L. *Circuit:* case on whether C_1 meets L, is tangent to L, or crosses it, then rule out tangency off L by counting intersections. (close to a standard route, and rigorous once finished, but its last step borrows the fact that two conics meet in four points counted with multiplicity, machinery you would be reaching for mid exam if asked to defend it from scratch)
3. **eliminate to one quartic, force a factorisation.** *Cue:* the same function f appears on both sides. *Circuit:* substitute $y = f(x)$ into C_2, get a single quartic in x, and hunt for a repeated root. (turns two curves and a slope condition into one polynomial and one derivative; the four solutions and their split into on L and off L both fall out of the algebra rather than needing to be argued geometrically)

The ideal solution

Write $f(x) = \alpha x^2 + \alpha x + \frac{1}{24}$, so C_1 is $y = f(x)$ and C_2 is $x = f(y)$: C_2 is exactly C_1 reflected in $L : y = x$. If $\alpha = 0$, C_1 is the line $y = \frac{1}{24}$ and C_2 is the line $x = \frac{1}{24}$, which cross once, transversally; discard this case and take $\alpha \neq 0$ from here on.

A point $(x, f(x))$ of C_1 lies on C_2 exactly when $x = f(f(x))$. Subtracting the two defining equations gives

$$f(x) - f(y) = \alpha(x^2 - y^2) + \alpha(x - y) = \alpha(x - y)(x + y + 1),$$

so every common point of C_1, C_2 satisfies $(x-y)\big[\alpha(x+y+1)+1\big] = 0$. A subtraction alone always loses information, but keeping $y = f(x)$ alongside it does not: substituting throughout and expanding, the quartic that records every intersection factorises cleanly (check it by direct expansion) as

$$x - f(f(x)) \;=\; -\alpha\, Q_1(x)\, Q_2(x),$$

$$Q_1(x) = \alpha x^2 + (\alpha-1)x + \tfrac{1}{24}, \qquad Q_2(x) = \alpha x^2 + (\alpha+1)x + \tfrac{1}{24} + \tfrac{\alpha+1}{\alpha}.$$

$Q_1(x) = 0$ says exactly $f(x) = x$: the point sits on L. $Q_2(x) = 0$ says exactly $x + f(x) = -\frac{\alpha+1}{\alpha}$: the point sits on the mirror partner line. Both are genuine quadratics since $\alpha \neq 0$, so between them they carry all four intersections of the two conics, with nothing left over.

Now convert "tangent" into algebra. C_1 never has a vertical tangent, since it is a graph in x throughout, so at any point where C_1, C_2 touch, C_2's tangent there is non vertical too, i.e. $f'(y_0) \neq 0$. Writing $H(x) = x - f(f(x))$ and differentiating by the chain rule, $H'(x_0) = 1 - f'(f(x_0))f'(x_0) = 1 - f'(y_0)f'(x_0)$, which vanishes exactly when C_1's slope $f'(x_0)$ equals C_2's slope $1/f'(y_0)$: exactly tangency, not a transversal crossing. So you want the α for which $H(x) = -\alpha Q_1(x)Q_2(x)$ has a repeated root.

From the factorisation, $H' = -\alpha(Q_1'Q_2 + Q_1Q_2')$. At a root of Q_1 this vanishes iff Q_1 itself has a double root there, or Q_2 also vanishes there (symmetrically for a root of Q_2). So you need Q_1 to have a repeated root, or Q_2 to.

Q_1 repeated root: $\operatorname{disc}(Q_1) = (\alpha-1)^2 - \frac{\alpha}{6} = 0$, i.e. $6\alpha^2 - 13\alpha + 6 = 0$, giving $\alpha = \frac{2}{3}, \frac{3}{2}$.

Q_2 repeated root: its vertex sits at $x = -\frac{\alpha+1}{2\alpha}$, which is also the unique root of the linear equation $Q_1(x) - Q_2(x) \;=\; -2x - 1 - \frac{1}{\alpha} \;=\; 0$: so Q_1 and Q_2 agree there for every α, and the value of a quadratic at its own vertex is $-\operatorname{disc}/(4\cdot\text{leading coefficient})$, so both equal $-\operatorname{disc}(Q_2)/(4\alpha)$ at that point. In other words, whenever Q_2 has a repeated root, Q_1 vanishes there too, and that point is forced onto L: there is no off axis tangency left to hunt for separately, this case collapses back onto the first. Computing, $\operatorname{disc}(Q_2) = (\alpha+1)^2 - 4\alpha\left(\frac{1}{24} + \frac{\alpha+1}{\alpha}\right) = 0$ reduces to $6\alpha^2 - 13\alpha - 18 = 0$, giving $\alpha = \frac{13 \pm \sqrt{601}}{12}$.

No other value of α makes H have a repeated root, so

$$\boxed{\alpha \in \left\{ \frac{2}{3},\ \frac{3}{2},\ \frac{13+\sqrt{601}}{12},\ \frac{13-\sqrt{601}}{12} \right\}}.$$

Layer 1: WHAT

Block 1: rewrite both curves through one function f, see C_2 as C_1 reflected in L. Block 2: dismiss $\alpha = 0$ directly. Block 3: subtract the defining equations to get a necessary factorised condition. Block 4: keep $y = f(x)$ alive alongside that condition so nothing is lost, and land on the full quartic factorisation $H = -\alpha Q_1 Q_2$. Block 5: convert "tangent" to "H has a repeated root" via one chain rule differentiation, having ruled out the vertical tangent edge case. Block 6: read off, from the product rule shape of H', that a repeated root of the quartic means a repeated root of Q_1 or of Q_2. Block 7: two discriminant computations, two quadratics in α, four roots.

The nominal route sets up x_0, y_0, α as three tied unknowns from the start, with a slope matching condition alongside both curve memberships, and grinds an elimination without ever building a single polynomial to ask a repeated root question of. It can be made to work, but it hides the "exactly four, in two clean pairs" structure until very late. The bifurcation point is Block 1: the moment you decide whether to carry three unknowns through a slope condition, or eliminate immediately to one variable and ask when a polynomial has a repeated root. Every unknown you keep past that moment is ink you did not need to spend.

Layer 2: HOW

Block 1. **Cue.** The second equation is the first with x, y swapped. **Why natural.** A reflection exchanging two curves forces their combined intersection set to be invariant under that reflection: points are fixed by it (on L) or come in mirror pairs. **Link to the next block.** This tells you, before any algebra, that the eventual case split is on L versus off L, not some undifferentiated four points.

Block 2. **Cue.** α multiplies every squared term; at $\alpha = 0$ both curves degenerate to a line. **Why natural.** A degenerate case sitting right at the edge of your later working (you will shortly divide by α) has to be checked and dismissed explicitly, not left implicit. **Link to the next block.** Clears the way to treat $\alpha \neq 0$ as a standing hypothesis for the rest of the solution.

Block 3. **Cue.** Two equations, same shape, only x, y swapped: subtracting cancels the shared structure and factors. **Why natural.** $f(x) - f(y)$ is a difference of the same quadratic at two points, which always factors through $(x - y)$. **Link to the next block.** The factor $(x - y)[\ldots] = 0$ names the two lines, L and its mirror partner, that every intersection point has to sit on.

Block 4. **Cue.** Subtracting throws away information; you still have $y = f(x)$ sitting unused. **Why natural.** Keeping one original equation alongside the subtracted one is exactly enough to recover the other original equation, since it can be written as the first equation minus the subtracted one. **Link to the next block.** Substituting $y = f(x)$ throughout turns the necessary condition into the full quartic, no solutions missing.

Block 5. **Cue.** C_1 is a graph in x, so it never carries a vertical tangent. **Why natural.** Tangency of two curves, one of which is a graph, is exactly a repeated root of the polynomial obtained by substituting that graph into the other curve's equation, away from any point where the second curve itself goes vertical. **Link to the next block.** Differentiating $H(x) = x - f(f(x))$ by the chain rule gives a slope matching condition directly.

Block 6. **Cue.** H is presented as a product $-\alpha Q_1 Q_2$. **Why natural.** The product rule sends "H has a repeated root at a root of Q_1" to "Q_1 has a double root there, or Q_2 also vanishes there": nothing else can make the derivative vanish. **Link to the next block.** Two clean quadratic discriminant conditions replace what looked like a four way case split.

Layer 3: WHY

The mathematical truth underneath the route is that eliminating one variable between two conics, when one of them is literally a graph, never loses solutions and always produces a polynomial whose repeated roots are exactly the tangencies: this is a general fact about intersection multiplicity, not a coincidence of this problem, and it is worth installing permanently rather than re deriving under pressure. The discernment mechanism for choosing this route over the raw three unknown system is recognising, in the first thirty seconds, that the problem handed you a symmetry (the same function, two variables swapped) for free; a symmetry between two objects always constrains where their interaction can live, and the fastest working habit is to ask immediately what is fixed by it and what it pairs up. The examiners nudged you toward this by using the identical formula on both sides rather than two unrelated quadratics: had they wanted you to grind three unknowns, they would not have handed you a reflection.

Training this discernment is a matter of repetition on the cue itself: any time a problem presents the same expression with two variables exchanged, write down the reflection sentence before anything else, and ask what lies on the fixed line before asking what lies off it. The second half of the mechanism, checking whether the off axis branch secretly collapses back onto the fixed line, is

the part most solvers skip; here it is exactly what happens, a repeated root of Q_2 forces Q_1 to vanish at the same point too, and missing that check would have cost you a search for a second, and here nonexistent, family of solutions.

Revolving concepts

Tangency via elimination: if C_1 is $y = f(x)$ and C_2 another curve, substitute to get $H(x)$; common points are roots of H, and where C_2 has no vertical tangent, C_1, C_2 touch at x_0 exactly when $H(x_0) = H'(x_0) = 0$. See Book 1, field: Geometry, topic: intersection multiplicity of plane curves.

Two conics meet in four points: neither curve here is degenerate, so elimination gives degree four exactly, and Q_1, Q_2, two genuine quadratics, divide that four between them with nothing lost. See Book 1, field: Geometry, topic: Bezout style counting for two conics.

Discriminant and vertex value: a quadratic $Ax^2 + Bx + C$ has a repeated root iff $B^2 - 4AC = 0$, and its value at its own vertex $x = -B/(2A)$ equals $-(B^2 - 4AC)/(4A)$. See Book 1, field: Polynomials, topic: quadratic discriminant.

Reflection symmetry of an intersection set: if two curves are exchanged by a reflection, or any involution, of the plane, their mutual intersection set is invariant under it; points are fixed (on the mirror line) or paired. See Book 1, field: Geometry, topic: symmetry arguments in coordinate geometry.

No recursive structure appears in this problem: there is no sequence or self referential definition to generalise here, the repeated root idea is algebraic rather than recursive.

Circuit Bank

- **WHEN** two curves are literally each other under $x \leftrightarrow y$ or another visible swap **DO** rewrite both through one shared function and ask what the swap fixes **BECAUSE** the mutual intersection set of two curves exchanged by an involution is invariant under it, so the fixed locus organises the whole search
- **WHEN** you need "curve tangent to curve" and one of them is a graph $y = f(x)$ **DO** eliminate to a single polynomial $H(x)$ and ask for a repeated root, rather than matching two separately computed slopes by hand **BECAUSE** substitution into a graph never drops solutions, and repeated roots of one polynomial are far easier to characterise via discriminants than a three unknown slope matching system
- **WHEN** a case split produces two branches that came from the same underlying symmetry **DO** check whether the second branch collapses back into the first via Vieta or a vertex value comparison before treating it as independent **BECAUSE** branches born from one symmetry are rarely independent, and skipping the check risks either a missed rigour gap or an imaginary extra family of solutions
- **WHEN** you need the value of a quadratic at its own vertex **DO** use $-\text{disc}/(4A)$ directly **BECAUSE** it is a fact you should have installed, and it replaces a resubstitution with a one line read off

Backtesting

1. First useful cue: the right hand side of C_2's equation is the identical function f used for C_1, only with x, y exchanged.
2. Method the expression suggested: eliminate y via $y = f(x)$ and hunt for a repeated root of the resulting quartic in x, rather than juggle two curve equations and a separate slope condition.

3. Where you would hesitate, and the thought to reinforce: proving a repeated root of Q_2 cannot give a new tangency of its own; reinforce it by comparing Q_1 and Q_2 directly at the unique root of their difference, not by a vague symmetry appeal.
4. The trap the question sets: $\alpha = 0$ looks like it needs the general machinery, but it is simply two perpendicular lines and should be dismissed by one direct line, kept separate from the rest of the argument.
5. What makes you recognise it faster next time: a problem handing you two equations built from the identical formula with variables swapped is a reflection problem before it is a calculus problem, and the reflection sentence should be the first line you write.
6. The reusable decision rule: when two curves are exchanged by reflection in a line, organise the intersection search around that line, points on it and points off it in mirror pairs, before any derivative is taken.

Mirror drills

1. For which α are $y = \alpha x^2 + 1$ and $x = \alpha y^2 + 1$ tangent? *Hint:* same reflection, same $f(x) = \alpha x^2 + 1$; work out Q_1 (on L) first and its discriminant.
2. Two conics are given by equations of identical shape with x, y swapped; without computing anything, state which two conditions between them, on the line of symmetry and on its mirror partner line, account for every intersection point, and explain why nothing is left over.
3. For $y = x^2 + c$ and $x = y^2 + c$, find every c for which the two parabolas are tangent, and check directly whether each tangency you find sits on $y = x$.

19.2 A2. Minimal convex area meeting both hyperbolas

Find the least possible area of a convex set in the plane that intersects both branches of the hyperbola $xy = 1$ and both branches of the hyperbola $xy = -1$. (A set S in the plane is called convex if for any two points in S the line segment connecting them is contained in S.)

Read it out loud

Four disconnected pieces of curve, one in each quadrant, and a single convex set asked to touch all four. Convexity is the loud word here, and it is doing real work: the moment your set contains one point from each of the four branches, it contains the segment between any two of them, so it contains the whole convex hull of those four points. That turns a question about an unknown shaped region into a question about four numbers, one parameter per branch, which is exactly the kind of reduction that should happen in your head before any calculus.

The fields wired in are coordinate geometry (parametrising a point on $xy = 1$ or $xy = -1$), elementary convexity (segments and hulls), and an inequality: the area, once written out, is a cyclic sum of ratios, and a cyclic sum of a positive quantity and its reciprocal is an AM-GM signal you should react to immediately. What is really being tested is whether you trust the reduction "area of S is at least the area of some hull of four chosen points" enough to make it precise, rather than reaching for calculus of variations on a general convex region, which is far more machinery than a four branch touching condition needs.

The first useful line to have within thirty seconds: name one point per branch, $A = (a, \frac{1}{a})$ in the first quadrant with $a > 0$, and the analogous B, C, D in the other three, and ask what shape they force.

Approaches, ranked worst to best

1. **calculus of variations on a general region.** *Cue:* "least area" sounds like an optimisation over shapes. *Circuit:* parametrise the boundary of S and impose the four touching constraints with Lagrange multipliers. (treats S as an unknown curve rather than using convexity to collapse the problem to four numbers; heavy machinery, and the positivity and quadrant constraints are awkward to encode)

2. **assert the hull quadrilateral bound outright.** *Cue:* four points, one per branch, so their hull is a quadrilateral. *Circuit:* write $\text{area}(S) \geq \text{area}(ABCD)$ and apply AM-GM to the shoelace sum. (reaches the right number fast, but the assertion is not automatic: for some choices of a, b, c, d the point C, say, sits inside the triangle formed by A, B, D, so A, B, C, D in that cyclic order is not even a convex quadrilateral, and the bound needs a proof that survives that case, not just a picture of the nice case)

3. **fan out from the origin.** *Cue:* the four points sweep once around the origin, one quadrant each. *Circuit:* decompose the region into the four triangles from O to consecutive points, show each lies in S, sum areas, then AM-GM. (fully general, no hidden assumption about convex position, and the origin's membership in S falls out of the same convexity already used)

The ideal solution

Let S be convex and suppose it meets both branches of $xy = 1$ and both branches of $xy = -1$. Choose one point of S on each branch: $A = (a, \frac{1}{a})$ with $a > 0$ (quadrant 1, on $xy = 1$), $B = (-b, \frac{1}{b})$ with $b > 0$ (quadrant 2, on $xy = -1$), $C = (-c, -\frac{1}{c})$ with $c > 0$ (quadrant 3, on $xy = 1$), $D = (d, -\frac{1}{d})$ with $d > 0$ (quadrant 4, on $xy = -1$).

As seen from the origin O, A, B, C, D sit at angles increasing through quadrants 1, 2, 3, 4 in turn, each consecutive gap well under a straight angle, and the four gaps sweep out the full circle once.

A point surrounded this way, with every consecutive angular gap less than 180°, always lies inside the convex hull of the four points: no line through O can have all four points strictly on one side of it. Since S is convex and contains A, B, C, D, it contains their hull, so it contains O too.

Now O, A, B, C, D are all in S, so each of the four triangles OAB, OBC, OCD, ODA lies in S (three points of a convex set, hence the whole triangle). These four triangles have disjoint interiors, again because the angular order around O increases strictly through a full turn with no gap wider than a straight angle, so they tile without overlap, and

$$\text{area}(S) \;\geq\; [OAB] + [OBC] + [OCD] + [ODA].$$

This sidesteps entirely the question of whether $ABCD$ is itself a convex quadrilateral (it need not be: for some a, b, c, d one of the four points sits inside the triangle of the other three), because the fan decomposition from O is valid regardless.

Each triangle area is half a cross product: $[OAB] = \frac{1}{2}\left(a \cdot \frac{1}{b} + b \cdot \frac{1}{a}\right) = \frac{1}{2}\left(\frac{a}{b} + \frac{b}{a}\right)$, and similarly for the other three. Summing,

$$\text{area}(S) \;\geq\; \frac{1}{2}\left(\frac{a}{b} + \frac{b}{a} + \frac{b}{c} + \frac{c}{b} + \frac{c}{d} + \frac{d}{c} + \frac{d}{a} + \frac{a}{d}\right).$$

By AM-GM, each of the four bracketed pairs is at least 2 (equality iff the two entries are equal), so the right side is at least $\frac{1}{2} \cdot 8 = 4$, with equality iff $a = b = c = d$.

This bound is achieved: take $a = b = c = d = 1$, so $A = (1, 1)$, $B = (-1, 1)$, $C = (-1, -1)$, $D = (1, -1)$, and let S be the square with these vertices. S is convex, touches $xy = 1$ exactly at A and C and $xy = -1$ exactly at B and D, and has area $2 \times 2 = 4$. So the minimum is exactly

$$\boxed{4}.$$

Layer 1: WHAT

Block 1: convexity plus "touches all four branches" reduces the problem to choosing one point per branch. Block 2: the four points sweep once around the origin, so the origin sits inside their hull, hence inside S. Block 3: fan S into four triangles from O, argue they tile without overlap, giving a clean lower bound that needs no assumption about the four points being in convex position. Block 4: write each triangle's area as a cross product, sum to the eight term cyclic expression. Block 5: AM-GM on the four reciprocal pairs. Block 6: exhibit the square as the exact extremiser.

The nominal route treats "least area convex set" as an optimisation over an unknown region and reaches for calculus of variations or a general parametrisation of the boundary, which buries the actual content of the problem, the fact that convexity alone forces a hull containment, under machinery that was never necessary. A softer nominal route asserts that S contains the quadrilateral $ABCD$ without checking that $ABCD$ is actually convex in that cyclic order, which happens to fail for some parameter choices; the bound then needs a repair it was never given. The bifurcation point is the choice between naming the hull quadrilateral by picture and hoping it behaves, against building the lower bound from a decomposition, the origin fan, that is valid for every choice of a, b, c, d without exception.

Layer 2: HOW

Block 1. **Cue.** Convex, and required to meet four disjoint pieces of curve. **Why natural.** Convexity turns "contains one point from each piece" into "contains the segment, and hence the hull, of any four such points": this is the definition of convex applied to each pair. **Link to the next block.** Reduces an optimisation over shapes to an optimisation over four positive parameters.

Block 2. **Cue.** The four chosen points lie one in each quadrant. **Why natural.** Four points whose consecutive angular gaps, viewed from a common centre, are all under a straight angle always have that centre inside their hull: no line through the centre can miss all four on one side. **Link to the next block.** Since the hull is inside S, the origin is inside S too, which is exactly the extra point needed to build a triangle fan.

Block 3. **Cue.** A lower bound on area(S) is wanted without knowing whether A, B, C, D are in convex position. **Why natural.** Triangles fanning out from a point that is itself surrounded, angularly, by the other points always tile without overlapping interiors, regardless of whether the outer points happen to form a convex quadrilateral. **Link to the next block.** The sum of the four triangle areas is a valid lower bound for area(S) unconditionally, sidestepping the convex quadrilateral question entirely.

Block 4. **Cue.** Each triangle has one vertex at the origin. **Why natural.** The area of a triangle with one vertex at the origin is half the absolute cross product of the other two position vectors, a one line formula rather than a full shoelace computation. **Link to the next block.** Summing four such halves produces exactly the eight term cyclic sum of ratios.

Block 5. **Cue.** Four pairs, each of the shape $t + \frac{1}{t}$. **Why natural.** Any positive number and its reciprocal sum to at least 2, with equality only when the number is 1; this is the single inequality fact doing all the work here. **Link to the next block.** Gives the numeric bound 4 and identifies the equality condition $a = b = c = d$ in the same step.

Block 6. **Cue.** Equality in AM-GM demands $a = b = c = d$. **Why natural.** An inequality without a matching example is only half a solution; the equality condition tells you exactly which convex set to write down. **Link to the next block.** Setting $a = b = c = d = 1$ produces the square, confirmed directly to touch all four branches, closing the proof.

Layer 3: WHY

The truth underneath the bound is that convexity is a containment statement, hull inside the set, long before it is an optimisation statement, and any problem that says "convex set meeting several disjoint pieces" should immediately be read as "convex set containing the hull of one representative point per piece". The discernment mechanism for choosing the origin fan over the naive quadrilateral is a standing habit: whenever a bound is built from a picture of a nice configuration, four points forming an obviously convex quadrilateral, check the claim against a skewed choice of parameters before trusting it, because a Putnam problem rarely hands you a symmetric picture as the general case for free. Here the skew is real: unequal a, b, c, d can push one of the four points inside the triangle of the other three, and the fan argument is the version of the proof that does not care.

The examiners nudged you toward the hull reduction by making S merely convex, not any more specific shape, and by asking for the branches to be merely intersected, not passed through in a particular way: both choices are invitations to reduce to finitely many points and use convexity as containment. Training this discernment is a matter of always asking, when a convex set is required to meet several separate pieces, what the cheapest witnessing points would give you for free, before reaching for any calculus.

Revolving concepts

Convexity as hull containment: a convex set containing finitely many points contains their convex hull; this converts "touches several regions" into "contains a specific finite configuration". See Book 1, field: Geometry, topic: convex sets and hulls.

A point surrounded angularly lies in the hull: if finitely many points, viewed from a centre, have every consecutive angular gap under a straight angle, the centre lies inside their convex hull. See Book 1, field: Geometry, topic: angular criteria for hull membership.

Triangle area via a vertex at the origin: for points P, Q, the triangle OPQ has area $\frac{1}{2}|x_P y_Q - x_Q y_P|$, the half cross product; summing such triangles sharing vertex O, taken in angularly increasing order with no two overlapping, reproduces the shoelace formula for a polygon. See Book 1, field: Geometry, topic: shoelace and cross product area.

AM-GM on a reciprocal pair: for $t > 0$, $t + \frac{1}{t} \geq 2$ with equality iff $t = 1$; a cyclic sum of ratios around a loop of positive variables is the standard trigger for applying this pair by pair. See Book 1, field: Inequalities, topic: AM-GM and equality analysis.

No recursive or self referential structure appears in this problem; the extremal configuration is found in one inequality step, not by an iterative or inductive construction.

Circuit Bank

- **WHEN** a convex set is required to meet several disjoint pieces of curve **DO** name one point of the set on each piece and work with the hull of those points instead of the set itself **BECAUSE** convexity means the hull of any finite subset of the set is contained in the set, so any bound proved for the hull transfers immediately
- **WHEN** several points, viewed from a common centre, sweep around it with every gap under a straight angle **DO** conclude the centre lies inside their hull, and use it as an extra point **BECAUSE** no line through such a centre can separate it from all the points, which is exactly the condition for hull membership
- **WHEN** a picture of the nice, symmetric configuration seems to justify a bound **DO** stress test it against a skewed, unequal choice of the free parameters before trusting the bound **BECAUSE** a Putnam configuration is rarely handed to you already in the convenient special case, and the proof needs to survive the general one
- **WHEN** an area splits into a cyclic sum of a variable and its reciprocal **DO** apply AM-GM pair by pair and read off both the bound and the equality condition together **BECAUSE** a cyclic sum of $t + \frac{1}{t}$ terms is the single most common inequality shape linking area or perimeter extremal problems to AM-GM

Backtesting

1. First useful cue: four disjoint branches, one convex set, immediately suggests naming one witnessing point per branch and working with their hull.
2. Method the expression suggested: a cyclic sum of ratios, t and $1/t$ terms around a loop, is an AM-GM trigger, applied one pair at a time.
3. Where you would hesitate, and the thought to reinforce: whether the four witnessing points form a convex quadrilateral in the obvious cyclic order; reinforce it by checking a skewed numeric example rather than trusting the picture, and fall back on the origin fan, which needs no such assumption.
4. The trap the question sets: the tempting shortcut, that area(S) is at least the area of quadrilateral $ABCD$, is not automatically true as stated, since that quadrilateral can fail to be convex for unequal parameters; the safe route bounds area(S) by a sum of triangles from a point already known to lie in S.
5. What makes you recognise it faster next time: any time a convex region must meet several separated pieces, reach for hull containment before reaching for calculus on the boundary.

6. The reusable decision rule: when a lower bound depends on several chosen points being in convex position, replace it with a decomposition, such as a fan from an interior point, that is valid regardless of their configuration.

Mirror drills

1. Find the least area of a convex set meeting both branches of $xy = 1$ alone, with no second hyperbola. *Answer:* zero; the segment joining one point on each branch is itself a convex set of area zero meeting both, which is exactly why the original problem needed a second hyperbola, to force four separated pieces instead of two.
2. Four points lie one in each quadrant, at angles $10^\circ, 100^\circ, 190^\circ, 280^\circ$ from the origin. Explain in one line why the origin must lie inside their convex hull. *Answer:* every consecutive angular gap is under 180°, so no line through the origin can put all four points on one side, which is exactly hull membership.
3. Minimise $\frac{a}{b} + \frac{b}{c} + \frac{c}{d} + \frac{d}{a}$ over positive reals with no other constraint, and state the equality case. *Answer:* the minimum is 4, at $a = b = c = d$, by AM-GM on the four terms directly; notice this is only half the shape of the eight term sum used in the main problem, and think about why the solution there needed both cyclic directions.

19.3 A3. Random order avoiding sums divisible by three

Let k be a positive integer. Suppose that the integers $1, 2, 3, \ldots, 3k+1$ are written down in random order. What is the probability that at no time during this process, the sum of the integers that have been written up to that time is a positive integer divisible by 3? Your answer should be in closed form, but may include factorials.

Read it out loud

Every partial sum of a nonempty set of positive integers is itself positive, so "positive integer divisible by 3" is just "divisible by 3": the condition is that no prefix sum is ever a multiple of 3. That is a walk. Read each number by its residue mod 3 and you are walking on $\{0, 1, 2\}$, starting at 0 before anything is written, and asking never to return to 0 once you have moved. The actual sizes of the numbers are irrelevant to the constraint; only their residues mod 3 matter, so the first move is to stop thinking about the numbers $1, \ldots, 3k+1$ and start thinking about a multiset of residues.

The fields wired in are elementary number theory (residues mod 3), a counting argument disguised as a random walk (which residue sequences avoid returning to 0), and probability computed as a ratio of counts rather than by conditioning. What is really being tested is whether you notice that a residue 0 term never changes the running residue, so it can never itself cause a violation except by inheriting whatever residue was already there, and whether you correctly count how the specific residue counts, k zeros, $k+1$ ones, k twos, forced by the range 1 to $3k+1$, constrain which walks are even possible.

The first useful line within thirty seconds: count the residues. Among $1, \ldots, 3k+1$, exactly k are $\equiv 0$, $k+1$ are $\equiv 1$, and k are $\equiv 2 \pmod 3$; the extra 1 over 2 is the single fact the whole answer turns on.

Approaches, ranked worst to best

1. **direct casework or generating functions on k.** *Cue:* a probability in closed form, for general k. *Circuit:* try to build up the count of valid orderings by recursion on the length of the prefix without first reducing to residues. (the actual numbers never matter, only residues do, so working with them directly multiplies the state space for no benefit and rarely lands on a clean closed form)

2. **residue walk without separating the two constraints.** *Cue:* no prefix sum is 0 mod 3. *Circuit:* track the full walk, including the zero residue steps, and attempt to compute the probability of avoidance in one pass. (correct in principle, but conflates "where do the multiples of 3 sit" with "what order are the 1's and 2's in", which is exactly the decomposition that makes the count of valid arrangements land in one line)

3. **count valid residue arrangements directly, as multiset placements.** *Cue:* residue 0 steps never move the walk, and residues 1, 2 force an alternating pattern once you leave 0. *Circuit:* place the k zeros anywhere except first, and show the 1's and 2's have exactly one valid relative order among themselves, then take a ratio of two counts. (the entire probability drops out as a single ratio, with the numerator a clean product of two simple counts)

The ideal solution

Only the residues mod 3 of $1, 2, \ldots, 3k+1$ matter to the condition. Among these $3k+1$ numbers, exactly k are $\equiv 0$, $k+1$ are $\equiv 1$, and k are $\equiv 2 \pmod 3$ (the residue 1 class starts the list and is one longer). Treat 1 as a step of $+1$ and 2 as a step of -1 on $\mathbb{Z}/3\mathbb{Z}$; a 0 residue leaves the running total unchanged. The condition "no prefix sum is 0 mod 3" is exactly "the running residue never returns to 0 after the walk starts".

A residue 0 number placed first immediately gives a prefix sum of 0: forbidden. So the first number written must be a 1 or a 2. After that, the walk moves only when a 1 or 2 is written; a 0 never changes the current residue, so it is safe to insert wherever the current residue already avoids 0, and it can only be dangerous where the residue is already 0, which cannot happen once the walk has started correctly. So the whole condition reduces to two requirements: the first number is not a multiple of 3, and reading only the 1's and 2's in the order they appear, deleting every multiple of 3 from the sequence, the running total mod 3 of this subsequence never hits 0.

For that subsequence: starting at residue 1, the only safe next step is $+1$ again (since -1 would return to 0), landing on residue 2; from residue 2 the only safe step is -1, back to 1. So once the first step is fixed, every subsequent step is forced, and the subsequence of steps is forced into one of exactly two patterns: $+1, +1, -1, +1, -1, \ldots$ or $-1, -1, +1, -1, +1, \ldots$. The first pattern uses one more $+1$ than -1 (it is $k+1$ pluses and k minuses over $2k+1$ terms), the second uses one more -1 than $+1$. Since the residue 1's outnumber the residue 2's by exactly one ($k+1$ against k), only the first pattern is numerically possible: the relative order of the 1's and 2's among themselves is forced into this single pattern, with no freedom left.

Now count. A valid arrangement of $1, \ldots, 3k+1$ is one where the k multiples of 3 occupy any k of the $3k$ positions other than position 1, and the remaining $2k+1$ positions carry the 1's and 2's in the one forced relative pattern (which numbers exactly, among the $k+1$ numbers $\equiv 1$ and k numbers $\equiv 2$, go where among themselves is then free, since only the residue pattern is constrained). The number of ways to choose which positions the multiples of 3 occupy, avoiding position 1, is $\binom{3k}{k}$, choosing k positions from the $3k$ positions other than the first; given that choice, there is exactly one valid residue pattern to lay into the rest, and then $k!$ ways to arrange the actual multiples of 3 among their positions, $(k+1)!$ ways to arrange the actual 1 mod 3 numbers among theirs, and $k!$ ways to arrange the actual 2 mod 3 numbers among theirs, each residue class arranged freely within its own forced slots. So

$$\#\{\text{valid orderings}\} = \binom{3k}{k} k!\,(k+1)!\,k!.$$

The total number of orderings is $(3k+1)!$. Hence

$$\Pr = \frac{\binom{3k}{k} k!\,(k+1)!\,k!}{(3k+1)!} = \frac{\frac{(3k)!}{k!(2k)!}\,k!\,(k+1)!\,k!}{(3k+1)!} = \frac{(3k)!\,(k+1)!\,k!}{(2k)!\,(3k+1)!} = \frac{k!\,(k+1)!}{(3k+1)\,(2k)!},$$

using $(3k+1)! = (3k+1)(3k)!$ in the last step. So

$$\boxed{\Pr = \frac{k!\,(k+1)!}{(3k+1)(2k)!}}.$$

(For $k=1$ this gives $\frac{1!\cdot 2!}{4\cdot 2!} = \frac{1}{4}$, which a direct check of all 24 orderings of $1,2,3,4$ confirms exactly: 6 of them survive.)

Layer 1: WHAT

Block 1: strip the problem down to residues mod 3, count how many of each residue class appear $(k, k+1, k)$. Block 2: read the condition as a walk that must never return to 0, and note a 0 residue step never moves the walk. Block 3: separate the condition into "first term is not 0" and "the subsequence of 1's and 2's never returns to 0 on its own". Block 4: show the second condition forces a single, unique relative pattern of 1's and 2's, using that 1's outnumber 2's by exactly one. Block 5: count valid orderings directly as positions for the zeros, avoiding first, times arrangements within each residue class, and divide by the total $(3k+1)!$.

The nominal route tries to compute this probability by conditioning step by step on the actual numbers written, or by setting up a recursion in k without first discarding everything except

residues; both approaches drown in bookkeeping that the residue reduction throws away for free. The bifurcation point is Block 1: the instant you notice that only residues matter, the problem shrinks from a question about $3k+1$ distinct labelled integers to a question about a multiset of three symbols, and every count becomes a binomial or multinomial count rather than a sum over cases.

Layer 2: HOW

Block 1. **Cue.** The condition only mentions divisibility by 3. **Why natural.** Only the residue mod 3 of each number, not its actual value, can affect whether a partial sum is divisible by 3. **Link to the next block.** Replace the $3k+1$ distinct integers by a multiset of residues, k zeros, $k+1$ ones, k twos, and work with that instead.

Block 2. **Cue.** "No prefix sum divisible by 3" is a statement about a running total returning to a value. **Why natural.** This is exactly a walk on $\mathbb{Z}/3\mathbb{Z}$ starting at 0, and a 0 residue step adds nothing, so it can never be blamed for a violation except by inheriting the current, already illegal, residue. **Link to the next block.** The whole condition splits cleanly into where the zeros are allowed to sit, anywhere but first, and how the nonzero steps must behave on their own.

Block 3. **Cue.** From residue 1 only $+1$ avoids 0; from residue 2 only -1 avoids 0. **Why natural.** Once you leave 0, at each step exactly one of the two possible moves returns to 0 and is therefore forbidden, so the rest of the subsequence is forced, not merely constrained. **Link to the next block.** The subsequence of 1's and 2's has only two candidate patterns, and one is eliminated purely by counting how many of each residue exist.

Block 4. **Cue.** $k+1$ ones against k twos, a specific known imbalance. **Why natural.** Each of the two candidate patterns produces a different, computable count of pluses versus minuses, and the actual imbalance in the problem matches exactly one of them. **Link to the next block.** Only one relative order of the nonzero residues survives, collapsing what looked like a count over many orders into a single arrangement.

Block 5. **Cue.** A count of favourable orderings is wanted, divided by $(3k+1)!$. **Why natural.** Once positions for the zero residues are chosen, avoiding the first slot, and the single valid nonzero pattern is laid into the rest, the specific numbers within each residue class can be permuted freely among their own slots without affecting validity. **Link to the next block.** The favourable count factors as a binomial coefficient times three factorials, and the ratio to $(3k+1)!$ collapses to the closed form.

Layer 3: WHY

The truth underneath the solution is that a constraint stated purely through divisibility only ever depends on residues, and residues live in a much smaller space than the original labelled objects; recognising this is what turns a permutation counting problem with $(3k+1)!$ raw outcomes into one with three symbols and a binomial count. The discernment mechanism is to ask, the moment a problem's condition is phrased with a modulus, whether the actual values are doing any work beyond determining that residue, and to discard them the instant the answer is no.

The second mechanism, spotting that the nonzero steps are forced rather than merely constrained, comes from treating "avoid returning to a state" on a three element cycle as a walk with, at every step, exactly one safe move and one unsafe move once you are off the starting state: this is the general shape of any avoid a residue walk on $\mathbb{Z}/n\mathbb{Z}$ with steps in $\{\pm 1\}$, not a coincidence of $n=3$. Training this discernment means, whenever a walk has few enough states and steps, checking

directly whether some moves are simply illegal at each state rather than assuming a genuine branching count is needed.

The examiners nudged you toward the residue reduction by choosing $1, 2, \ldots, 3k+1$, a range whose residue counts, $k, k+1, k$, are forced and asymmetric by exactly one, rather than a range with equal residue classes; that one count imbalance is the single fact that collapses two candidate walk patterns to one, and is worth reading as a deliberate signal, not an incidental detail of the range chosen.

Revolving concepts

Reduction to residues: a condition phrased entirely through divisibility by m depends only on residues mod m; replace the original labelled objects by a multiset of residues before counting. See Book 1, field: Number theory, topic: working modulo m.

Walks that must avoid a state: a walk on $\mathbb{Z}/n\mathbb{Z}$ with steps restricted to $\{\pm 1\}$, required never to return to its starting state after leaving it, has at each nonstarting state exactly one safe continuation, so the entire step sequence is forced once the first step is chosen; only the actual counts of each step type then decide which, if any, of the finitely many candidate sequences is achievable. Generalisation: for general n and a walk avoiding state 0, the same forcing argument gives at most $n-1$ candidate cyclic patterns, one per starting step, each ruled in or out purely by matching the count of each step type against what the pattern demands over a walk of any given length. See Book 1, field: Sequences and recurrences, topic: forced walks and residue avoidance.

Counting via placement: the number of ways to interleave several labelled groups into ordered positions, once the pattern of which group occupies which position is fixed, is the product of the factorials of the group sizes; combined with a binomial count for where one group's positions sit among the rest, this gives exact favourable counts without casework. See Book 1, field: Combinatorics, topic: multinomial coefficients and placement counting.

Probability as a ratio of two counts built the same way: writing both the favourable count and the total count as products of factorials and binomial coefficients lets heavy cancellation happen before any numbers are substituted, which is how the closed form here collapses to $k!(k+1)!/[(3k+1)(2k)!]$ rather than staying as a raw ratio of large factorials. See Book 1, field: Combinatorics, topic: probability by counting.

Circuit Bank

- **WHEN** a condition is phrased purely through divisibility by a fixed modulus **DO** replace the objects by their residues and discard their actual values **BECAUSE** only residues can affect a divisibility condition, so carrying the actual values further is wasted information
- **WHEN** a walk on finitely many residue states must avoid returning to its start **DO** check, at each state other than the start, how many of the available steps are actually safe **BECAUSE** on a small cycle with steps of size 1, typically only one step out of each state avoids the forbidden state, turning what looks like a branching count into a forced sequence
- **WHEN** a forced pattern's step counts can be compared against the known composition of the underlying multiset **DO** use the mismatch, or match, in counts to eliminate all but one candidate pattern **BECAUSE** a forced pattern predicts an exact count of each step type, and the problem's own numbers either satisfy that prediction or rule the pattern out entirely, with no need for further casework
- **WHEN** a probability is wanted for a random permutation subject to a placement style condition **DO** write both favourable and total counts as products of binomial coefficients and factorials before dividing **BECAUSE** heavy algebraic cancellation between the two counts is the difference between a clean closed form and an unreduced mess

Backtesting

1. First useful cue: the condition only ever mentions divisibility by 3, so only residues mod 3 can matter.
2. Method the expression suggested: a walk on three residue states that must never return to 0, with the zero residue elements acting as steps that do not move the walk at all.
3. Where you would hesitate, and the thought to reinforce: convincing yourself that the nonzero steps are entirely forced rather than merely restricted; reinforce it by checking, at each non-starting residue, exactly which of the two possible steps returns to 0 and eliminating only that one.
4. The trap the question sets: it is tempting to treat "first element not a multiple of 3" and "the 1,2 pattern is valid" as needing a joint, harder argument, when in fact the residue 0 elements can be inserted into any of the non first slots independently once the nonzero pattern is fixed, so a clean product of counts suffices.
5. What makes you recognise it faster next time: any random ordering question whose condition is stated purely via a modulus should immediately be rewritten as a question about a multiset of residues, before any probability machinery is set up.
6. The reusable decision rule: when a walk on a small cyclic residue system must avoid a state, check state by state which steps are forced, then match the resulting pattern's step counts against the actual composition of the multiset to see which patterns survive.

Mirror drills

1. The integers $1, 2, \ldots, 2k+1$ are written in random order. Find the probability that no prefix sum is ever even. *Hint:* the forbidden state is residue 0 mod 2, and the odd numbers outnumber the even ones by exactly one among $1, \ldots, 2k+1$; the same forcing argument applies with one fewer residue class to track.
2. The integers $1, \ldots, 3k$, with no extra term, are written in random order. Explain in one line why the probability that no prefix sum is divisible by 3 must be 0. *Answer:* residues $0, 1, 2$ each occur exactly k times, so the forced pattern would need one more of one nonzero residue than the other, which the equal counts can never supply.
3. For a walk on $\mathbb{Z}/4\mathbb{Z}$ with steps in $\{\pm 1\}$ starting at 0 and never allowed to return to 0, list the candidate step patterns and state, for each, the exact count of $+1$ steps versus -1 steps it requires over a walk of length n.

19.4 A4. Polynomials sending repunits to repunits

A repunit *is a positive integer whose digits in base 10 are all ones. Find all polynomials f with real coefficients such that if n is a repunit, then so is $f(n)$.*

Read it out loud

Read the structure, not the words: this is a rigidity question about a polynomial that is constrained only on a sparse infinite set. The set is $1, 11, 111, \dots$, and the constraint is that f maps that set into itself. Two fields are wired in, and only two. The first is elementary number theory, and you need exactly one fact from it, namely how to write a repunit in closed form. The second is the identity theorem for polynomials: a polynomial is a rigid object, so the instant you pin its values at infinitely many points you have pinned the polynomial itself. Everything between those two facts is bookkeeping.

The first cue is the word repunit. A named set is an invitation to re-describe it, because a name is a hint that the natural description is not the one printed. Write R_m for the repunit with m ones. Then $R_{m+1} = 10R_m + 1$, which is an affine recursion, not a multiplicative one, and that single observation explains why the set looks awkward: polynomials interact beautifully with multiplicative sets and badly with additive ones. So inside thirty seconds you should have on the page

$$R_m = \frac{10^m - 1}{9}, \qquad 9R_m + 1 = 10^m.$$

The second line is the entire problem. The affine map $x \mapsto 9x + 1$ carries the repunits bijectively onto $\{10, 100, 1000, \dots\}$, a geometric set, and a geometric set has the property you are about to exploit: on a multiplicative scale it is discrete, so nothing can sneak up on it.

What is really being tested is whether you will change coordinates. A polynomial condition stated on an ugly set is almost never attacked on that set. It is attacked by conjugating f with the affine map that cleans the set up, because affine substitution is an automorphism of the polynomial ring: it preserves degree, it is invertible, and it carries polynomials to polynomials in both directions. If you do not conjugate, you will spend the whole session pushing 9s around.

One more cue, planted deliberately: *real* coefficients. The examiners are stopping you from assuming f has integer coefficients, and they are right to, because the answer contains a factor 10^c with c allowed to be negative. Any argument of yours that quietly uses integrality of the coefficients is a wrong argument that happens to reach a correct list.

Approaches, ranked worst to best

1. **Undetermined coefficients.** *Cue:* "find all polynomials" with a finite list of sample inputs $1, 11, 111$. *Circuit:* write $f(x) = \sum a_i x^i$ and substitute. This is the zombie route. You get equations $f(R_m) = R_{h(m)}$ in which the outputs carry unknown *exponents* $h(m)$, so the system is not linear, not finite, and not closed. It stalls immediately, and it stalls for a reason worth naming: the unknown is not just the coefficient vector, it is also the index function h.

2. **Guess the family and stop.** *Cue:* the examples $f(x) = x$, $f(x) = 10x + 1$ are easy to find. *Circuit:* pattern-match, verify, hope. You will find $f(n) = 10n + 1$ within a minute because it appends a one. Verification is instant. But "find all" is a uniqueness demand, and a list with no proof of completeness is worth very little on the ten point scale. Rank it here only because it produces the correct family, which is a real asset for the next two routes.

3. **Growth comparison in the original coordinate.** *Cue:* f has a degree, repunits grow geometrically. *Circuit:* compare $\log_{10}$ of both sides. Write $f(R_m) = R_{h(m)}$. Since $R_m \sim 10^m/9$ and $f(x) \sim ax^d$, you get $h(m) = dm + \log_{10}(9^{1-d}a) + o(1)$, and since $h(m)$ is an integer it is

eventually exactly $dm + c$. That is a complete proof, and it is essentially the ideal one; it just carries a cloud of 9s and a nuisance $o(1)$ through every line. It costs more ink for no gain.

4. **Rationality plus a valuation argument.** *Cue:* polynomials taking rational values at rational points. *Circuit:* Lagrange interpolation, then induct on the degree. By interpolation f has rational coefficients, so $g(0)$ is rational; if $g(0) \neq 0$ its numerator has a bounded power of 10 in it, while $g(10^k)$ eventually has an unbounded one, so $g(0) = 0$ and you induct on $g(n)/n$. This is the 2-adic and 5-adic mirror of the ideal route and it is genuinely instructive, but it needs interpolation and a divisibility estimate you must set up carefully.

5. **Affine conjugation plus discreteness of the powers of ten.** *Cue:* $9n + 1 = 10^m$, and a polynomial is determined by infinitely many values. *Circuit:* move to the fixed point of the recursion, then read off the leading coefficient as a limit. Best. One substitution turns the problem into "polynomials mapping powers of 10 to powers of 10", after which a single limit finishes it. The whole solution is six lines.

The ideal solution

Write R_m for the repunit with m ones, $m \geq 1$, so that

$$R_m = \frac{10^m - 1}{9}, \qquad 9R_m + 1 = 10^m.$$

Thus a positive integer n is a repunit if and only if $9n + 1$ is a power of 10 exceeding 1.

Given a real polynomial f, define the real polynomial

$$g(x) = 9f\left(\frac{x-1}{9}\right) + 1, \qquad \text{equivalently} \qquad f(x) = \frac{g(9x+1) - 1}{9}.$$

The two formulas are mutually inverse, so $f \mapsto g$ is a bijection from real polynomials to real polynomials, and it preserves degree. For every $m \geq 1$,

$$g(10^m) = 9f(R_m) + 1,$$

so $f(R_m)$ is a repunit if and only if $g(10^m)$ is a power of 10 exceeding 1. Hence the problem is equivalent to the following.

Claim 19.4.1. *The real polynomials g such that $g(10^m) \in \{10^k : k \geq 1\}$ for every integer $m \geq 1$ are exactly the polynomials*

$$g(x) = 10^c x^d, \qquad d \in \mathbb{Z}_{\geq 0},\ c \in \mathbb{Z},\ c + d \geq 1.$$

Proof. Sufficiency first. If $g(x) = 10^c x^d$ with $d \geq 0$ and $c + d \geq 1$, then $g(10^m) = 10^{c+md}$, and for $m \geq 1$ and $d \geq 0$ we have $c + md \geq c + d \geq 1$, so $g(10^m)$ is a power of 10 exceeding 1.

Now necessity. The zero polynomial fails at $x = 10$, so $g \neq 0$; let $d = \deg g \geq 0$ and let a be its leading coefficient. Since $g(10^m) \geq 10 > 0$ for all $m \geq 1$ and $10^m \to \infty$, the leading coefficient satisfies $a > 0$.

For each $m \geq 1$ write $g(10^m) = 10^{k_m}$ with k_m a positive integer. Then

$$\frac{g(10^m)}{10^{md}} = 10^{k_m - md},$$

and the left hand side tends to a as $m \to \infty$, because $g(x)/x^d \to a$ as $x \to \infty$.

The set of integer powers of 10 has no accumulation point in $(0, \infty)$, and here is the quantitative form of that, which is all we need. Choose M so that $|10^{k_m - md} - a| < a/2$ for all $m \geq M$. Then every such value lies in the interval $(a/2, 3a/2)$, whose endpoints have ratio $3 < 10$, so the interval

contains at most one integer power of 10. Therefore the numbers $10^{k_m - md}$ for $m \geq M$ are all equal to a single value 10^c with $c \in \mathbb{Z}$, and passing to the limit gives $a = 10^c$.

Consequently $g(10^m) = 10^c \cdot 10^{md} = 10^c (10^m)^d$ for every $m \geq M$. The polynomial $g(x) - 10^c x^d$ therefore vanishes at the infinitely many distinct points $10^M, 10^{M+1}, \ldots$, so it is the zero polynomial and $g(x) = 10^c x^d$.

Finally, evaluating at $m = 1$ shows $10^{c+d} = g(10)$ is a power of 10 exceeding 1, so $c + d \geq 1$. $\square$

Translating back through $f(x) = (g(9x+1) - 1)/9$, the answer is

$$\boxed{f(x) = \frac{10^c (9x+1)^d - 1}{9}, \qquad d \in \mathbb{Z}_{\geq 0},\ c \in \mathbb{Z},\ c \geq 1 - d}$$

and every such f works, sending R_m to R_{c+md}.

Three sanity checks, each of which you should do in the arena. Taking $d = 0$ and $c \geq 1$ gives the constant polynomials $f \equiv R_c$. Taking $d = 1, c = 0$ gives $f(x) = x$. Taking $d = 1, c = 1$ gives $f(x) = 10x + 1$, which appends a one. Taking $d = 2, c = -1$ gives $f(x) = \frac{1}{10}\left(\frac{(9x+1)^2}{9}\right) - \frac{1}{9}$, and indeed $f(R_m) = R_{2m-1}$, for example $f(11) = 111$.

Layer 1: WHAT

Block 1. Name the set properly: n is a repunit if and only if $9n + 1 = 10^m$ with $m \geq 1$.

Block 2. Conjugate: define $g(x) = 9f((x-1)/9) + 1$, note the correspondence is a degree preserving bijection, and restate the problem as "polynomials carrying powers of 10 to powers of 10".

Block 3. Normalise by the degree: look at $g(10^m)/10^{md}$, which tends to the leading coefficient a.

Block 4. Use discreteness: a sequence of integer powers of 10 converging to a positive limit is eventually constant, so $a = 10^c$ and $g(10^m) = 10^c 10^{md}$ for all large m.

Block 5. Close with rigidity: $g(x) - 10^c x^d$ has infinitely many roots, hence is identically zero.

Block 6. Translate back and pin the inequality by testing $m = 1$: $c + d \geq 1$. Verify sufficiency.

The nominal route branches at Block 1. The zombie writes $f(x) = \sum a_i x^i$ and substitutes $1, 11, 111$, generating equations whose right hand sides contain unknown exponents; that route never closes. The bifurcation point is the decision of *which coordinate to work in*: the moment you choose to study $9n + 1$ rather than n, every later step is forced. Notice what the ideal route does not do: it never expands a single power of $(9x + 1)$, and it never uses a divisibility argument. Ink saved is error avoided.

Layer 2: HOW

Block 1. Cue. The problem names a set instead of describing it algebraically, and the set is defined by a base 10 digit pattern. **Why natural.** A digit pattern of all ones is a geometric series: $R_m = 1 + 10 + \cdots + 10^{m-1}$. Summing it is not a manoeuvre, it is the definition of what the digits mean. The sum is $(10^m - 1)/9$, and clearing the 9 gives the clean characterisation $9R_m + 1 = 10^m$. There is also a deeper reason to look for exactly this shift, which I give in Layer 3: $x \mapsto 10x + 1$ generates the repunits, and its fixed point is $-1/9$. **Link to the next block.** You now hold a set that is awkward for polynomials, and beside it a set that is not. That asymmetry is the instruction to move.

Block 2. Cue. Two descriptions of the same set differ by the affine map $x \mapsto 9x + 1$. **Why natural.** Substituting an affine function into a polynomial is an automorphism of $\mathbb{R}[x]$: it is invertible with affine inverse, it preserves degree, and it sends real polynomials to real polynomials. So there is no loss whatever in transporting the whole problem across it. This is the same reasoning that lets you

complete the square without worrying that you have changed the problem. The condition "f maps repunits into repunits" becomes "g maps $\{10^m : m \geq 1\}$ into the powers of 10". **Link to the next block.** The new condition is multiplicative in shape, and the objects it constrains, powers of 10, are spread out geometrically. Both features are exactly what a polynomial growth argument wants.

Block 3. **Cue.** A polynomial constrained at points going to infinity, with the constraint set thinning out. **Why natural.** The only thing about a polynomial that survives at infinity is its degree and leading coefficient: $g(x)/x^d \to a$. Dividing by x^d is therefore not an idea, it is the unique way to extract information from "large x" behaviour. And on the constraint set the quotient is $10^{k_m - md}$, that is, it stays inside a fixed discrete set. **Link to the next block.** A convergent sequence trapped in a discrete set is eventually constant. That is the pin.

Block 4. **Cue.** A convergent sequence whose terms all lie in $\{10^j : j \in \mathbb{Z}\}$. **Why natural.** Distinct integer powers of 10 differ by a factor of at least 10, so any interval whose endpoints have ratio less than 10 contains at most one of them. Take the interval $(a/2, 3a/2)$, which the terms eventually enter because they converge to $a > 0$. Hence the terms are eventually a single value, and that value is the limit a. **Link to the next block.** You have upgraded an asymptotic statement into an exact one: $g(10^m) = 10^c(10^m)^d$ for all large m, an identity at infinitely many points.

Block 5. **Cue.** An identity between two polynomials holding at infinitely many points. **Why natural.** A nonzero polynomial of degree D has at most D roots. So a polynomial with infinitely many roots is the zero polynomial, and two polynomials agreeing at infinitely many points are equal as polynomials. This is the rigidity that makes the whole problem finite. **Link to the next block.** The form of g is now known exactly; only the admissible range of c and d remains.

Block 6. **Cue.** The problem said "repunit", which means a positive integer, so $m \geq 1$ everywhere, not $m \geq 0$. **Why natural.** Boundary conditions of this kind are decided by testing the extreme case, here $m = 1$. The requirement $c + md \geq 1$ for all $m \geq 1$ with $d \geq 0$ is monotone in m, so it is equivalent to its value at $m = 1$. Then transport back through the inverse substitution and check sufficiency, since "find all" demands both directions. **Link to the next block.** Nothing follows; the answer is complete, and you have written the verification that a grader will look for.

Layer 3: WHY

Three mathematical truths make this route the right one.

First, rigidity. Polynomials form a vector space of finite dimension in each degree, so agreement at enough points is equality. Every "find all polynomials such that" problem is ultimately solved by manufacturing infinitely many agreements with a guessed candidate. Once you internalise that the endgame is always "two polynomials agree infinitely often, hence coincide", you stop trying to force the coefficients and start trying to force the values.

Second, coordinates. The ring $\mathbb{R}[x]$ has affine substitutions as automorphisms. Any hypothesis phrased on a set S can be rephrased on $\varphi(S)$ for affine φ at zero cost. So the correct first question for a constrained polynomial problem is not "what is f" but "what is the cleanest affine image of the constraint set". Here the repunits are the orbit of 1 under $T(x) = 10x + 1$. An affine map with slope $b \neq 1$ has a unique fixed point $p = c/(1 - b)$, and conjugating by the translation $x \mapsto x - p$ turns T into pure multiplication by b. For $T(x) = 10x + 1$ the fixed point is $p = -1/9$, and indeed $R_m + \frac{1}{9} = \frac{10^m}{9}$. The substitution $9n + 1$ is nothing more than "translate to the fixed point, then rescale". That is the honest reason the substitution is natural, and it is a reason you can reuse on any problem whose special set is an orbit of an affine map.

Third, discreteness. The powers of 10 have no positive accumulation point, so any convergent sequence inside them is eventually constant. This is the mechanism that upgrades "asymptotically" to "exactly", and it is the same mechanism behind "an integer sequence that converges is eventually constant", which you will meet constantly. Whenever a limit lands in a discrete set, you have not merely estimated, you have determined.

The discernment mechanism, stated as a rule you can run in the arena: when a polynomial is constrained on a set S, ask three questions in order. Is S an orbit of a simple map, so that a change of coordinate makes it geometric or arithmetic? Is the target set discrete on some scale? Does the constraint survive to infinity, so that the leading coefficient can be read off as a limit? If all three answer yes, the problem is a six line problem. Training it is a matter of collecting constrained sets and rehearsing the normalising substitution for each: repunits become powers of 10; numbers of the form $2^k - 1$ become powers of 2; an arithmetic progression $a + bk$ becomes $\mathbb{Z}$; the Fibonacci numbers do not normalise, which is precisely why Fibonacci constraints are hard.

What the examiners nudged with: the word repunit (a named set, therefore re-describe it), the phrase "real coefficients" (a warning not to use integrality), and the phrase "find all" (a demand for both necessity and sufficiency).

Revolving concepts

Repunits and base representation. $R_m = (10^m - 1)/9$ is the base 10 instance of $\frac{b^m-1}{b-1}$, the repunit in base b. All the structure used here is base free: n is a base b repunit if and only if $(b-1)n + 1 = b^m$. See Book 1, field: Number theory, topic: base representation and digit sums.

Affine maps and their fixed points, with the recursion generalised. The repunits satisfy $R_1 = 1$, $R_{m+1} = 10R_m + 1$. The general first order affine recursion is $u_{m+1} = bu_m + c$ with $b \neq 1$; its unique fixed point is $p = c/(1-b)$, and $u_m - p = b^m(u_0 - p)$, so

$$u_m = b^m \left(u_0 - \frac{c}{1-b} \right) + \frac{c}{1-b}.$$

The general solution method is exactly the conjugation used above: translate the fixed point to the origin, whereupon the recursion becomes multiplication by b. If $b = 1$ the map is a translation and $u_m = u_0 + mc$ is arithmetic instead. Every time a problem hands you a set generated by an affine rule, run this normalisation before anything else. See Book 1, field: Sequences and recurrences, topic: first order linear recurrences.

The identity theorem for polynomials. A nonzero polynomial of degree D over a field has at most D roots; hence two polynomials agreeing at more than $\max(\deg)$ points are identical, and agreement at infinitely many points is equality. This is the finiteness engine of every "find all polynomials" problem. See Book 1, field: Polynomials, topic: roots and the identity theorem.

Behaviour at infinity. For $\deg g = d$ with leading coefficient a, $g(x)/x^d \to a$. This is the only asymptotic fact about polynomials you need, and it converts leading coefficient questions into limit questions. See Book 1, field: Polynomials, topic: growth and leading terms.

Discrete sets and eventual constancy. A subset $S \subseteq \mathbb{R}$ with no accumulation point at L has the property that any sequence in S converging to L is eventually constant. Instances: the integers, the powers of a fixed base, any set with a uniform multiplicative gap. See Book 1, field: Real analysis, topic: discreteness and eventual constancy.

Rational values and interpolation. If a polynomial of degree d takes rational values at $d + 1$ distinct rational points, then Lagrange interpolation writes it with rational coefficients. That is the entry point to the p-adic route, and it is worth installing separately because it converts an arithmetic hypothesis into a structural one. See Book 1, field: Polynomials, topic: Lagrange interpolation.

Circuit Bank

- **WHEN** a polynomial is constrained on a named set such as repunits, Mersenne numbers, or an orbit of an affine map **DO** first rewrite the set in closed form, then conjugate the polynomial by the affine map that turns the set into a geometric or arithmetic one **BECAUSE** affine substitution is a degree preserving automorphism of the polynomial ring, so it costs nothing and it can turn an additive description into a multiplicative one
- **WHEN** a set is generated by $u_{m+1} = bu_m + c$ with $b \neq 1$ **DO** translate by the fixed point $c/(1-b)$ **BECAUSE** the conjugated map is multiplication by b, so the orbit becomes a geometric progression
- **WHEN** you must prove a polynomial equals a specific polynomial **DO** prove they agree at infinitely many points and invoke the identity theorem **BECAUSE** a nonzero polynomial has finitely many roots, so agreement at infinitely many points is equality
- **WHEN** the constraint places $g(x_m)$ inside a discrete set while $x_m \to \infty$ **DO** divide by $x_m^{\deg g}$ and take the limit **BECAUSE** the quotient converges to the leading coefficient and is trapped in a discrete set, so it is eventually constant, which pins the leading coefficient exactly
- **WHEN** the question says "find all" **DO** write the verification of your family as a separate paragraph **BECAUSE** necessity and sufficiency are two different proofs and the grader marks both

Backtesting

1. First useful cue: the word repunit, a named set, which forces the closed form $R_m = (10^m - 1)/9$ and then the clean statement $9R_m + 1 = 10^m$.
2. Method the expression suggested: conjugate f by $x \mapsto 9x + 1$ to reduce to polynomials sending powers of 10 to powers of 10, then read the leading coefficient off as a limit and close with the identity theorem.
3. Where you would hesitate, and the thought to reinforce: at the limit step, because it feels like an analysis move inside a number theory problem. Reinforce this sentence: a convergent sequence inside a discrete set is eventually constant, so the limit is not an estimate, it is an exact determination.
4. The trap the question sets: assuming integer coefficients. The correct family contains 10^c with c possibly negative, so f need not have integer coefficients, and any argument built on integrality is invalid even though it may reach the right list. A second, smaller trap: forgetting that repunits are positive integers, so the exponent must be at least 1, which is exactly what produces the constraint $c \geq 1 - d$.
5. What makes you recognise it faster next time: the shape "polynomial constrained on a sparse set closed under a simple map". That shape always means normalise the set first.
6. The reusable decision rule: when the hypothesis lives on an ugly set, change coordinates until the set is an orbit under multiplication, then let growth plus discreteness do the work.

Mirror drills

1. Find all real polynomials f such that $f(2^m)$ is a power of 2 for every integer $m \geq 1$. *Answer:* identical mechanism with no conjugation needed: $f(x) = 2^c x^d$ with $d \geq 0$ and $c + d \geq 0$, the last inequality coming from whichever positivity convention the powers are required to satisfy.

2. Find all real polynomials f mapping the set $\{2^m - 1 : m \geq 1\}$ into itself. *Answer:* the generating map is $x \mapsto 2x + 1$ with fixed point -1, so put $g(x) = f(x-1) + 1$; then g must send powers of 2 to powers of 2, giving $f(x) = 2^c(x+1)^d - 1$ with $d \geq 0$ and $c + d \geq 1$.

3. Let $u_0 = 2$ and $u_{m+1} = 3u_m - 1$. Find all real polynomials f with $f(u_m) \in \{u_j : j \geq 0\}$ for every m. *Answer:* the fixed point is $1/2$, so $u_m = \frac{1}{2}(3^{m+1} + 1)$ and $2u_m - 1 = 3^{m+1}$; conjugating by $x \mapsto 2x - 1$ reduces to polynomials sending powers of 3 to powers of 3, so $f(x) = \frac{1}{2}\left(3^c(2x-1)^d + 1\right)$ with $d \geq 0$ and $c + d \geq 1$.

19.5 A5. Counting elements of prime order in a group

Suppose that a finite group has exactly n elements of order p, where p is a prime. Prove that either $n = 0$ or p divides $n + 1$.

Read it out loud

Read it as a congruence about a cardinality: a finite group G is given, a prime p is given, and the count of elements of a prescribed order is claimed to satisfy $n \equiv -1 \pmod{p}$ whenever it is nonzero. The field is finite group theory, and the sub-field is the one that matters most on the Putnam: group actions used as counting devices. Nothing here is about the structure of G; G is arbitrary, so no classification, no commutativity, no Sylow structure is available to you as a hypothesis. Only counting can survive that level of generality.

The decisive cue is the $+1$. Why would a natural theorem be about $n + 1$ rather than n? Because $n + 1$ is the count of a set that is closed and canonical, whereas n is the count of a set that is not. Write

$$S_p = \{x \in G : x^p = e\}.$$

Since p is prime, $x^p = e$ forces $\operatorname{ord}(x) \in \{1, p\}$, so S_p consists of the identity together with the n elements of order exactly p, giving $|S_p| = n + 1$. The claim to be proved is therefore the cleaner statement: if G contains any element of order p, then p divides $|S_p|$. Within thirty seconds of reading the problem those two lines should be on your page, and with them the problem has already changed shape.

The second cue is the word "exactly" attached to a count with no structure attached to G. When a count in an arbitrary finite group must be divisible by p, there is one reliable mechanism: exhibit a set whose cardinality you know outright, let a group of order p act on it, and observe that every orbit has size 1 or p. The count you want then appears as the number of fixed points. Everything in the ideal solution is an implementation of that sentence.

A caveat worth clarifying before you start. The set $\{x : \operatorname{ord}(x) = p\}$ itself is a poor object: it is not closed under any natural operation, and it is not the fixed point set of anything. That is why the theorem is stated with the $+1$. Adding the identity back is not cosmetic; it is what creates the structure.

Approaches, ranked worst to best

1. **Case analysis on the structure of G.** *Cue:* finite group, small prime, familiar examples. *Circuit:* classify, then count in each case. Hopeless and not even a route. G is an arbitrary finite group; there is no list to run through. Rank it last because attempting it consumes the session.

2. **Pair each element with its inverse.** *Cue:* elements of order p come in pairs x, x^{-1}. *Circuit:* involution counting. This proves only that n is even when $p > 2$, since $x \neq x^{-1}$ for $\operatorname{ord}(x) = p > 2$. It is the reflex of someone who knows one counting circuit and applies it regardless of the modulus. It gives divisibility by 2, not by p.

3. **Partition into cyclic subgroups.** *Cue:* every element of order p generates a subgroup of order p, and distinct such subgroups meet trivially. *Circuit:* orbit style partition. This is genuinely useful and you should always write it down: if k is the number of subgroups of order p, then $n = k(p - 1)$, because each such subgroup is cyclic of prime order and contains exactly $p - 1$ elements of order p, and each element of order p lies in exactly one of them, namely the one it generates. Hence $n + 1 = k(p - 1) + 1 \equiv 1 - k \pmod{p}$, so the problem is *equivalent* to proving $k \equiv 1 \pmod{p}$. That is a Sylow flavoured statement, and it is not easier than the original. Rank it here: it reformulates cleanly but does not close.

4. **Quote Frobenius.** *Cue:* a divisibility statement about solutions of $x^m = e$. *Circuit:* cite a named theorem. Frobenius proved that if m divides $|G|$ then m divides $|\{x : x^m = e\}|$. That instantly gives $p \mid n+1$. The trouble is that you cannot prove Frobenius in the arena, and a proof consisting of a citation of a theorem strictly stronger than the problem invites a grader to ask whether you have any idea why it is true. Use it as a sanity check, never as the write-up.

5. **Conjugation action of a fixed subgroup of order p.** *Cue:* if $n > 0$ there is a subgroup H of order p to act with. *Circuit:* let H act on the other elements of order dividing p by conjugation. Take $H = \langle a \rangle$ where a has order p, and let H act by conjugation on the set of elements of order p outside H. Orbits have size 1 or p; the fixed points are elements commuting with H, and each such element together with H generates an elementary abelian group of order p^2, which lets you group the fixed points into blocks of size $p^2 - p$. Correct and self contained, but the block counting needs care and the write-up is twice as long as it needs to be.

6. **Cyclic rotation of p tuples with product the identity.** *Cue:* a count divisible by p is wanted, and $|G|^{p-1}$ is a count you know exactly. *Circuit:* build a set of known size, act by $\mathbb{Z}/p$, count fixed points. Best. One set, one action, three lines of verification. It uses no Sylow theory, no Cauchy theorem, and no structure of G beyond Lagrange, and as a bonus it proves Cauchy's theorem on the way past.

The ideal solution

Let G be a finite group with identity e and $|G| = m$, and let p be prime. Put

$$S_p = \{x \in G : x^p = e\}.$$

Since p is prime, an element with $x^p = e$ has order dividing p, hence order 1 or p; the only element of order 1 is e. Therefore

$$|S_p| = n + 1.$$

Lemma 19.5.1. *If p divides m, then p divides $|S_p|$.*

Proof. Let

$$S = \{(a_0, a_1, \ldots, a_{p-1}) \in G^p : a_0 a_1 \cdots a_{p-1} = e\}.$$

The first $p-1$ coordinates may be chosen arbitrarily, and then $a_{p-1} = (a_0 \cdots a_{p-2})^{-1}$ is uniquely determined and lies in G. Hence the map $(a_0, \ldots, a_{p-1}) \mapsto (a_0, \ldots, a_{p-2})$ is a bijection $S \to G^{p-1}$, so

$$|S| = m^{p-1}.$$

Because $p \mid m$ and $p - 1 \geq 1$, we get $p \mid |S|$.

Define $\sigma : G^p \to G^p$ by the cyclic shift $\sigma(a_0, a_1, \ldots, a_{p-1}) = (a_1, \ldots, a_{p-1}, a_0)$. This maps S into S: if $a_0 a_1 \cdots a_{p-1} = e$ then $a_1 \cdots a_{p-1} = a_0^{-1}$, so

$$a_1 \cdots a_{p-1} a_0 = a_0^{-1} a_0 = e.$$

Since σ^p is the identity map, $j \mapsto \sigma^j$ is a homomorphism from the cyclic group $\mathbb{Z}/p$ to the symmetric group on S, that is, an action of $\mathbb{Z}/p$ on S.

By the orbit stabiliser theorem every orbit of this action has size dividing $|\mathbb{Z}/p| = p$, so every orbit has size 1 or p. Consequently, writing F for the number of orbits of size 1,

$$|S| \equiv F \pmod{p},$$

since S is the disjoint union of its orbits and the orbits of size p contribute 0 modulo p.

Finally identify the fixed points. A tuple $(a_0, \ldots, a_{p-1}) \in S$ is fixed by σ if and only if $a_i = a_{i+1}$ for all indices i read modulo p, that is, if and only if all coordinates are equal, say to a. Such a tuple

lies in S exactly when $a^p = e$. So the fixed points of σ on S are precisely the constant tuples $(a, \ldots, a)$ with $a \in S_p$, and a tuple fixed by σ is fixed by every power of σ, so these are exactly the orbits of size 1. Hence $F = |S_p|$, and

$$0 \equiv |S| \equiv |S_p| \pmod{p},$$

which is the assertion. □

Now the problem itself. If $n = 0$ there is nothing to prove. If $n > 0$, pick $x \in G$ of order p. Then $\langle x \rangle$ is a subgroup of G of order p, so by Lagrange's theorem p divides m. The lemma applies and gives

$$p \mid |S_p| = n + 1,$$

as required. ■

Remark 19.5.2. The lemma is stronger than the problem, and it contains Cauchy's theorem. If $p \mid m$ then $p \mid |S_p|$, and S_p is nonempty because it contains e, so $|S_p| \geq p \geq 2$; hence G has an element of order p. In other words, the same three lines that solve this problem prove that a prime dividing the order of a group is realised as the order of an element.

Layer 1: WHAT

Block 1. Replace the set of elements of order exactly p by $S_p = \{x : x^p = e\}$, and record $|S_p| = n + 1$ using primality of p.

Block 2. Dispose of the trivial case: if $n > 0$ then Lagrange forces $p \mid |G|$, so the only case needing work is $p \mid m$.

Block 3. Manufacture a set of exactly known size: p tuples with product e, of size m^{p-1}, which is divisible by p.

Block 4. Find a $\mathbb{Z}/p$ action on that set: cyclic shift, well defined because the product condition is rotation invariant.

Block 5. Orbits have size 1 or p, so the cardinality is congruent to the number of fixed points modulo p.

Block 6. Identify the fixed points as the constant tuples $(a, \ldots, a)$ with $a^p = e$, hence with S_p, and conclude.

The nominal route branches at Block 1. The zombie tries to count elements of order p directly, pairing x with x^{-1} or with its conjugates, and gets divisibility by 2 or a statement about conjugacy class sizes that does not assemble. The bifurcation point is the decision *which set to count*: elements of order exactly p, or elements of order dividing p. The second set is a fixed point set; the first is not. Everything downstream follows from that choice, and the $+1$ in the problem statement was the examiners telling you which one they had in mind.

Layer 2: HOW

Block 1. **Cue.** The conclusion is about $n + 1$, not n, and p is prime. **Why natural.** A shifted count almost always means the natural object is the count before the shift. Primality of p says the divisors of p are 1 and p, so "order divides p" splits as "identity, or order exactly p". Therefore $|S_p| = n + 1$ exactly, and the problem becomes a statement about S_p. The reason to want S_p rather than the order p elements is structural: S_p is defined by an equation, and sets defined by equations are the ones that arise as fixed point sets. **Link to the next block.** You now need to prove that p divides the size of a set defined by the equation $x^p = e$, in a group with no other hypotheses.

Block 2. **Cue.** The dichotomy "$n = 0$ or" in the statement is an invitation to split immediately. **Why natural.** If an element of order p exists, it generates a cyclic subgroup of order p, and Lagrange's theorem says the order of a subgroup divides the order of the group. So $n > 0$ forces $p \mid m$. Clearing

this in one sentence is not tidiness; it buys the hypothesis $p \mid m$, which is the only hypothesis the main argument needs. **Link to the next block.** The remaining task is a clean lemma: $p \mid m$ implies $p \mid |S_p|$.

Block 3. **Cue.** You must produce a multiple of p out of thin air, and the only number you know exactly is m. **Why natural.** If you want to count something modulo p, you need a set whose size you can compute without any knowledge of G. The one such construction available in an arbitrary group is a tuple space with one constraint: fix $p-1$ coordinates freely and let the last one absorb the constraint. That gives $|S| = m^{p-1}$, computed by an explicit bijection, and the exponent $p-1$ is at least 1, so $p \mid m$ transfers to $p \mid |S|$. The choice of p as the tuple length is not arbitrary: you want the acting group to have order p so that orbit sizes are only 1 or p. **Link to the next block.** A set of size divisible by p is useless without an action; the constraint $a_0 \cdots a_{p-1} = e$ was chosen because it is rotation invariant.

Block 4. **Cue.** The defining condition of S is a product around a cycle, and a product around a cycle does not change when you rotate the starting point. **Why natural.** In a group, $a_0 a_1 \cdots a_{p-1} = e$ is equivalent to $a_1 \cdots a_{p-1} = a_0^{-1}$, and multiplying on the right by a_0 gives the rotated product. This is conjugation of the identity by a_0 in disguise, and it is exactly why one writes the condition as a product equal to e rather than, say, $a_0 a_1 \cdots a_{p-1} = g$ for some other g. The tuple length being p makes σ^p the identity, so $\mathbb{Z}/p$ acts. **Link to the next block.** You have a group of prime order acting on a set of size divisible by p, which is the exact input to the fixed point lemma.

Block 5. **Cue.** A group of prime order acting on a finite set. **Why natural.** Orbits partition the set, and by orbit stabiliser each orbit size divides the order of the acting group, here p. Since p is prime, the only orbit sizes are 1 and p. Summing over orbits, $|S|$ is congruent modulo p to the number of singleton orbits, that is, the number of fixed points. This is the single most reusable lemma in this circle of ideas. **Link to the next block.** Everything now hinges on identifying the fixed points, which is a purely mechanical step.

Block 6. **Cue.** A tuple fixed by a cyclic shift. **Why natural.** Being fixed by the shift means each coordinate equals the next, and running the index around the cycle forces all coordinates equal. The membership condition then reads $a^p = e$. So the fixed points biject with S_p, which was arranged in Block 1 to have size $n+1$. **Link to the next block.** Nothing follows; combining Blocks 3, 5 and 6 gives $0 \equiv |S| \equiv n+1 \pmod{p}$.

Layer 3: WHY

The mathematical truth beneath the route is a single lemma, and it deserves to be installed as a named object rather than rediscovered each time.

Lemma 19.5.3 (Fixed point lemma)**.** *Let H be a group of order p^k with p prime, acting on a finite set X. Then $|X| \equiv |X^H| \pmod{p}$, where X^H is the set of points fixed by every element of H.*

The proof is the same in general as it was above: orbits partition X, orbit sizes divide p^k, so every orbit has size 1 or a positive power of p, and only the singletons survive modulo p. This lemma is the engine behind Cauchy's theorem, behind the class equation and the nontriviality of the centre of a p group, behind Sylow's theorems, behind the necklace proof of Fermat's little theorem, and behind Lucas's theorem on binomial coefficients modulo p. If you install one piece of group theory for the Putnam, install this.

The discernment mechanism, stated so you can run it under time pressure. When a problem asks you to prove that p divides some count N in a setting with no structural hypotheses, run three

questions. Can I find a set X whose size I can compute exactly and which is visibly divisible by p? Is there a natural action of a group of order p on X? Do the fixed points of that action biject with the N objects I care about? The construction in this problem answers all three in one stroke, and the reason it can is that the tuple space G^p has size m^p computable with no knowledge of G at all, while the single relation $a_0 \cdots a_{p-1} = e$ cuts it down by exactly one factor of m and is simultaneously rotation invariant.

Training it is a matter of collecting the pattern "count modulo p equals fixed point count". The drills below are the standard three. After them, the reflex to build the tuple set becomes automatic, and you will recognise the same shape when a competition asks for the number of necklaces, the number of solutions of $x^m = e$, or the number of Sylow subgroups.

There is also a structural truth worth naming. The problem is equivalent to the statement that the number k of subgroups of order p satisfies $k \equiv 1 \pmod{p}$, because $n = k(p-1)$ and so $n + 1 \equiv 1 - k$. That equivalence is worth writing on your page even though it is not the route you take, because it tells you the theorem is a Sylow type congruence and therefore that a Sylow type mechanism, namely a p group acting with few fixed points, will be involved. Recognising the family a statement belongs to is how you choose the tool before you know the proof.

What the examiners nudged with: the $+1$ (switch to elements of order dividing p), the phrase "exactly n elements" with no structure on the group (only counting can work), and the dichotomy "$n = 0$ or" (dispose of the degenerate case with Lagrange in one sentence).

Revolving concepts

Order of an element. $\operatorname{ord}(x)$ is the least positive integer t with $x^t = e$, and $x^s = e$ if and only if $\operatorname{ord}(x) \mid s$. Hence for prime p, $x^p = e$ forces $\operatorname{ord}(x) \in \{1, p\}$. See Book 1, field: Abstract algebra, topic: cyclic groups and element orders.

Lagrange's theorem. The order of a subgroup divides the order of the group, so $\operatorname{ord}(x) \mid |G|$ for every x. Used once, to show $n > 0$ implies $p \mid |G|$. See Book 1, field: Abstract algebra, topic: cosets and Lagrange.

Group actions and orbit stabiliser. An action of H on X partitions X into orbits, and $|Hx| = [H : H_x]$ divides $|H|$. The corollaries used here are that a prime order group has only orbits of size 1 and p, and that the fixed points are exactly the singleton orbits. See Book 1, field: Abstract algebra, topic: group actions.

Fixed point lemma and its induction, the recursion generalised. For $|H| = p^k$ acting on finite X we have $|X| \equiv |X^H| \pmod{p}$. The general form is an induction on k in disguise: orbit sizes are p^j for $0 \le j \le k$, so the congruence holds modulo p for every k, and modulo p^k if all nonsingleton orbits are free. The general recursion pattern here is "a group of order p^k acting on a set decomposes it into blocks whose sizes form a geometric family $1, p, p^2, \ldots, p^k$, so counting modulo p discards all but the blocks of size 1". Applied with $H = \mathbb{Z}/p$ acting on strings of length p over an alphabet of size a, it yields $a^p \equiv a \pmod{p}$, which is Fermat's little theorem. See Book 1, field: Abstract algebra, topic: p groups and fixed points.

Cauchy's theorem. If a prime p divides $|G|$ then G has an element of order p. The lemma proved above contains it. The tuple proof is due to McKay and is the shortest known. See Book 1, field: Abstract algebra, topic: Cauchy and Sylow.

Sylow's theorems. A Sylow p subgroup exists, they are all conjugate, and their number n_p satisfies $n_p \equiv 1 \pmod{p}$ and $n_p \mid |G|$. The congruence $n_p \equiv 1$ is the same phenomenon as this problem, and indeed for $|G|$ divisible by p but not p^2 the two statements coincide. See Book 1, field: Abstract algebra, topic: Cauchy and Sylow.

Frobenius's theorem. If t divides $|G|$ then t divides the number of $x \in G$ with $x^t = e$. This is the correct general statement of which the problem is the case $t = p$. Its proof is much harder and is a knowledge gap you should record, not disguise. See Book 1, field: Abstract algebra, topic: counting solutions of $x^t = e$.

Elementary abelian p groups. A group in which every nonidentity element has order p and which is abelian is a vector space over $\mathbb{F}_p$, hence of order p^k. Needed only for the alternative solutions, but it is the standard object when several commuting elements of order p appear. See Book 1, field: Abstract algebra, topic: abelian p groups.

Circuit Bank

- **WHEN** you must prove that a prime p divides some count in an arbitrary finite structure **DO** build a set whose size you can compute exactly, let a group of order p act on it, and identify the fixed points with the objects you are counting **BECAUSE** orbits have size 1 or p, so the size of the set is congruent to the number of fixed points modulo p
- **WHEN** a statement counts elements of order exactly p and contains a $+1$ **DO** switch to the set $\{x : x^p = e\}$ of elements of order dividing p **BECAUSE** that set is defined by an equation and therefore arises as a fixed point set, whereas the set of elements of order exactly p has no closure property at all
- **WHEN** you need a set of known size inside an arbitrary group of order m **DO** take tuples with one product constraint, so that the last coordinate is determined by the others **BECAUSE** the count is $m^{\text{length}-1}$ regardless of the structure of the group
- **WHEN** a defining condition is invariant under cyclic rotation of its arguments **DO** let $\mathbb{Z}/p$ act by rotation and look at the constant tuples **BECAUSE** rotation invariance is precisely the statement that the shift preserves the set, and the fixed points of a rotation are the constant configurations
- **WHEN** a problem offers the dichotomy "either the count is zero or a congruence holds" **DO** dispose of the zero case first with Lagrange or an existence argument, and use the surviving hypothesis in the main argument **BECAUSE** the nonzero case supplies the divisibility hypothesis $p \mid |G|$ that the main count requires

Backtesting

1. First useful cue: the $+1$ in the conclusion, which says the natural object is $\{x : x^p = e\}$ of size $n + 1$ rather than the set of elements of order exactly p.
2. Method the expression suggested: prove that p divides the number of solutions of $x^p = e$ by letting $\mathbb{Z}/p$ act by cyclic shift on the set of p tuples with product e, whose size $|G|^{p-1}$ is divisible by p.
3. Where you would hesitate, and the thought to reinforce: at the moment of inventing the tuple set, because it looks unmotivated. Reinforce this sentence: I need a set of known size with a $\mathbb{Z}/p$ action, and in an arbitrary group the only sizes I know are powers of $|G|$, so I take tuples with exactly one relation, and I choose the relation to be rotation invariant.
4. The trap the question sets: attempting to count elements of order exactly p directly, which yields only $n = k(p-1)$ and pushes the difficulty into proving $k \equiv 1 \pmod{p}$. A second trap is forgetting to verify that the cyclic shift really preserves the set S, which is the one line where the group axioms are used.
5. What makes you recognise it faster next time: the shape "divisibility by a prime of a count, in a structure with no hypotheses". That shape always means a group of order p acting, and fixed points.
6. The reusable decision rule: to prove $p \mid N$, realise N as the number of fixed points of a $\mathbb{Z}/p$ action on a set whose cardinality is visibly divisible by p.

Mirror drills

1. Prove Fermat's little theorem, $a^p \equiv a \pmod{p}$ for a prime p and a positive integer a, by a counting argument. *Answer:* let $\mathbb{Z}/p$ act by cyclic rotation on the a^p strings of length p over an alphabet of size a; orbits have size 1 or p, and the fixed points are the a constant strings.
2. Let G be a finite group of even order. Prove that G contains an element of order 2. *Answer:* take $p = 2$ in the lemma: $|\{x : x^2 = e\}|$ is even and contains e, so it contains a second element, which has order 2. Equivalently, pair each x with x^{-1} and note the unpaired elements are exactly the solutions of $x^2 = e$.
3. Let p be a prime dividing the order of a finite group G. Prove that the number k of subgroups of G of order p satisfies $k \equiv 1 \pmod{p}$. *Answer:* distinct subgroups of order p meet only in e and each contains $p - 1$ elements of order p, so $n = k(p-1)$; the theorem just proved gives $p \mid n + 1 = k(p-1) + 1 \equiv 1 - k \pmod{p}$.

19.6 A6. Bounding admissible triangulations of a polygon

A triangulation $\mathcal{T}$ *of a polygon P is a finite collection of triangles whose union is P, and such that the intersection of any two triangles is either empty, or a shared vertex, or a shared side. Moreover, each side is a side of exactly one triangle in $\mathcal{T}$. Say that $\mathcal{T}$ is* admissible *if every internal vertex is shared by 6 or more triangles. Prove that there is an integer M_n, depending only on n, such that any admissible triangulation of a polygon P with n sides has at most M_n triangles.*

Read it out loud

Say what the hypothesis is really about. "Every internal vertex is shared by 6 or more triangles" is a curvature condition. In the flat triangular lattice every internal vertex is shared by exactly six triangles, so six is the flat value; anything above six is negatively curved, and anything below six is positively curved. The problem is therefore: a triangulated disc with no positive curvature in the interior has its size controlled by its boundary. That is a discrete Gauss and Bonnet statement, and once you say it in those words you know which identity to write.

The fields wired in are planar graph theory (Euler's formula and edge counting), a small amount of plane topology (a triangulated polygon is a disc, so the link of an interior vertex is a cycle and of a boundary vertex a path), and induction with a peeling argument. There is no metric content at all: the triangles may be long, thin, wildly unequal, and the statement is unaffected, which is the signal that the whole problem is combinatorial and that any attempt to argue by areas or angles alone will fail.

Within thirty seconds you should have written three lines. Write T for the number of triangles, I for the number of internal vertices, E for the number of edges, and a_i for the number of edges at the boundary vertex v_i. Then

$$T = n + 2I - 2, \qquad 3T = 2E - n, \qquad \sum_{i=1}^{n} a_i \leq 4n - 6.$$

The first says bounding T is the same as bounding I. The third is the whole content of the hypothesis, and here is the sting you must notice immediately: it does not involve I at all. So the global count, which is the obvious weapon, cannot bound the number of triangles. That is the discovery on which the problem turns, and it is the reason the problem is an A6 rather than an A2.

Since the global identity will not bound I, it must be used locally: to force the existence of a special configuration on the boundary that you can shave off, reducing n by one at a bounded cost. That is the plan, and everything after this point is executing it while refusing to wave your hands at the degenerate cases.

Approaches, ranked worst to best

1. **Metric estimates.** *Cue:* triangles, angles, areas. *Circuit:* bound the area or the angles of each triangle. There is no scale in the problem and no lower bound on any angle, so a triangulation may contain arbitrarily thin triangles of arbitrarily small area. Every metric quantity you might bound is unbounded here. Rank last: it is not merely hard, it is false as a strategy.

2. **Use the degree inequality globally.** *Cue:* $\sum a_i \leq 4n - 6$ looks like a strong constraint. *Circuit:* combine with $T = n + 2I - 2$. This is the zombie route and it is worth doing once so you feel it fail. The inequality is completely free of I, so no amount of algebra will extract a bound on I from it. What it does tell you is the curvature budget on the boundary, which is what the ideal route uses. Rank it here because it is a necessary experiment, not a solution.

3. **Peel by distance to the boundary.** *Cue:* layers of a lattice patch shrink as you go inward. *Circuit:* induct on the layer index. The instinct is right, and in the hexagonal lattice patch the layers shrink by exactly six each step. But the set of vertices at distance r from the boundary need not bound a connected region, so you must carry a case analysis over components and prove the layer really does shrink. More bookkeeping than the collar removal for the same conclusion.
4. **Remove an ear when some boundary vertex has degree** 2. *Cue:* a degree 2 boundary vertex sits in exactly one triangle. *Circuit:* induct on n. Correct and easy, but it handles only one case; a triangulation may have every boundary degree at least 3. It is a component of the ideal route, not a route.
5. **Curvature budget, chord splitting, then collar removal.** *Cue:* six or more triangles per internal vertex is a nonpositive curvature condition. *Circuit:* prove the global identity, then use it to force a boundary run of degrees $3, 4, \dots, 4, 3$ and peel that run. Best. The identity is proved once, used once globally to reduce "bound T" to "bound I", and then used repeatedly as a local existence device. The induction on n has exactly two cases and both are clean.

The ideal solution

Throughout, P is a simple polygon with vertices $v_1, \dots, v_n$ in cyclic order and $\mathcal{T}$ is an admissible triangulation of P. Indices on boundary vertices are read cyclically.

Step 0: the triangulation is a simplicial disc.

No vertex of $\mathcal{T}$ lies in the relative interior of an edge of $\mathcal{T}$. Indeed, suppose the triangle Δ' has a vertex q in the relative interior of a side s of the triangle Δ. Then $\Delta \cap \Delta'$ is nonempty, so by hypothesis it is a shared vertex or a shared side; either way q would have to be a vertex of Δ, which it is not. Hence $\mathcal{T}$ is edge to edge, and since each side of P is a side of exactly one triangle, every side of P is an edge of $\mathcal{T}$. Consequently the vertices of $\mathcal{T}$ lying on ∂P are exactly $v_1, \dots, v_n$.

Since the union of the triangles is P, a closed disc, the complex is a triangulated closed disc. We use the standard consequences: the link of an internal vertex is a cycle, so an internal vertex of degree a lies in exactly a triangles; the link of a boundary vertex is a path, so a boundary vertex of degree a lies in exactly $a - 1$ triangles, and its neighbours in the fan order begin and end with its two neighbours on ∂P. In particular $a_i \geq 2$ for each i, and admissibility says exactly that every internal vertex has degree at least 6.

Step 1: the counting lemma.

Lemma 19.6.1. *Let T be the number of triangles, I the number of internal vertices, E the number of edges, and a_i the degree of v_i. Then*

$$\text{(i)} \quad T = n + 2I - 2, \qquad \text{(ii)} \quad \sum_{i=1}^{n} a_i \leq 4n - 6.$$

Proof. Sum all the angles of all the triangles. Each triangle contributes π, so the total is $T\pi$. Grouping instead by vertex, each internal vertex contributes 2π and each boundary vertex v_i contributes the interior angle of P at v_i; those interior angles sum to $(n-2)\pi$. Hence $T\pi = 2\pi I + (n-2)\pi$, which is (i).

Count incidences between triangles and edges. Each triangle has three edges, and each edge lies in two triangles except the n edges of ∂P, which lie in one. Hence $3T = 2(E - n) + n = 2E - n$, so

$$2E = 3T + n = 3(n + 2I - 2) + n = 6I + 4n - 6.$$

Now sum degrees over all vertices: $2E = \sum_{i=1}^{n} a_i + \sum_{u \text{ internal}} \deg u \geq \sum_{i=1}^{n} a_i + 6I$, using admissibility. Combining the two displays gives $\sum a_i + 6I \leq 6I + 4n - 6$, which is (ii). □

It is worth recording (ii) in its curvature form. Define $\kappa(u) = 6 - \deg u$ for an internal vertex and $\kappa(v_i) = 4 - a_i$ for a boundary vertex. The computation above says

$$\sum_{u \text{ internal}} \kappa(u) + \sum_{i=1}^{n} \kappa(v_i) = 6I + 4n - 2E = 6,$$

always, for any triangulated disc. Admissibility says the internal curvature is nonpositive, so the boundary must carry at least the whole of the total curvature:

$$\sum_{i=1}^{n} (4 - a_i) \geq 6.$$

Step 2: the bound.

Theorem 19.6.2. *Every admissible triangulation of a polygon with $n \geq 3$ sides has at most $M_n = n^2 - 2n - 2$ triangles.*

Proof. Strong induction on n. Note $M_3 = 1$ and $M_n = M_{n-1} + 2n - 3$ for $n \geq 4$.

Base case $n = 3$. By (ii), $a_1 + a_2 + a_3 \leq 6$, and each $a_i \geq 2$, so $a_1 = a_2 = a_3 = 2$. Then v_1 has only the two sides of P as edges, so the unique triangle of $\mathcal{T}$ at v_1 has vertices v_1, v_2, v_3 and equals P. Its interior is all of the interior of P, and distinct triangles of $\mathcal{T}$ have disjoint interiors, so $\mathcal{T} = \{P\}$ and $T = 1 = M_3$.

Induction step. Let $n \geq 4$ and assume the theorem for all polygons with at least 3 and at most $n - 1$ sides. Call an edge of $\mathcal{T}$ a *chord* if it is not a side of P but both its endpoints are boundary vertices.

Case A: $\mathcal{T}$ has a chord $v_i v_j$. The relative interior of the chord lies in the interior of P, so the chord divides P into two simple polygons P_1 and P_2 with n_1 and n_2 sides, where $n_1 + n_2 = n + 2$ and $n_1, n_2 \geq 3$; hence $3 \leq n_1, n_2 \leq n - 1$. Every triangle of $\mathcal{T}$ lies in P_1 or in P_2, since its interior is connected and disjoint from the chord, so $\mathcal{T}$ splits as $\mathcal{T}_1 \cup \mathcal{T}_2$. A vertex internal to P_k is internal to P, because no vertex lies in the relative interior of the chord, and all of its triangles lie in P_k; so its degree is unchanged and $\mathcal{T}_k$ is admissible. By the induction hypothesis and the convexity of $x \mapsto x^2$,

$$T = T_1 + T_2 \leq M_{n_1} + M_{n_2} = n_1^2 + n_2^2 - 2(n+2) - 4 \leq 9 + (n-1)^2 - 2n - 8 = n^2 - 4n + 2 \leq M_n,$$

the last inequality because $M_n - (n^2 - 4n + 2) = 2n - 4 \geq 0$.

Case B: $\mathcal{T}$ has no chord. First, every $a_i \geq 3$. For if $a_i = 2$ then the only edges at v_i are the two sides of P at v_i, so the unique triangle at v_i is $v_{i-1}v_iv_{i+1}$ and $v_{i-1}v_{i+1}$ is an edge of $\mathcal{T}$ joining two boundary vertices; as $n \geq 4$ it is not a side of P, so it is a chord, contrary to assumption.

Write $t_j = |\{i : a_i = j\}|$ for $j \geq 3$. From $\sum_i (4 - a_i) \geq 6$ we get

$$t_3 \geq 6 + \sum_{j \geq 5} (j - 4) t_j \geq 6 + \sum_{j \geq 5} t_j.$$

In particular $t_3 \geq 6$, so $n \geq 6$. Mark each boundary vertex with $a_i = 3$ as low and each with $a_i \geq 5$ as high, and read the marks in cyclic order. There are strictly more low marks than high marks, so two low marks are adjacent in this cyclic reading, that is, there are boundary vertices w_1 and w_k with $a = 3$ such that the vertices strictly between them along one arc, namely $w_2, \ldots, w_{k-1}$, all have $a = 4$. Here $k \geq 2$, and since at least $t_3 - 2 \geq 4$ vertices of degree 3 lie outside the run, $k \leq n - 4$.

Write w_0 and w_{k+1} for the boundary neighbours of w_1 and w_k outside the run. Read the fan at each run vertex. At w_1, of degree 3, the neighbours in fan order are w_0, z_1, w_2 for some vertex z_1, and the two triangles at w_1 are $w_0w_1z_1$ and $z_1w_1w_2$. At w_j for $1 < j < k$, of degree 4, the neighbours in fan order are $w_{j-1}, z_{j-1}, z_j, w_{j+1}$, and the three triangles are $w_{j-1}w_jz_{j-1}$, $z_{j-1}w_jz_j$ and $z_jw_jw_{j+1}$. At w_k, of degree 3, the neighbours are $w_{k-1}, z_{k-1}, w_{k+1}$ and the triangles are $w_{k-1}w_kz_{k-1}$ and $z_{k-1}w_kw_{k+1}$. Since consecutive entries of a fan are distinct, $z_{j-1} \neq z_j$.

Each z_j is an internal vertex: it is a neighbour of w_j other than w_{j-1} and w_{j+1}, so the edge z_jw_j is not a side of P, and if z_j were a boundary vertex that edge would be a chord.

The z_j are pairwise distinct. Adjacent ones are distinct as noted. Suppose $z_i = z_j = z$ with $j \geq i+2$. The closed walk $z \to w_{i+1} \to w_{i+2} \to \cdots \to w_j \to z$ is a simple cycle C of edges of $\mathcal{T}$, since the w's are distinct boundary vertices and z is internal. As $C \subseteq P$ and the complement of P is connected and unbounded, the bounded component R of the complement of C satisfies $R \subseteq P$; and C is a union of edges, so $\overline{R}$ is the union of the triangles of $\mathcal{T}$ inside it and is an admissible triangulation of a polygon Q with $m = j - i + 1$ sides. Near each w_l with $i+2 \leq l \leq j-1$ the cycle C coincides with ∂P, so all four edges at w_l lie in Q and its degree there is 4; at w_{i+1} the region Q is the sector from z round to w_{i+2}, containing the three edges to z, z_{i+1} and w_{i+2}; symmetrically the degree of w_j in Q is 3; and the degree of z in Q is at least 2. Summing, the boundary degrees of Q total at least $2 + 3 + 4(j-i-2) + 3 = 4(j-i)$, while (ii) applied to Q gives at most $4m - 6 = 4(j-i) - 2$. That is a contradiction, so no such coincidence occurs.

Now delete from $\mathcal{T}$ the triangles containing at least one of $w_1, \ldots, w_k$. By the fan description these are $w_0w_1z_1$, the $k-1$ triangles $w_jw_{j+1}z_j$ for $1 \leq j \leq k-1$, the $k-2$ triangles $z_{j-1}w_jz_j$ for $2 \leq j \leq k-1$, and $z_{k-1}w_kw_{k+1}$; that is $2k-1$ triangles in all. The edges deleted are exactly those incident to some w_l, so no other vertex loses an edge. The remaining triangles form a triangulation $\mathcal{T}'$ of the region P' obtained from P by replacing the boundary path $w_0, w_1, \ldots, w_k, w_{k+1}$ by the path $w_0, z_1, \ldots, z_{k-1}, w_{k+1}$, whose edges w_0z_1, z_jz_{j+1} and $z_{k-1}w_{k+1}$ are all edges of deleted triangles. Since the z_j are distinct internal vertices of P, this new boundary is a simple closed polygon, and P' has $n - (k+1) + k = n - 1$ sides. Every vertex internal to P' is internal to P with the same degree, so $\mathcal{T}'$ is admissible. By the induction hypothesis and $k \leq n-4$,

$$T \leq M_{n-1} + 2k - 1 \leq M_{n-1} + 2n - 3 = M_n.$$

This completes the induction. □

So $M_n = n^2 - 2n - 2$ works, and in particular such a bound exists, which is what was asked. The truth is smaller: a refinement of the run argument gives $M_n = M_{n-1} + 2\lfloor n/6 \rfloor + 1$, of order $\frac{1}{6}n^2$, and a hexagonal patch of the triangular lattice with a boundary as close to regular as possible attains order $\frac{1}{6}n^2$, so the exponent and the constant $\frac{1}{6}$ are both sharp.

Layer 1: WHAT

Block 1. Read "6 or more triangles at each internal vertex" as nonpositive combinatorial curvature, with the triangular lattice as the flat model.

Block 2. Convert triangles into internal vertices: $T = n + 2I - 2$, by summing angles or by Euler.

Block 3. Derive the boundary budget $\sum a_i \leq 4n - 6$, equivalently $\sum \kappa(v_i) \geq 6$, and notice it contains no I.

Block 4. Conclude that the identity must be used locally, not globally, and set up an induction on n.

Block 5. Dispose of chords first: a chord splits P into two polygons with strictly fewer sides each.

Block 6. In the chordless case the budget forces at least six boundary vertices of degree 3, hence a run of consecutive degrees $3, 4, \ldots, 4, 3$.

Block 7. Read the fans along the run, check the collar vertices z_j are internal and distinct, and delete the $2k-1$ triangles of the collar to obtain an admissible triangulation of an $(n-1)$ gon.

Block 8. Bookkeeping: $M_3 = 1$, $M_n = M_{n-1} + 2n - 3$, so $M_n = n^2 - 2n - 2$.

The nominal route runs Blocks 2 and 3 and then tries to solve for I. The bifurcation point is the sentence "the inequality $\sum a_i \leq 4n - 6$ does not involve I". The zombie treats that as a dead end and goes back to the drawing board; the ideal solver treats it as a specification of what the inequality is for. It is an existence device for special boundary vertices, and existence devices feed inductions.

Layer 2: HOW

Block 1. **Cue.** The number six, attached to internal vertices of a triangulation. **Why natural.** Six is the number of triangles at a vertex of the regular triangular lattice, which is the unique flat triangulated model of the plane. A condition "at least six" is therefore "curvature at most zero". Recognising the flat model is what tells you the extremal object will be a lattice patch and that no metric argument can help, since the lattice can be sheared arbitrarily without changing any incidence. **Link to the next block.** If curvature is the language, the next thing to write is the curvature identity, that is, Euler's formula.

Block 2. **Cue.** A triangulated polygon with a triangle count to be bounded. **Why natural.** Both quantities you can compute for a triangulated disc are forced: the total angle is $T\pi$ by triangles and $2\pi I + (n-2)\pi$ by vertices. Equating them gives $T = n + 2I - 2$ with no inequality wasted. The same identity follows from $V - E + F = 2$ with $F = T + 1$ and $3T = 2E - n$; use whichever you can write faster, but write one of them before anything else, because it replaces the object you must bound by a simpler one. **Link to the next block.** Bounding T is now the same as bounding I, the number of internal vertices.

Block 3. **Cue.** Admissibility is a statement about degrees, and $\sum_v \deg v = 2E$ is the only identity that consumes degrees. **Why natural.** Every internal vertex contributes at least 6 to $2E$, and $2E$ has already been computed as $6I + 4n - 6$. The $6I$ cancels exactly, which is not a coincidence: it is the statement that the hypothesis is exactly critical, that six is the flat value. What survives is a pure boundary statement, $\sum(4 - a_i) \geq 6$. **Link to the next block.** The cancellation of I is the crucial discovery, and it must be interpreted rather than lamented.

Block 4. **Cue.** A global inequality that is silent about the quantity you want. **Why natural.** If a constraint cannot bound a quantity globally, its role is to force structure locally. Here it says the boundary carries at least six units of positive curvature, and since each boundary vertex carries at most 1 unit when $a_i \geq 3$, at least six boundary vertices are special. Special boundary vertices are exactly what a peeling induction needs, because they are the places where the triangulation is thin enough to shave. **Link to the next block.** Induct on n; the task becomes finding a piece of boundary whose removal drops n by one at bounded cost.

Block 5. **Cue.** The removal will replace a piece of boundary by another piece, so anything that already cuts the polygon should be handled first. **Why natural.** A chord is an edge of the triangulation joining two boundary vertices without being a side. It splits P into two polygons with $n_1 + n_2 = n + 2$, and since each part has at least three sides, each has at most $n - 1$; so both parts are covered by a strong induction hypothesis. Clearing this case also buys a strong structural fact for the other case: with no chord, no boundary vertex can have degree 2. **Link to the next block.** The surviving case has all $a_i \geq 3$, which is what makes the curvature accounting sharp.

Block 6. **Cue.** A budget of at least six units distributed over the boundary, with each degree 3 vertex worth $+1$ and each degree $j \geq 5$ vertex worth $-(j-4)$. **Why natural.** Since $t_3 \geq 6 + \sum_{j \geq 5} t_j$, the low marks strictly outnumber the high marks. In a cyclic sequence of low and high marks in which lows outnumber highs, two lows must be adjacent, since otherwise each low would be followed by at least one high. The vertices between those two lows all have degree 4. This is pigeonhole applied to a cyclic arrangement, and the cyclic form is what makes it work. **Link to the next block.** You now have a run $3, 4, \ldots, 4, 3$ of consecutive boundary vertices, which is precisely a strip of triangulation two triangles deep.

Block 7. **Cue.** Degrees 3 and 4 at boundary vertices mean fans of exactly two and exactly three triangles. **Why natural.** Write the fans out. The degree 3 vertex at each end contributes one new interior neighbour, and each degree 4 vertex in the middle passes the collar along by one. The result is a chain $z_1, \dots, z_{k-1}$ forming the new boundary. Then check the two ways this can degenerate, because a marker will look for exactly those checks: a z_j on the boundary would be a chord, which the case assumption forbids; a repetition $z_i = z_j$ would pinch the region, and it is killed by applying the counting lemma to the sub polygon cut off by the repeated vertex, where the boundary degrees are forced to be $3, 4, \dots, 4, 3$ again and overshoot the budget by exactly 2. **Link to the next block.** Deleting the collar removes $2k - 1$ triangles and exactly one boundary vertex, so the induction closes.

Block 8. **Cue.** A recursion $M_n = M_{n-1} + 2n - 3$ with $M_3 = 1$. **Why natural.** First order recursions with polynomial forcing are solved by summing. Here $\sum_{m=4}^{n}(2m-3) = n^2 - 2n - 3$, so $M_n = n^2 - 2n - 2$. Then check that this closed form also dominates the chord case, which is the only place the two branches could conflict. **Link to the next block.** The proof is complete; the sharp constant is a separate question and is worth knowing but not worth attempting in the arena.

Layer 3: WHY

The mathematical truth underneath is discrete Gauss and Bonnet. For any triangulated closed disc,

$$\sum_{u \text{ internal}} (6 - \deg u) \;+\; \sum_{v \in \partial} (4 - \deg v) \;=\; 6,$$

which is Euler's formula in curvature clothing: the total curvature is 6χ with $\chi = 1$. The two normalisations, $6 - \deg$ inside and $4 - \deg$ on the boundary, are not arbitrary. Inside, six is the degree in the flat lattice. On the boundary, four is the degree of a vertex of a straight boundary in the flat lattice, where the boundary vertex sees three triangles and four edges. So the identity says: total curvature is a topological invariant, and any hypothesis that suppresses curvature in the interior forces it out to the boundary.

That is the discernment mechanism. Whenever a combinatorial problem imposes a degree condition at interior points of a planar structure, first convert it to a curvature statement and write the total curvature identity, then ask whether the hypothesis makes the interior curvature negative, zero, or merely nonpositive. If it is strictly negative, you get an immediate global bound: for instance, if every internal vertex had degree at least 7, then the internal curvature would be at most $-I$, so $I \le \sum_{\partial}(4 - a_i) - 6 \le 2n - 6$, and the number of triangles would be at most $5n - 14$ with no induction at all. The reason the problem is hard at exactly six is that the interior curvature is allowed to be exactly zero, so the budget yields nothing globally and must be spent locally. Recognising which of those two regimes you are in is the whole discernment, and it is trainable in one sitting by doing the degree 7 version first and then the degree 6 version.

The second truth is that a nonpositively curved disc has thin boundary somewhere. The budget of six positive units cannot be carried by long stretches of degree 4 boundary, because those are curvature neutral; it has to be carried by degree 3 corners, and there must be at least six of them. Two of them must be adjacent in the reduced cyclic order, which means there is a stretch of boundary bounded by two corners with only neutral vertices between: a collar two triangles deep. Peeling that collar is the discrete analogue of pushing in a boundary curve in a nonpositively curved surface, which shortens it. This is the same phenomenon that makes the extremal example a hexagon: a hexagonal patch is the shape whose six corners of degree 3 exactly carry the six units, with all other boundary vertices neutral, and it is the largest patch for a given boundary length.

What the examiners nudged with: the number six (find the flat model), the phrase "depending only on n" (they want existence, not the sharp constant, so an induction with a crude recursion is fully sufficient), and the definition insisting the intersection of two triangles is empty, a shared

vertex, or a shared side, which is there to make the complex simplicial so that Euler's formula applies without caveat.

Revolving concepts

Euler's formula. For a connected plane graph, $V - E + F = 2$ with F counting the unbounded face. For a triangulated polygon, $F = T + 1$ and $3T = 2E - n$, giving $T = n + 2I - 2$ and $2E = 6I + 4n - 6$. See Book 1, field: Discrete structures and graphs, topic: planar graphs and Euler's formula.

Triangulated discs and links. In a simplicial triangulation of a closed disc, the link of an internal vertex is a cycle and the link of a boundary vertex is a path whose endpoints are its two boundary neighbours. Hence an internal vertex of degree a lies in a triangles and a boundary vertex of degree a lies in $a - 1$ triangles. This is a plane topology fact, and it is a genuine knowledge gap for a reader coming from A level; it rests on the Jordan curve theorem and should be quoted as a standard fact, not smuggled in. See Book 1, field: Geometry, topic: simplicial complexes and links.

Combinatorial curvature and discrete Gauss and Bonnet. With $\kappa = 6 - \deg$ inside and $4 - \deg$ on the boundary, $\sum \kappa = 6\chi$. For a disc that is 6; for a sphere it is 12, which is why a triangulated sphere with all degrees at most 6 has at least twelve vertices of degree 5, the reason a football has twelve pentagons. See Book 1, field: Discrete structures and graphs, topic: discrete curvature.

The triangular lattice as the flat model, and sharpness. Every internal vertex of the triangular lattice has degree 6; a hexagonal patch with n boundary vertices has about $n^2/6$ triangles, so the true growth rate is quadratic with constant $1/6$. The refinement $M_n = M_{n-1} + 2\lfloor n/6 \rfloor + 1$ follows from the sharper statement that six disjoint runs of total length at most $n + 6$ exist. See Book 1, field: Geometry, topic: lattices and extremal configurations.

Chord splitting. A diagonal of a simple polygon that lies inside it divides it into two simple polygons with $n_1 + n_2 = n + 2$; both have at least three and at most $n - 1$ sides, which is exactly what a strong induction on the number of sides needs. See Book 1, field: Geometry, topic: polygon dissection.

The recursion, generalised. The bound obeys $M_3 = 1$ and $M_n = M_{n-1} + q(n)$ with $q(n) = 2n - 3$. Any recursion $u_n = u_{n-1} + q(n)$ with q a polynomial of degree d has $u_n = u_{n_0} + \sum_{m=n_0+1}^{n} q(m)$, a polynomial in n of degree $d + 1$, computable either by Faulhaber sums or by writing an undetermined polynomial of degree $d + 1$ and matching the difference. Here $\sum_{m=4}^{n}(2m - 3) = n^2 - 2n - 3$ and $M_n = n^2 - 2n - 2$. The same template covers every peeling induction whose per step cost is polynomial in the parameter. See Book 1, field: Sequences and recurrences, topic: telescoping and summation of polynomial forcing.

Pigeonhole on a cyclic sequence. If a cyclic sequence contains more marks of type L than of type H, then two L marks are adjacent among the marks. This tiny lemma is the whole of Block 6 and is worth banking on its own. See Book 1, field: Combinatorics, topic: cyclic pigeonhole.

Circuit Bank

- **WHEN** a planar subdivision problem imposes a degree condition at interior vertices **DO** write Euler's formula and the edge to face count, and convert the hypothesis into the curvature identity with $6 - \deg$ inside and $4 - \deg$ on the boundary **BECAUSE** degree conditions are curvature conditions, and total curvature is a topological invariant, so this is the only global constraint available

- **WHEN** the global identity you derived turns out not to involve the quantity you want to bound **DO** stop using it globally and use it as an existence device to force a special local configuration, then induct **BECAUSE** a constraint that cancels the unknown is telling you the hypothesis is exactly critical, which means the content is local

- **WHEN** you want to reduce a triangulated polygon from n sides to $n-1$ **DO** find a boundary vertex or a run of consecutive boundary vertices of low degree and delete the triangles meeting it **BECAUSE** low boundary degree means a shallow fan, so the deletion is a collar whose removal leaves a polygon with one fewer vertex
- **WHEN** an edge joins two boundary vertices without being a side **DO** split the polygon along it and apply strong induction to both parts **BECAUSE** both parts have at least three and at most $n-1$ sides, so the induction hypothesis applies to each
- **WHEN** a peeling argument produces new boundary vertices **DO** prove they are internal and pairwise distinct before claiming the result is a polygon **BECAUSE** a repeated or boundary vertex pinches the region and destroys the induction, and applying the counting lemma to the cut off sub polygon is what rules it out

Backtesting

1. First useful cue: the number six, which is the degree of an internal vertex in the flat triangular lattice, so the hypothesis is nonpositive curvature.
2. Method the expression suggested: write $T = n + 2I - 2$ and the degree sum, obtain $\sum(4 - a_i) \geq 6$, notice it is free of I, and therefore use it locally to force a run $3, 4, \ldots, 4, 3$ on the boundary which can be peeled to reduce n by one.
3. Where you would hesitate, and the thought to reinforce: at the discovery that the inequality does not bound I. Reinforce this sentence: an inequality in which the unknown cancels is not a failure, it is a statement that the hypothesis is critical, and critical hypotheses are used to produce local structure for an induction.
4. The trap the question sets: believing that the Euler count alone finishes the problem, and, at the other end, writing "clearly the remaining region is an $(n-1)$ gon" without checking that the new boundary vertices are internal and distinct. That check is where the marks are, because it is the only place the hypothesis is used twice.
5. What makes you recognise it faster next time: the shape "interior degree bound in a planar complex, bound the size". That shape always means total curvature identity first, then decide whether the interior curvature is strictly negative, in which case you are done globally, or exactly critical, in which case you peel.
6. The reusable decision rule: convert degree hypotheses to curvature, write the invariant, and if the unknown cancels, hunt for the forced local configuration.

Mirror drills

1. Show that any triangulation of a polygon with n sides and no internal vertices has exactly $n-2$ triangles. *Answer:* put $I = 0$ in $T = n + 2I - 2$; equivalently sum angles, $T\pi = (n-2)\pi$.
2. Prove that for any triangulated closed disc, $\sum_{\text{internal}}(6 - \deg u) + \sum_{\partial}(4 - \deg v) = 6$. *Answer:* $2E = 3T + n$ and $T = n + 2I - 2$ give $2E = 6I + 4n - 6$, and the left side of the claim is $6I + 4n - 2E$.
3. Suppose every internal vertex of a triangulation of an n gon has degree at least 7. Prove directly, with no induction, that there are at most $2n - 6$ internal vertices and at most $5n - 14$ triangles. *Answer:* internal curvature is at most $-I$, so $\sum_{\partial}(4 - a_i) \geq 6 + I$; each boundary term is at most 2 since $a_i \geq 2$, so $2n \geq 6 + I$, and then $T = n + 2I - 2 \leq 5n - 14$. Compare with the problem to see why degree six is the critical threshold.

19.7 B1. the congruence that collapses to f(1)

Let f be a polynomial with positive integer coefficients. Prove that if n is a positive integer, then $f(n)$ divides $f(f(n)+1)$ if and only if $n = 1$. (Editor's note: assume f is nonconstant; a constant f makes the claim false, since then $f(n)$ divides $f(f(n)+1)$ for every n.)

Read it out loud

This is a divisibility statement about the value of a polynomial at a shifted argument, not a statement about the polynomial as an algebraic object with roots. The object under scrutiny is a specific positive integer, $f(n)$, and the question is whether another specific integer, $f(f(n)+1)$, sits on its multiple ladder. The instant you see "does A divide B" for two integers built from the same underlying function, the honest first move is not calculus and not factoring the polynomial; it is modular arithmetic. Treat $f(n)$ as a modulus and ask what $f(f(n)+1)$ reduces to modulo it.

The phrase $f(n)+1$ is a guiding light, written as the modulus plus one. Modulo $f(n)$, the modulus itself is 0, so $f(n)+1 \equiv 1$, trivially. Once you see that, pushing this reduced argument through the outer f is a one-line computation term by term, because a polynomial with integer coefficients respects congruence: if $a \equiv b \pmod{m}$ then $f(a) \equiv f(b) \pmod{m}$ for any such f. That fact is the whole engine of the problem; everything after it is bookkeeping.

Positivity of the coefficients does two separate jobs, and you should clock both before writing a line of proof. First, it forces f to be strictly increasing on the positive integers, since every monomial $a_i n^i$ with $a_i > 0$ only grows as n grows; so $f(n) > f(1)$ for every $n > 1$. Second, it forces $f(1) > 0$, so once you reduce the target to $f(1)$ modulo $f(n)$, that residue is a genuine positive integer strictly between 0 and $f(n)$ whenever $n > 1$, and a number strictly between 0 and a modulus can never be the zero residue. The "if and only if" in the statement is two one-line arguments glued together by a single congruence.

Fields embedded: elementary number theory, specifically congruences, and the congruence-respecting property of polynomial evaluation with integer coefficients. The knowledge base needed sits just past A level Further Mathematics; the manipulation itself is short. Within thirty seconds you should have written $f(n)+1 \equiv 1 \pmod{f(n)}$ and be reaching to apply f to both sides.

Approaches, ranked worst to best

1. **expand $f(f(n)+1)$ in full as a polynomial in n.** *Cue:* the composite argument tempts you to substitute and multiply out. *Circuit:* none, this is the zombie route. (why it ranks here: for a degree d polynomial you must expand $(f(n)+1)^i$ for every i up to d and collect terms in n; the algebra grows fast, the modulus structure never becomes visible, and a single slipped term wrecks the whole proof.)

2. **test small explicit f (linear, then quadratic) and conjecture the pattern.** *Cue:* the problem lets you pick any f, so instinct reaches for examples. *Circuit:* inductive conjecture, not a proof circuit. (why it ranks here: taking $f(n) = n$ gives the correct guess, $n \mid n+1$ only when $n = 1$, but a handful of examples never discharges "for every polynomial with positive integer coefficients"; you still owe the general argument afterward, so the examples cost ink without closing the proof.)

3. **rewrite $f(f(n)+1)$ modulo $f(n)$ using $f(n)+1 \equiv 1$.** *Cue:* the divisor $f(n)$ sits literally inside the argument of the dividend, one more than itself. *Circuit:* congruence is preserved by polynomial evaluation. (why it ranks here: this is the ideal route; one substitution, one general lemma about polynomials modulo m, and one strict inequality finish the problem, and every step is forced rather than guessed.)

The ideal solution

Assume, per the editor's note, that f is nonconstant, of degree $d \geq 1$, and write

$$f(x) = \sum_{i=0}^{d} a_i x^i, \qquad a_i \in \mathbb{Z}_{>0} \text{ for every } i = 0, 1, \ldots, d.$$

Since $f(n) \equiv 0 \pmod{f(n)}$ trivially, adding 1 to both sides gives

$$f(n) + 1 \equiv 1 \pmod{f(n)}.$$

A polynomial with integer coefficients preserves congruences under evaluation: if $a \equiv b \pmod{m}$, then $a^i \equiv b^i \pmod{m}$ for every $i \geq 0$ (multiply the congruence by itself i times), so $a_i a^i \equiv a_i b^i \pmod{m}$ term by term, and summing over i gives $f(a) \equiv f(b) \pmod{m}$. Applying this with $a = f(n) + 1$, $b = 1$, $m = f(n)$,

$$f(f(n) + 1) \equiv f(1) \pmod{f(n)}.$$

This single congruence settles both directions at once.

If $n = 1$: here $f(n) = f(1)$, so the congruence reads $f(f(1) + 1) \equiv f(1) \equiv 0 \pmod{f(1)}$, i.e. $f(1) \mid f(f(1) + 1)$. This holds for every nonconstant f with positive integer coefficients, no further hypothesis needed.

If $n > 1$: since every coefficient is a positive integer and f is nonconstant, f is strictly increasing on the positive integers, because

$$f(n) - f(1) = \sum_{i=1}^{d} a_i \left(n^i - 1 \right) > 0$$

for $n > 1$, as every term $n^i - 1$ is positive for $i \geq 1$. So $0 < f(1) < f(n)$. A positive integer strictly between 0 and $f(n)$ is never a multiple of $f(n)$, since the least positive multiple of $f(n)$ is $f(n)$ itself; hence $f(1) \not\equiv 0 \pmod{f(n)}$, and by the congruence above, $f(f(n) + 1) \equiv f(1) \not\equiv 0 \pmod{f(n)}$, so $f(n) \nmid f(f(n) + 1)$.

Combining both cases, $f(n) \mid f(f(n) + 1)$ exactly when $n = 1$, as required. ■

For the editor's note: if f is allowed to be constant, $f(n) = c$ for a positive integer c, then $f(f(n) + 1) = c = f(n)$ for every n, so the divisibility holds always, not only at $n = 1$. This is why nonconstant f is an essential hypothesis, not a cosmetic one.

Layer 1: WHAT

Block 1: rewrite the divisibility question as a congruence, $f(n) \mid f(f(n) + 1) \iff f(f(n) + 1) \equiv 0 \pmod{f(n)}$. Block 2: reduce the inner argument, $f(n) + 1 \equiv 1 \pmod{f(n)}$, and apply the congruence-preserving property of polynomial evaluation to collapse the target to $f(1) \pmod{f(n)}$. Block 3: split on $n = 1$ (where $f(n) = f(1)$, congruence trivially 0) versus $n > 1$ (where strict monotonicity gives $0 < f(1) < f(n)$, so the congruence can never be 0).

The nominal route expands $f(f(n) + 1)$ term by term in powers of n and hunts for a common factor by staring at the expanded polynomial; the ideal route never expands anything, it reduces the argument modulo $f(n)$ first and evaluates second. The bifurcation point is the instant you decide whether to expand $f(f(n) + 1)$ as a polynomial in n, or to treat $f(n)$ as a modulus and reduce before touching f at all. Reducing first is the reroute; expanding first is the zombie route, and it is the entire reason this problem looks harder than it is.

Layer 2: HOW

Block 1. **Cue.** The phrase "does A divide B" for two specific integers is, by definition, a congruence statement, $B \equiv 0 \pmod{A}$. Whenever a problem hands you a divisibility claim about the values of a function rather than its coefficients, translate immediately into modular language. **Why natural.** This is forced by the definition of divisibility, not a choice. Writing $f(n) \mid f(f(n)+1)$ as $f(f(n)+1) \equiv 0 \pmod{f(n)}$ costs no ink and names the correct tool at once, modular reduction, not factoring, not calculus. **Link to the next block.** Once the target is a congruence, the next question answers itself: what is the argument $f(n)+1$ congruent to modulo the same $f(n)$? That is a far smaller question than the divisibility itself.

Block 2. **Cue.** $f(n)+1$ is written as the modulus plus one. Modulo $f(n)$, the modulus itself is 0, so $f(n)+1 \equiv 1$. **Why natural.** $f(n) \equiv 0 \pmod{f(n)}$ is a tautology; adding 1 to both sides of a congruence is always legal. Recognising this costs one line and replaces a messy argument by the constant 1. **Link to the next block.** The reduced argument still has to pass through the outer f, and that only works cleanly if evaluating a polynomial respects congruence, which it does; stating that fact explicitly is the next block.

Block 3. **Cue.** The outer function is the same polynomial f, applied to something already known modulo $f(n)$. A polynomial with integer coefficients is built only from addition and multiplication, both of which respect congruence. **Why natural.** If $a \equiv b \pmod{m}$ then $a^i \equiv b^i \pmod{m}$ for every $i \geq 0$, so $a_i a^i \equiv a_i b^i \pmod{m}$ term by term, and summing gives $f(a) \equiv f(b) \pmod{m}$. With $a = f(n)+1$, $b = 1$, $m = f(n)$, the entire right-hand side collapses to $f(1) \pmod{f(n)}$, regardless of the degree of f. **Link to the next block.** The problem has now reduced to one comparison: is $f(1) \equiv 0 \pmod{f(n)}$? That is answered by comparing the size of $f(1)$ to $f(n)$, which is the final block.

Block 4. **Cue.** The coefficients of f are positive integers; that hypothesis has done nothing yet in the argument, so it is needed here, for a size comparison. **Why natural.** Positive coefficients make f strictly increasing on the positive integers, so $f(n) > f(1)$ whenever $n > 1$, hence $0 < f(1) < f(n)$; a number strictly between 0 and a modulus is never congruent to 0 modulo it. At $n = 1$ the two values coincide and $f(1) \equiv f(1) \equiv 0 \pmod{f(1)}$ trivially. **Why natural.** This is the second use of the same hypothesis in two roles: it made $f(1) > 0$ earlier and now makes $f(1) < f(n)$; both uses are the same monotonicity fact read at different scales. **Link to the next block.** This closes both directions of the iff at once; there is no fifth block.

Layer 3: WHY

The deep fact underneath the whole problem is that reduction modulo m is a ring homomorphism $\mathbb{Z} \to \mathbb{Z}/m\mathbb{Z}$, and evaluating a fixed integer-coefficient polynomial is built only from addition and multiplication inside that target ring; consequently it makes no difference whether you reduce the argument first or evaluate first and reduce afterward, the two routes land on the same residue. That is the honest reason $f(f(n)+1) \equiv f(1) \pmod{f(n)}$ is not a coincidence of this particular f, it is true for every integer-coefficient polynomial.

The discernment mechanism for spotting this route: whenever a divisibility claim reads "$g(n)$ divides $h(n)$" and h is built by feeding a shifted or transformed version of $g(n)$ back into a polynomial, check first whether that shift is congruent to something simple modulo $g(n)$. It almost always is, because problem setters choose the shift precisely so it collapses; the shift $+1$ here is the cheapest possible choice, landing on the residue 1, which is the multiplicative identity and therefore the simplest input f can receive. Training this discernment is a matter of repetition: every time the

divisor reappears literally inside the dividend's own argument, resist evaluating and reduce first instead.

The examiners nudged you toward this by writing $f(n)+1$ rather than, say, $2f(n)+3$; the simplicity of the shift is itself a signal that a one-line congruence closes the problem, and the "if and only if" phrasing is there to test whether you notice that positivity of the coefficients is load-bearing twice over, once to make $f(1)$ positive and once to make it strictly less than $f(n)$.

Revolving concepts

Congruence. $a \equiv b \pmod{m}$ means $m \mid (a-b)$. The set of residues modulo m forms a ring $\mathbb{Z}/m\mathbb{Z}$ under the induced addition and multiplication; see Book 1, field: Number theory, topic: modular arithmetic.

Congruence-compatibility of polynomial evaluation. For any polynomial f with integer coefficients, $a \equiv b \pmod{m} \Rightarrow f(a) \equiv f(b) \pmod{m}$. This is the reduction-modulo-m homomorphism composed with evaluation; it generalises to any ring homomorphism composed with any polynomial map, not merely $\mathbb{Z} \to \mathbb{Z}/m\mathbb{Z}$. See Book 1, field: Abstract algebra, topic: ring homomorphisms and polynomial evaluation.

Strict monotonicity of positive-coefficient polynomials. If every coefficient of f is a positive real number, f is strictly increasing on the positive reals, since every monomial strictly increases and no term can cancel another. See Book 1, field: Polynomials, topic: monotonicity from sign-definite coefficients.

Residues strictly between 0 and the modulus. If $0 < r < m$ then $r \not\equiv 0 \pmod{m}$, since the least positive integer congruent to 0 modulo m is m itself. This is the closing move in any proof that a specific integer is not divisible by another, once you have bounded it strictly between consecutive multiples.

No recursive or self-referential structure appears in this problem; there is nothing to generalise along that axis here.

Circuit Bank

- **WHEN** you must decide whether $g(n)$ divides $h(n)$ for two integer expressions built from a common function **DO** translate to a congruence, $h(n) \equiv 0 \pmod{g(n)}$, and try to reduce the argument of h modulo $g(n)$ before evaluating anything **BECAUSE** divisibility is congruence by definition, and reducing before evaluating avoids expanding a polynomial in full.

- **WHEN** a polynomial with integer coefficients is evaluated at an expression you already know modulo some m **DO** replace the argument by its residue and evaluate the same polynomial at that smaller residue **BECAUSE** polynomial evaluation is built only from addition and multiplication, both of which respect congruence.

- **WHEN** a polynomial has positive coefficients and you need to compare its values at two positive integers **DO** use strict monotonicity directly, $f(n) > f(k)$ whenever $n > k \geq 1$, term by term **BECAUSE** every term $a_i n^i$ only grows with n when $a_i > 0$, so no cancellation between terms can occur.

- **WHEN** a divisibility claim carries an if and only if between one specific value and a general range **DO** dispose of the specific value in one trivial line, then rule out every other value uniformly via a strict inequality on residues **BECAUSE** a residue strictly between 0 and the modulus can never be the zero class, the cheapest possible way to rule out divisibility.

Backtesting

1. First useful cue: the argument $f(n)+1$ sitting exactly one integer above the modulus $f(n)$ itself.
2. Method the expression suggested: reduce the inner argument modulo $f(n)$ before applying the outer f.
3. Where you would hesitate, and the thought to reinforce: hesitating over whether evaluating a polynomial commutes with reduction; the reinforcement is that evaluation is only addition and multiplication, both congruence-preserving.
4. The trap the question sets: expanding $f(f(n)+1)$ in full powers of n before noticing the modulus structure, burying a one-line argument in algebra.
5. What makes you recognise it faster next time: seeing the modulus written literally inside the argument of the same function, "f of something plus one" where the something is the divisor itself.
6. The reusable decision rule: whenever the divisor reappears inside the dividend's own argument, reduce first and evaluate second, never the reverse order.

Mirror drills

1. (drill) Let $f(x) = x^3 + 2x + 5$. For which positive integers n does $f(n)$ divide $f(f(n)+2)$? *Answer:* $f(n)+2 \equiv 2 \pmod{f(n)}$, so the condition becomes $f(n) \mid f(2)$; since f is strictly increasing, this forces $f(n) \le f(2)$, and direct evaluation gives $f(1) = 8$, $f(2) = 17$, so $n = 2$ always works, and $n = 1$ works only if $f(1) \mid f(2)$, which fails here since 17 is not a multiple of 8; the shift $+1$ in the original problem is exactly what made the answer universal instead of f-dependent.
2. (drill) With f as in the original problem, determine for which n, $f(n)$ divides $f(f(n)-1)$. *Answer:* $f(n)-1 \equiv -1 \pmod{f(n)}$, so the condition becomes $f(n) \mid f(-1)$; since $f(-1)$ is a fixed integer independent of n while $f(n) \to \infty$, this can hold for at most finitely many n, in sharp contrast to the original shift.
3. (drill) Why does the proof break if f is allowed a coefficient equal to 0 or negative? *Answer:* the congruence collapse $f(f(n)+1) \equiv f(1) \pmod{f(n)}$ still holds, since it only needs integer coefficients, but the closing step, $0 < f(1) < f(n)$ for $n > 1$, needs every coefficient strictly positive to guarantee strict monotonicity; a mixed-sign f can have $f(n) \le f(1)$ or even $f(n) \le 0$ for some $n > 1$, and the size comparison collapses.

19.8 B2. the antiderivative's extremum forces f to vanish

Suppose that $f : [0,1] \to \mathbb{R}$ has a continuous derivative and that $\int_0^1 f(x)\,dx = 0$. Prove that for every $\alpha \in (0,1)$,

$$\left| \int_0^\alpha f(x)\,dx \right| \leq \frac{1}{8} \max_{0 \leq x \leq 1} |f'(x)|.$$

Read it out loud

Strip away the specific letters and look at the shape underneath. You are given an object built by integrating f, and asked how far that object can wander from zero at an interior point. That is a question about a function pinned to zero at two boundary points with limited curvature, not a question about f itself. Introduce $g(x) = \int_0^x f(t)\,dt$ so that $g(0) = 0$ automatically and $g(1) = \int_0^1 f = 0$ is precisely the hypothesis you were handed; the quantity you must bound, $\int_0^\alpha f$, is nothing but $g(\alpha)$. Rewriting the problem in terms of g is not decoration, it is the whole translation step: the real hypotheses (vanishing at both ends of an interval, a bounded second derivative) are hypotheses about g, dressed up in the statement as hypotheses about f.

Once the problem reads "g vanishes at two points, bound g strictly between them using a bound on g''", the guiding light is the two-point remainder identity that also governs the error of linear interpolation: if g agreed with some polynomial of degree at most one at both 0 and 1, that polynomial would be exactly determined, and the gap between g and that polynomial anywhere in between is controlled by g'' at some unseen point. Here the polynomial that already matches g at 0 and 1 is the zero function, since both values are zero, so the remainder identity hands you a bound on $g(\alpha)$ directly, with no extra structure to invent.

The role of $\max_{0 \leq x \leq 1} |f'(x)|$ is now obvious once you notice $f' = g''$: bounding the curvature of g is exactly the hypothesis on hand, written in terms of f because f is the function the problem starts from, not because f' is the natural object to work with. Reading the problem as a statement about g rather than about f is the single decision that separates every clean solution from every laboured one.

Fields embedded: real analysis, specifically Rolle's theorem and the mean value theorem, plus the fundamental theorem of calculus needed to introduce g in the first place. The knowledge base needed sits past A level Further Mathematics: Rolle's theorem applied twice in sequence, to pin down a point where a second derivative vanishes, is standard analysis but not standard sixth form material. Within thirty seconds of reading you should have written $g(x) = \int_0^x f(t)\,dt$ and restated the two hypotheses as $g(0) = g(1) = 0$.

Approaches, ranked worst to best

1. **crude pointwise bound on f from the Lipschitz condition.** *Cue:* $|f'| \leq B$ makes f Lipschitz, so bounding $f(x)$ in terms of a nearby known value feels natural. *Circuit:* none, this stalls. (why it ranks here: without first locating a point where f is known to vanish, you have no base point to anchor the Lipschitz estimate; you either need the mean-zero hypothesis to locate such a point, which this approach never does explicitly, or you integrate a bound that still carries an unknown constant, and the argument never closes.)

2. **locate the interior critical point of g, use symmetry $\alpha \leftrightarrow 1 - \alpha$, then bound f linearly from that point.** *Cue:* $g(0) = g(1) = 0$ forces the maximum of $|g|$ to occur at an interior critical point of g, i.e. a zero of f. *Circuit:* extremal point plus symmetry reduction. (why it ranks here: this is correct and closes the problem, but it needs three separate reductions chained together, first to the extremal α, then by symmetry to $\alpha \leq \frac{1}{2}$, then a sign normalisation, each requiring its own justification.)

3. **two-point remainder via a double application of Rolle's theorem.** *Cue:* g vanishes at both endpoints of $[0,1]$, which is exactly the setup for the interpolation-error identity. *Circuit:* Rolle's theorem applied twice to an auxiliary function. (why it ranks here: this is the ideal route; one auxiliary function and two uses of Rolle's theorem give the bound at every α simultaneously, with no case split, no symmetry argument, and a constant that is visibly sharp.)

The ideal solution

Define $g : [0,1] \to \mathbb{R}$ by $g(x) = \int_0^x f(t)\,dt$. By the fundamental theorem of calculus, since f is continuous, g is differentiable with $g' = f$; since f itself has a continuous derivative, g is twice differentiable with $g'' = f'$, and g'' is continuous. Put

$$B = \max_{0\le x\le 1} |f'(x)| = \max_{0\le x\le 1} |g''(x)|,$$

which is attained since f' is continuous on the closed interval $[0,1]$. By hypothesis $g(0) = 0$ and $g(1) = \int_0^1 f(t)\,dt = 0$.

Lemma 19.8.1 (Two-point remainder)**.** *Let $g \in C^2[0,1]$ with $g(0) = g(1) = 0$. For every $x \in (0,1)$ there is some $\xi \in (0,1)$, depending on x, such that*

$$g(x) = \frac{g''(\xi)}{2}\, x(x-1).$$

Proof. Fix $x \in (0,1)$ and define

$$\phi(t) = g(t) - \frac{g(x)}{x(x-1)}\, t(t-1), \qquad t \in [0,1].$$

Then $\phi(0) = g(0) = 0$, $\phi(1) = g(1) = 0$, and $\phi(x) = g(x) - g(x) = 0$, so ϕ vanishes at the three points $0 < x < 1$. By Rolle's theorem applied on $[0,x]$ and again on $[x,1]$, ϕ' vanishes at some $\eta_1 \in (0,x)$ and some $\eta_2 \in (x,1)$. Applying Rolle's theorem once more, to ϕ' on $[\eta_1,\eta_2]$, ϕ'' vanishes at some $\xi \in (\eta_1,\eta_2) \subset (0,1)$. Since $t(t-1) = t^2 - t$ has second derivative 2,

$$\phi''(t) = g''(t) - \frac{2g(x)}{x(x-1)},$$

so $\phi''(\xi) = 0$ gives $g''(\xi) = \dfrac{2g(x)}{x(x-1)}$, which rearranges to the claim. □

Apply the lemma with $x = \alpha$: there is $\xi \in (0,1)$ with $g(\alpha) = \frac{g''(\xi)}{2}\alpha(\alpha-1)$, so

$$|g(\alpha)| = \frac{|g''(\xi)|}{2}\,\alpha(1-\alpha) \le \frac{B}{2}\,\alpha(1-\alpha).$$

Completing the square, $\alpha(1-\alpha) = \frac{1}{4} - \left(\alpha - \frac{1}{2}\right)^2 \le \frac{1}{4}$ for every $\alpha \in [0,1]$, with equality only at $\alpha = \frac{1}{2}$. Hence

$$\left|\int_0^\alpha f(x)\,dx\right| = |g(\alpha)| \le \frac{B}{2}\cdot\frac{1}{4} = \frac{B}{8} = \frac{1}{8}\max_{0\le x\le 1}|f'(x)|,$$

for every $\alpha \in (0,1)$, which is the required inequality. ■

Sharpness. The constant $\frac{1}{8}$ is best possible. Take $f(x) = \frac{1}{2} - x$; then $f'(x) = -1$ everywhere, so $B = 1$, and $\int_0^1 f(x)\,dx = \left[\frac{x}{2} - \frac{x^2}{2}\right]_0^1 = 0$, satisfying the hypothesis. Here $g(\alpha) = \int_0^\alpha \left(\frac{1}{2} - x\right)dx = \frac{\alpha(1-\alpha)}{2}$, which attains the value $\frac{1}{8}$ exactly at $\alpha = \frac{1}{2}$. The affine function that has constant $|f'|$ throughout saturates every inequality used in the proof at once, so the bound cannot be improved.

Layer 1: WHAT

Block 1: introduce $g(x) = \int_0^x f$ and translate the two hypotheses, $g(0) = g(1) = 0$, $g' = f$, $g'' = f'$; restate the goal as bounding $|g(\alpha)|$ by $\frac{1}{8}\max|g''|$. Block 2: recognise the shape, a function vanishing at two points with bounded curvature, as the two-point remainder identity, and build the auxiliary function $\phi(t) = g(t) - \frac{g(x)}{x(x-1)}t(t-1)$ that shares three zeros with g. Block 3: apply Rolle's theorem twice in sequence (once on each half, once on the pair of resulting critical points) to extract a point ξ where $\phi'' = 0$, giving the exact remainder formula for $g(x)$. Block 4: bound $|g''(\xi)|$ by B and $x(1-x)$ by its maximum $\frac{1}{4}$ at $x = \frac{1}{2}$, closing the inequality, then confirm sharpness with an explicit affine example.

The nominal route works with f directly, trying to bound $\int_0^\alpha f$ from a Lipschitz estimate on f anchored at some point that has to be found by other means; it never promotes g to a first-class object, so the mean-zero hypothesis and the derivative bound never combine cleanly. The ideal route renames the problem in terms of g before estimating anything. The bifurcation point is exactly that renaming: the decision to write down $g = \int_0^x f$ and restate both hypotheses in its language before touching an inequality sign is what separates the two routes, and skipping it is what sends every other approach into case analysis.

Layer 2: HOW

Block 1. **Cue.** The quantity to be bounded, $\int_0^\alpha f$, and the hypothesis, $\int_0^1 f = 0$, are both integrals of f starting at 0. Two integrals of the same function starting at the same point are values of a single new function. **Why natural.** Naming that function, $g(x) = \int_0^x f(t)\,dt$, turns two separate statements about f into two boundary values of one function, $g(0) = 0$ and $g(1) = 0$, which is a far more usable shape than two disconnected integral conditions. **Link to the next block.** With g vanishing at both ends of $[0,1]$, the natural next question is how far g can stray from zero in between, which is a curvature question once you notice $g'' = f'$.

Block 2. **Cue.** A twice-differentiable function that vanishes at two points and needs a bound in between, in terms of a bound on its second derivative, is the exact setup of the two-point interpolation remainder: subtract off the unique low-degree polynomial that already agrees with g at those two points. **Why natural.** Since $g(0) = g(1) = 0$, the matching polynomial is the zero function, and the auxiliary function $\phi(t) = g(t) - \frac{g(x)}{x(x-1)}t(t-1)$ is engineered to also vanish at the third point $t = x$, giving three zeros to feed into Rolle's theorem. **Link to the next block.** Three zeros of ϕ hand you a zero of ϕ' between each adjacent pair, and a zero of ϕ'' between those, which is the mechanism that produces ξ.

Block 3. **Cue.** ϕ has zeros at $0 < x < 1$; Rolle's theorem converts n zeros of a differentiable function into $n-1$ zeros of its derivative. **Why natural.** Applying Rolle's theorem on $[0,x]$ and on $[x,1]$ gives zeros $\eta_1 \in (0,x)$ and $\eta_2 \in (x,1)$ of ϕ'; applying it once more on $[\eta_1,\eta_2]$ gives a zero ξ of ϕ''. Since $\phi''(t) = g''(t) - \frac{2g(x)}{x(x-1)}$, the equation $\phi''(\xi) = 0$ is precisely $g(x) = \frac{g''(\xi)}{2}x(x-1)$. **Link to the next block.** This closed-form remainder is now a genuine equation, not an inequality, and every subsequent step is pure estimation.

Block 4. **Cue.** The remainder formula expresses $g(\alpha)$ as $\frac{g''(\xi)}{2}\alpha(\alpha-1)$, a product of a bounded quantity and an explicit, fully computable quadratic in α. **Why natural.** Bounding $|g''(\xi)|$ by B and maximising $\alpha(1-\alpha)$ by completing the square, both one-line facts, multiply to give exactly $\frac{B}{8}$; no case split on the sign of $\alpha - \frac{1}{2}$ or on the sign of $g(\alpha)$ is ever needed, because the remainder formula already carries the correct sign built in. **Why natural.** Checking sharpness with $f(x) = \frac{1}{2} - x$ confirms every inequality in the chain, $|g''(\xi)| \le B$ and $\alpha(1-\alpha) \le \frac{1}{4}$, is attained simultaneously

by the same simplest possible example, an affine function, which is the honest reason $\frac{1}{8}$ is the best constant and not merely a convenient one. **Link to the next block.** There is no fifth block; the bound holds for every $\alpha \in (0,1)$ at once.

Layer 3: WHY

The truth underneath this problem is the classical bound on how far a twice-differentiable function can be pushed away from zero once it is pinned to zero at both ends of an interval and its curvature is controlled: for $g \in C^2[0,L]$ with $g(0) = g(L) = 0$ and $|g''| \le B$, the same double-Rolle argument gives $|g(x)| \le \frac{B}{2}x(L-x) \le \frac{BL^2}{8}$ for $x \in (0,L)$. The exponent 2 on the interval length is not an accident, it is the same exponent that appears in every bound relating a function to its second derivative through a boundary condition, from the error term of linear interpolation to the discretisation error of the trapezoidal rule to the Green's function of the operator $-\frac{d^2}{dx^2}$ on $[0,L]$ with zero boundary values, whose maximum value is exactly $\frac{L}{4}$ at the midpoint, matching the $\frac{1}{4}$ that appears here.

The discernment mechanism for spotting this route: whenever a problem's hypotheses describe an integral of a given function vanishing at two points, and asks for a bound on that integral in terms of a bound on the given function's derivative, the hypotheses are secretly about the antiderivative, not the original function. Promote the antiderivative to a named object immediately and restate the problem in its language; the bound you need is then always governed by the two-point remainder identity, never by ad hoc estimation of the original function. Training this discernment is a matter of drilling the auxiliary function $\phi(t) = g(t) - \frac{g(x)}{x(x-1)}t(t-1)$ until writing it down becomes as automatic as writing $g(x) = \int_0^x f$ in the first place.

The examiners nudged you toward exactly this shape by restricting α to the open interval $(0,1)$, which is precisely where the auxiliary function's denominator $x(x-1)$ is nonzero, and by phrasing the bound using $\max|f'|$ rather than an integral norm of f', which only makes sense as a bound on a pointwise remainder term, not as a bound obtained from an averaging argument.

Revolving concepts

Fundamental theorem of calculus. For f continuous on $[0,1]$, $g(x) = \int_0^x f(t)\,dt$ is differentiable with $g' = f$; this is the move that manufactures the object the whole solution is built around. See Book 1, field: Calculus and integrals, topic: antiderivatives from integral hypotheses.

Rolle's theorem. If h is continuous on $[a,b]$, differentiable on (a,b), and $h(a) = h(b)$, then $h'(c) = 0$ for some $c \in (a,b)$. Applied twice in sequence, first to ϕ then to ϕ', it is the engine that produces the point ξ where the second derivative is pinned down. See Book 1, field: Real analysis, topic: Rolle's theorem and iterated applications.

Two-point Lagrange remainder. The generalisation is the remainder formula for polynomial interpolation at $k+1$ nodes $x_0 < x_1 < \cdots < x_k$ in $[a,b]$: if P is the unique polynomial of degree at most k agreeing with a C^{k+1} function h at those nodes, then for any $x \in (a,b)$ there is $\xi \in (a,b)$ with

$$h(x) - P(x) = \frac{h^{(k+1)}(\xi)}{(k+1)!}\prod_{i=0}^{k}(x - x_i).$$

This problem is the case $k = 1$, two nodes 0 and 1, with $P \equiv 0$ since g vanishes at both nodes; the same identity with $k = 2$ underlies Simpson's rule error bounds, and with general k underlies polynomial interpolation error throughout numerical analysis. See Book 1, field: Real analysis, topic: interpolation remainder formulas.

Maximising a quadratic by completing the square. $\alpha(1-\alpha) = \frac{1}{4} - \left(\alpha - \frac{1}{2}\right)^2$, maximised at $\alpha = \frac{1}{2}$; a one-line alternative to differentiating and solving for a stationary point. See Book 1, field: Inequalities, topic: completing the square for extremal problems.

No sequence-type recursion appears in this problem; the natural generalisation here runs along interval length and interpolation order instead, as stated above.

Circuit Bank

- **WHEN** a bound is requested on $\int_a^x f$ and the hypotheses force this integral to vanish at both endpoints of an interval **DO** introduce $g(x) = \int_a^x f$ explicitly and restate every hypothesis in the language of g before estimating anything **BECAUSE** the true structure, zero boundary values and a bounded higher derivative, belongs to g, not to the original f, and estimating f directly throws that structure away.
- **WHEN** a twice-differentiable function vanishes at two points and you need a bound on it strictly between them from a bound on its second derivative **DO** construct $\phi(t) = g(t) - \frac{g(x)}{x(x-1)} t(t-1)$ and apply Rolle's theorem twice **BECAUSE** this is the two-point Lagrange remainder in explicit form, and it produces the sharpest possible pointwise bound with an equation, not merely an inequality.
- **WHEN** you need the maximum of a quadratic such as $\alpha(1-\alpha)$ on a fixed interval **DO** complete the square rather than differentiate and solve for a stationary point **BECAUSE** completing the square exposes the location and the value of the maximum in the same line, with no need to check it is a maximum rather than a minimum.
- **WHEN** you have just proved a sharp-looking constant in an inequality **DO** exhibit the simplest function that saturates every inequality used in the proof, typically an affine or piecewise-constant one **BECAUSE** affine functions make every derivative-based inequality in a proof of this shape an equality simultaneously, confirming the constant is genuinely best possible rather than an artefact of the method.

Backtesting

1. First useful cue: the two conditions $\int_0^\alpha f$ and $\int_0^1 f = 0$ are both integrals of f from 0, begging to be named as one function.
2. Method the expression suggested: introduce $g(x) = \int_0^x f$ and treat the problem as bounding a function that vanishes at two points via a bound on its second derivative.
3. Where you would hesitate, and the thought to reinforce: hesitating over how to produce a point where the second derivative is pinned down exactly; the reinforcement is that Rolle's theorem, applied twice to an auxiliary function built to share three zeros with g, always produces exactly such a point.
4. The trap the question sets: trying to bound f directly from its derivative bound without first locating a base point where f vanishes, which leaves an unresolved constant in the estimate.
5. What makes you recognise it faster next time: seeing a function forced to equal zero at both ends of an interval alongside a bound on a derivative one order higher than that function's own order.
6. The reusable decision rule: whenever boundary values vanish and a higher derivative is bounded, reach for the two-point remainder identity via a double application of Rolle's theorem before reaching for any direct estimate.

Mirror drills

1. (drill) With g as in the lemma, show $\int_0^1 |g(x)|\,dx \le \frac{B}{12}$. *Answer:* integrate the pointwise bound $|g(x)| \le \frac{B}{2} x(1-x)$ over $[0,1]$; since $\int_0^1 x(1-x)\,dx = \frac{1}{6}$, the bound follows directly.
2. (drill) Suppose instead $g(0) = 0$ and $g(1) = c \neq 0$, with $|g''| \le B$ still. Bound $g(\alpha) - \ell(\alpha)$, where ℓ is the line through $(0,0)$ and $(1,c)$. *Answer:* subtracting a linear function does not

change g'', so the same double-Rolle argument applies to $g - \ell$, which vanishes at both endpoints, giving $|g(\alpha) - \ell(\alpha)| \le \frac{B}{8}$ unchanged.

3. (drill) Redo the lemma on $[0, L]$ instead of $[0, 1]$: if $g \in C^2[0, L]$ with $g(0) = g(L) = 0$ and $|g''| \le B$, find the sharp bound on $|g(x)|$. *Answer:* the identical construction gives $g(x) = \frac{g''(\xi)}{2} x(x - L)$, so $|g(x)| \le \frac{B}{2} x(L - x) \le \frac{BL^2}{8}$, showing the constant $\frac{1}{8}$ scales with the square of the interval length.

19.9 B3. eliminating a floor via its algebraic conjugate

Let $x_0 = 1$ and for $n \geq 0$, let $x_{n+1} = 3x_n + \lfloor x_n\sqrt{5}\rfloor$. In particular, $x_1 = 5$, $x_2 = 26$, $x_3 = 136$, $x_4 = 712$. Find a closed-form expression for x_{2007}. ($\lfloor a\rfloor$ means the largest integer $\leq a$.)

Read it out loud

The defining recursion mixes an ordinary integer multiple, $3x_n$, with the floor of an irrational multiple of the same variable, $\lfloor x_n\sqrt{5}\rfloor$. The instant a floor function wraps around an irrational multiple of a variable that is itself forced to stay an integer, the guiding light is to bound the floor between the irrational quantity and one less than it, then hunt for an integer combination of consecutive terms that makes the irrational part cancel exactly. That is the generic move for any sequence of the form $x_{n+1} = ax_n + \lfloor x_n c\rfloor$ with c irrational: eliminate the floor algebraically, do not try to reason about it term by term.

The problem hands you four terms explicitly, x_1 through x_4. That is a strong cue that a pattern is meant to be noticed, but noticing is not proving, and it depends on recognising the numbers 13, 34, 89 hiding inside $x_2/2$, $x_3/4$, $x_4/8$ as Fibonacci numbers, a recognition that either fires instantly or not at all. A systematic route that never needs this recognition is strictly more valuable to install as a circuit, because it produces the answer whether or not the Fibonacci connection ever crosses your mind, and it produces the SAME answer, since both routes describe the same sequence.

Once the floor is eliminated algebraically, what remains is a genuine linear recurrence with constant coefficients, and everything downstream is standard machinery: a characteristic equation, two roots, and a 2×2 linear system for two undetermined coefficients using the two earliest terms you have. Nothing about the index 2007 is special once a closed form exists; raising a fixed real number to the 2007th power already is the closed form, the problem is not asking for a decimal.

Fields embedded: sequences and recurrences, specifically floor-function recursions and constant-coefficient linear recurrences solved via characteristic equations, with a touch of number theory, the irrationality of $\sqrt{5}$ and the use of its algebraic conjugate. The specific combination, bounding a floor via an irrational argument and then eliminating that irrationality with a conjugate, sits past A level Further Mathematics, though each separate ingredient, solving a linear recurrence and using a conjugate surd identity like $(a + \sqrt{d})(a - \sqrt{d}) = a^2 - d$, is individually familiar. Within thirty seconds of reading you should have written $x_n\sqrt{5} - 1 < \lfloor x_n\sqrt{5}\rfloor < x_n\sqrt{5}$.

Approaches, ranked worst to best

1. **compute terms one by one up to $n = 2007$.** *Cue:* the recursion is explicit, so direct computation always technically works. *Circuit:* none, this is not a closed form at all. (why it ranks here: this never answers the question, since the problem explicitly demands a closed-form expression, and even as a warm-up it gives no route to the general term.)
2. **spot the Fibonacci numbers inside $x_1, \ldots, x_4$, conjecture $x_n = 2^{n-1}F_{2n+3}$, prove by induction.** *Cue:* the given values $13, 34, 89$ are recognisable Fibonacci numbers once divided out by powers of 2. *Circuit:* pattern recognition plus inductive verification. (why it ranks here: this works, but it depends on recognising specific numbers by sight, a recognition that is not guaranteed to fire, and the inductive step still has to reconstruct essentially the same conjugate bound derived below in order to verify the floor identity, so the recognition buys you the answer in advance without buying you less work.)
3. **eliminate the floor using the conjugate $3 - \sqrt{5}$, derive a floor-free linear recurrence, solve it directly.** *Cue:* the recursion has the shape $x_{n+1} = ax_n + \lfloor x_n c\rfloor$ with $a = 3$, $c = \sqrt{5}$, and $a - c = 3 - \sqrt{5}$ lies strictly between 0 and 1. *Circuit:* conjugate elimination of a floor. (why it ranks here: this is the ideal route; it needs no guessing, produces the recurrence and hence the closed form mechanically, and generalises immediately to any recursion of this shape.)

The ideal solution

Step 1: positivity and irrationality. By induction, x_n is a positive integer for every $n \geq 0$: $x_0 = 1$, and if x_n is a positive integer then $x_{n+1} = 3x_n + \lfloor x_n\sqrt{5} \rfloor$ is an integer, and positive since $x_n\sqrt{5} > 0$ gives $\lfloor x_n\sqrt{5} \rfloor \geq 0$. Since $\sqrt{5}$ is irrational and $x_n \neq 0$, the number $x_n\sqrt{5}$ is irrational, hence never an integer, so its fractional part lies strictly between 0 and 1:

$$x_n\sqrt{5} - 1 < \lfloor x_n\sqrt{5} \rfloor < x_n\sqrt{5}.$$

Step 2: a bracket for x_{n+1}. Since $\lfloor x_n\sqrt{5} \rfloor = x_{n+1} - 3x_n$, substituting into the bound above and rearranging gives

$$(3+\sqrt{5})x_n - 1 \;<\; x_{n+1} \;<\; (3+\sqrt{5})x_n. \tag{$\star$}$$

Step 3: eliminate $\sqrt{5}$ via the conjugate. Multiply $(\star)$ by $3-\sqrt{5}$, which is positive since $\sqrt{5} < 3$, so the inequalities are preserved. Using $(3+\sqrt{5})(3-\sqrt{5}) = 9 - 5 = 4$,

$$4x_n - (3-\sqrt{5}) \;<\; (3-\sqrt{5})x_{n+1} \;<\; 4x_n.$$

Rewrite $x_{n+1}\sqrt{5} = 3x_{n+1} - (3-\sqrt{5})x_{n+1}$, so negating the bracket above and adding $3x_{n+1}$ throughout gives

$$3x_{n+1} - 4x_n \;<\; x_{n+1}\sqrt{5} \;<\; 3x_{n+1} - 4x_n + (3-\sqrt{5}).$$

Since x_n, x_{n+1} are integers, $M := 3x_{n+1} - 4x_n$ is an integer, and $0 < 3 - \sqrt{5} < 1$, so $x_{n+1}\sqrt{5}$ lies strictly between M and $M + (3-\sqrt{5})$, an interval of length less than 1 contained in $(M, M+1)$. Hence

$$\lfloor x_{n+1}\sqrt{5} \rfloor = M = 3x_{n+1} - 4x_n.$$

Step 4: the floor-free recurrence. Substituting into the definition at index $n+1$,

$$x_{n+2} = 3x_{n+1} + \lfloor x_{n+1}\sqrt{5} \rfloor = 3x_{n+1} + (3x_{n+1} - 4x_n) = 6x_{n+1} - 4x_n,$$

valid for every $n \geq 0$. A check against the given values confirms it: $6 \cdot 5 - 4 \cdot 1 = 26 = x_2$, $6 \cdot 26 - 4 \cdot 5 = 136 = x_3$, $6 \cdot 136 - 4 \cdot 26 = 712 = x_4$.

Step 5: solve the linear recurrence. The characteristic equation $t^2 - 6t + 4 = 0$ has roots $t = 3 \pm \sqrt{5}$, both real and distinct, so

$$x_n = A(3+\sqrt{5})^n + B(3-\sqrt{5})^n$$

for constants A, B determined by $x_0 = 1$ and $x_1 = 5$. From x_0: $A + B = 1$. From x_1: $A(3+\sqrt{5}) + B(3-\sqrt{5}) = 5$, i.e. $3(A+B) + \sqrt{5}(A-B) = 5$, so $\sqrt{5}(A-B) = 2$ and $A - B = \frac{2}{\sqrt{5}}$. Solving the pair $A + B = 1$, $A - B = \frac{2}{\sqrt{5}}$ gives

$$A = \frac{1}{2} + \frac{1}{\sqrt{5}} = \frac{5+2\sqrt{5}}{10}, \qquad B = \frac{1}{2} - \frac{1}{\sqrt{5}} = \frac{5-2\sqrt{5}}{10}.$$

Therefore, for every $n \geq 0$,

$$x_n = \frac{5+2\sqrt{5}}{10}(3+\sqrt{5})^n + \frac{5-2\sqrt{5}}{10}(3-\sqrt{5})^n.$$

At $n = 2007$,

$$\boxed{x_{2007} = \frac{5+2\sqrt{5}}{10}(3+\sqrt{5})^{2007} + \frac{5-2\sqrt{5}}{10}(3-\sqrt{5})^{2007}.}$$

Remark (agreement with the Fibonacci-flavoured form). Writing $\varphi = \frac{1+\sqrt{5}}{2}$, the identity $\varphi^2 = \varphi + 1 = \frac{3+\sqrt{5}}{2}$ gives $3 + \sqrt{5} = 2\varphi^2$, and since $\varphi\left(\frac{1-\sqrt{5}}{2}\right) = -1$ also gives $3 - \sqrt{5} = 2\varphi^{-2}$. A short computation with $\varphi^3 = 2\varphi + 1 = \sqrt{5} + 2$ converts the boxed answer into

$$x_n = \frac{2^{n-1}}{\sqrt{5}}\left(\varphi^{2n+3} + \varphi^{-(2n+3)}\right) = 2^{n-1}F_{2n+3},$$

where F_k is the kth Fibonacci number, matching $x_1 = 2^0F_5 = 5$, $x_2 = 2^1F_7 = 26$, $x_3 = 2^2F_9 = 136$, $x_4 = 2^3F_{11} = 712$ exactly against the given data. This second form is equivalent to the boxed one; it is included as a cross check, not as a replacement, since the boxed form was reached without ever needing to notice a Fibonacci number.

Layer 1: WHAT

Block 1: establish x_n is a positive integer and $x_n\sqrt{5}$ is irrational, giving strict bounds $x_n\sqrt{5} - 1 < \lfloor x_n\sqrt{5}\rfloor < x_n\sqrt{5}$. Block 2: translate the definition into a bracket for x_{n+1} itself, $(3+\sqrt{5})x_n - 1 < x_{n+1} < (3+\sqrt{5})x_n$. Block 3: multiply by the conjugate $3 - \sqrt{5}$ to collapse the width of the bracket to less than 1, pinning $\lfloor x_{n+1}\sqrt{5}\rfloor$ down exactly as $3x_{n+1} - 4x_n$. Block 4: substitute back to obtain the floor-free recurrence $x_{n+2} = 6x_{n+1} - 4x_n$. Block 5: solve via the characteristic equation, fit the two constants to x_0, x_1, and evaluate at $n = 2007$.

The nominal route tries to recognise the given numbers as a known sequence and prove the guess correct afterward; the ideal route never guesses, it eliminates the floor first and the closed form falls out mechanically. The bifurcation point is the decision, on first reading the four given values, between reaching for pattern recognition (does this remind me of a sequence I know) and reaching for algebraic elimination (can I multiply by a conjugate to kill the irrational part). The second choice never depends on what you happen to remember.

Layer 2: HOW

Block 1. **Cue.** The recursion produces x_n as an integer at every step by construction, and involves $\sqrt{5}$, an irrational number, multiplied by that integer. **Why natural.** An irrational number times a nonzero integer is irrational, so it can never land exactly on an integer, which means its fractional part is strictly between 0 and 1, never touching either endpoint. That strictness is what will later guarantee a floor is pinned down uniquely rather than merely bounded. **Link to the next block.** Rewriting the floor as a strict double inequality converts the recursion from an equation involving an unfriendly floor function into an inequality you can manipulate freely.

Block 2. **Cue.** The floor in the definition equals $x_{n+1} - 3x_n$ by rearranging the recursion itself. **Why natural.** Substituting this into the bound from Block 1 turns a statement about $\lfloor x_n\sqrt{5}\rfloor$ into a direct two-sided bound on x_{n+1}, namely $(3+\sqrt{5})x_n - 1 < x_{n+1} < (3+\sqrt{5})x_n$, with no floor symbol left in it. **Link to the next block.** This bracket still contains $\sqrt{5}$ on both sides in an unavoidable way; the next move must remove it if a rational, integer linear recurrence is the goal.

Block 3. **Cue.** The bracket contains $3 + \sqrt{5}$, and its algebraic conjugate $3 - \sqrt{5}$ satisfies $(3 + \sqrt{5})(3 - \sqrt{5}) = 4$, a rational integer, and also satisfies $0 < 3 - \sqrt{5} < 1$. **Why natural.** Multiplying the whole bracket by $3 - \sqrt{5}$ turns the irrational coefficient $3 + \sqrt{5}$ into the rational integer 4 on one side, while the smallness of $3 - \sqrt{5}$ shrinks the width of the resulting window below 1; a window of width less than 1 around an irrational number determines its floor uniquely, exactly the fact needed to compute $\lfloor x_{n+1}\sqrt{5}\rfloor$. **Link to the next block.** With $\lfloor x_{n+1}\sqrt{5}\rfloor$ now known exactly as $3x_{n+1} - 4x_n$, feeding it back into the original definition at the next index produces a recurrence with no floor function at all.

Block 4. **Cue.** The defining recursion applies just as well at index $n+1$ as at index n. **Why natural.** Substituting the newly pinned-down floor, $x_{n+2} = 3x_{n+1} + (3x_{n+1} - 4x_n) = 6x_{n+1} - 4x_n$, is now a constant-coefficient linear recurrence, and every tool for that class of recurrence applies without further justification. **Link to the next block.** A linear recurrence with constant coefficients is solved by its characteristic equation; there is nothing sequence-specific left to discover.

Block 5. **Cue.** The recurrence $x_{n+2} = 6x_{n+1} - 4x_n$ has characteristic polynomial $t^2 - 6t + 4$. **Why natural.** Its two distinct real roots $3 \pm \sqrt{5}$ give a general solution $A(3+\sqrt{5})^n + B(3-\sqrt{5})^n$, and the two given values $x_0 = 1$, $x_1 = 5$ determine A, B uniquely via a 2×2 linear system, which is routine algebra. **Link to the next block.** Plugging $n = 2007$ into the resulting closed form finishes the problem; no further block is needed.

Layer 3: WHY

The mechanism underneath this problem is the algebra of the ring $\mathbb{Z}[\sqrt{5}]$: the number $3+\sqrt{5}$ has norm $(3+\sqrt{5})(3-\sqrt{5}) = 4$, a rational integer, and its conjugate $3-\sqrt{5}$ has absolute value strictly less than 1. Whenever a recursion is built from an algebraic integer whose conjugate is smaller than 1 in absolute value, bounding a floor and then multiplying by that conjugate always shrinks the resulting window below width 1, which is exactly the condition needed to read off a floor exactly rather than merely bound it. This is the same phenomenon, restricted to a single step, that underlies Pisot numbers: an algebraic integer greater than 1 all of whose other conjugates have absolute value less than 1 produces sequences, such as $\lfloor \beta^n \rfloor$ or the sequence in this problem, whose fractional parts behave in a controlled, eventually predictable way, because the conjugate's contribution to the exact value shrinks geometrically.

The discernment mechanism for spotting this route: whenever a recursion has the shape $x_{n+1} = ax_n + \lfloor x_n\sqrt{d} \rfloor$ for integers a, d, immediately compute the norm $a^2 - d$ and check whether $|a - \sqrt{d}| < 1$. If so, the three-step pattern, bound the floor, multiply by the conjugate, re-derive the next floor exactly, will always produce a floor-free integer linear recurrence with characteristic roots $a + \sqrt{d}$ and $a - \sqrt{d}$. Training this discernment means drilling that three-step pattern on several values of a, d until reaching for the conjugate is as automatic as reaching for the quadratic formula.

The examiners nudged you toward this by supplying four explicit terms, more than the two needed to seed a second-order recurrence; that surplus is there so you can either notice the Fibonacci pattern by trivia recognition, or, if you derive the recurrence systematically, use the extra terms as a numerical check that your derivation is correct, exactly as done in Step 4 above. The specific choice of $\sqrt{5}$ is a second-layer nudge toward the golden ratio for those who spot it, but the argument above never depends on recognising that connection at all.

Revolving concepts

Conjugate surds and norms. For a, d integers with d not a perfect square, $(a+\sqrt{d})(a-\sqrt{d}) = a^2 - d \in \mathbb{Z}$. This is the algebraic fact that converts an irrational coefficient into a rational one after multiplication. See Book 1, field: Number theory, topic: quadratic irrationals and their conjugates.

Floor bounds from irrationality. If y is irrational, $y - 1 < \lfloor y \rfloor < y$ strictly, with no equality possible at either end; this strictness is what lets a window of width less than 1 pin a floor down exactly. See Book 1, field: Number theory, topic: fractional parts of irrational multiples.

Linear recurrences with constant coefficients (the recursion here, generalised). For a recurrence $x_{n+k} = c_{k-1}x_{n+k-1} + \cdots + c_0 x_n$, form the characteristic polynomial $t^k - c_{k-1}t^{k-1} - \cdots - c_0$; if it has k distinct roots $\lambda_1, \ldots, \lambda_k$, every solution has the form $x_n = \sum_i A_i \lambda_i^n$, with the A_i determined by the first k terms via a linear system, and repeated roots contribute terms of the form $n^j A\lambda^n$ instead. The present problem is the case $k = 2$, $\lambda_{1,2} = 3 \pm \sqrt{5}$. The same solving method applies verbatim to any floor-eliminated recursion produced by the conjugate technique above, for any integers a, d with

$|a - \sqrt{d}| < 1$: the resulting recurrence is always $x_{n+2} = 2a\,x_{n+1} - (a^2 - d)x_n$, with roots $a \pm \sqrt{d}$. See Book 1, field: Sequences and recurrences, topic: characteristic equations for linear recurrences.

Fibonacci numbers and Binet's formula. $F_k = \frac{\varphi^k - \psi^k}{\sqrt{5}}$ with $\varphi = \frac{1+\sqrt{5}}{2}$, $\psi = \frac{1-\sqrt{5}}{2}$, itself the $k = 2$ instance of the general linear recurrence solving method above, applied to $F_{k+2} = F_{k+1} + F_k$; the connection to this problem is that $3 \pm \sqrt{5} = 2\varphi^{\pm 2}$, so the two closed forms are the same recurrence viewed through two different but algebraically equivalent root labellings. See Book 1, field: Sequences and recurrences, topic: Binet's formula and the golden ratio.

Circuit Bank

- **WHEN** a recursion mixes an integer coefficient with the floor of an irrational multiple of the same variable **DO** bound the floor between the irrational quantity and one less than it, then multiply by the algebraic conjugate of that irrational coefficient **BECAUSE** the conjugate's norm is a rational integer and its size below 1 shrinks the resulting window enough to pin the next floor down exactly, eliminating the floor from the recursion for good.
- **WHEN** a floor has just been eliminated and a genuine constant-coefficient linear recurrence remains **DO** solve it via its characteristic equation and fit the free constants using the two earliest available terms **BECAUSE** the resulting closed form is valid at every index simultaneously, so an index as large as 2007 costs no more work than an index of 2.
- **WHEN** a problem supplies more explicit terms of a sequence than the order of its recurrence requires **DO** treat the surplus terms as a numerical check on a systematically derived recurrence, not as the primary route to it **BECAUSE** a derivation confirmed against real data is stronger evidence than a pattern spotted from the data alone, and does not depend on recognising any particular named sequence.
- **WHEN** a quadratic irrational $a + \sqrt{d}$ appears inside a floor-elimination argument **DO** compute its norm $a^2 - d$ and its conjugate $a - \sqrt{d}$ immediately **BECAUSE** the conjugate's size relative to 1 tells you at a glance whether the elimination technique will succeed in pinning the next floor down exactly.

Backtesting

1. First useful cue: an integer-valued recursion built from $3x_n$ plus the floor of $x_n\sqrt{5}$, mixing a rational and an irrational coefficient.
2. Method the expression suggested: bound the floor strictly, then multiply by the conjugate $3 - \sqrt{5}$ to eliminate the irrational part from the next term.
3. Where you would hesitate, and the thought to reinforce: hesitating over whether the resulting window after multiplying by the conjugate is really short enough to pin a floor down; the reinforcement is to check explicitly that the conjugate's absolute value, here $3 - \sqrt{5} \approx 0.764$, is less than 1.
4. The trap the question sets: the four explicit values invite you to recognise Fibonacci numbers and stop there, without ever proving that the guessed formula satisfies the defining floor recursion in general.
5. What makes you recognise it faster next time: seeing a floor wrapped around an irrational multiple, $\lfloor x_n c \rfloor$, sitting inside an otherwise integer-valued recursion.
6. The reusable decision rule: whenever a floor and a conjugable irrational appear together in a recursion, eliminate the floor via the conjugate before attempting any pattern recognition.

Mirror drills

1. (drill) Let $y_0 = 1$ and $y_{n+1} = 2y_n + \lfloor y_n\sqrt{3}\rfloor$. Find the floor-free linear recurrence satisfied by y_n. *Answer:* here $a = 2$, $d = 3$, conjugate $2 - \sqrt{3} \approx 0.268 \in (0, 1)$, norm $(2 + \sqrt{3})(2 - \sqrt{3}) = 1$; the same three-step argument gives $y_{n+2} = 4y_{n+1} - y_n$.
2. (drill) Why does the elimination argument fail if the conjugate $a - \sqrt{d}$ is not strictly between -1 and 1? *Answer:* the window bounding the next term, of width $|a - \sqrt{d}|$ after scaling, would then have width at least 1, and could straddle two consecutive integers, so the floor would no longer be determined uniquely by the argument.
3. (drill) Confirm that the boxed closed form and the Fibonacci-flavoured form agree at $n = 2$ without recomputing x_2 from the original recursion. *Answer:* using $3 + \sqrt{5} = 2\varphi^2$ and $3 - \sqrt{5} = 2\varphi^{-2}$ with $\varphi = \frac{1+\sqrt{5}}{2}$, both forms reduce to the same rational-plus-surd expression once expanded, since they were shown above to be algebraically identical for every n, not merely checked numerically at small cases.

19.10 B4. Counting sums of two polynomial squares

Let n be a positive integer. Find the number of pairs P, Q of polynomials with real coefficients such that

$$(P(X))^2 + (Q(X))^2 = X^{2n} + 1$$

and $\deg P > \deg Q$.

Read it out loud

Say the structure aloud before you touch a pen. This is a counting question about representations of one fixed real polynomial as a sum of two squares of real polynomials, with a degree condition attached to break the symmetry between the two slots. Three words carry the whole problem: *sum of two squares*, *real coefficients*, *count*. Nothing else in the statement does any work; $X^{2n}+1$ is just a convenient target that will turn out to be squarefree with no real roots.

A sum of two squares is never to be read as a sum. It is a norm. Over the integers $a^2 + b^2 = (a + bi)(a - bi)$ is the norm of a Gaussian integer, and everything you know about which integers are sums of two squares, and in how many ways, comes from factorisation in $\mathbb{Z}[i]$. The same sentence transplants verbatim to polynomials: $P^2 + Q^2 = (P + iQ)(P - iQ)$ in $\mathbb{C}[X]$, and $\mathbb{C}[X]$ is a Euclidean domain, so it has unique factorisation and you know every factorisation of the target explicitly, because over $\mathbb{C}$ every polynomial splits into linear factors and you can write down the roots of $X^{2n}+1$ in your sleep. The fields wired into this problem are therefore: factorisation in $\mathbb{C}[X]$, the conjugation automorphism that pins down which factorisations come from *real* P and Q, roots of unity, and at the very end a two line count.

What is actually being tested is whether you convert an additive statement about real polynomials into a multiplicative statement about complex ones, and then whether you can say precisely which multiplicative data descends back to the reals. The second half is where marks are lost. Splitting $X^{2n}+1$ into $2n$ linear factors is free; deciding which subsets of those factors can be the factors of $P + iQ$ is the whole problem, and there is a published write-up of this problem that gets that step wrong (it gets the right count from the wrong subsets; see Layer 3).

Within thirty seconds you should have on the page: $P^2 + Q^2 = (P+iQ)(P-iQ)$; $\deg P = n$ with leading coefficient ± 1 and $\deg Q \le n-1$; and $X^{2n}+1 = \prod_{m=0}^{2n-1}(X - \zeta_m)$ with $\zeta_m = \exp\big(i\pi(2m+1)/(2n)\big)$. Everything after that is bookkeeping about conjugate pairs.

Approaches, ranked worst to best

1. **Undetermined coefficients.** *Cue:* a polynomial identity with unknown coefficients. *Circuit:* expand and compare coefficients. You set $P = \sum_{j=0}^{n} p_j X^j$ and $Q = \sum_{j=0}^{n-1} q_j X^j$ and match $2n+1$ coefficients. The equations are quadratic in $2n+1$ unknowns, and they are not decoupled. For $n = 1$ this is over in a line; for general n there is no route from here to a count, because you cannot even see the solution set. Worst, and it is worst for a structural reason: you have thrown away the multiplicative structure of the identity and replaced it by an unstructured nonlinear system.

2. **Small cases and a guessed pattern.** *Cue:* the answer is a number depending on n. *Circuit:* compute $n = 1, 2$, guess, stop. You get 4 and 8, guess 2^{n+1}, and write it down. The answer is right and the write-up is worth almost nothing, because the command term is "find the number" on a proof paper: the graders want the bijection. Worth doing in the arena as a sanity check on the real solution, never as the solution.

3. **Real quadratic factors plus the two squares identity.** *Cue:* $X^{2n}+1$ factors over $\mathbb{R}$ into n quadratics. *Circuit:* Brahmagupta and Fibonacci identity, multiply representations together. Write $X^{2n}+1 = \prod_{j=1}^{n}\left(X^2 - 2\cos\theta_j X + 1\right)$ with $\theta_j = \pi(2j-1)/(2n)$, notice each factor is

itself a sum of two squares, $X^2 - 2\cos\theta_j X + 1 = (X - \cos\theta_j)^2 + (\sin\theta_j)^2$, and combine them with $(a^2+b^2)(c^2+d^2) = (ac-bd)^2 + (ad+bc)^2 = (ac+bd)^2 + (ad-bc)^2$. Each of the $n-1$ multiplications offers two outcomes, so you manufacture representations in bulk. This is the correct mathematics in disguise, and it constructs plenty of pairs, but it gives you no upper bound: to prove there are no others you must show every representation arises this way, which is exactly the unique factorisation argument you were avoiding. It also costs far more ink, since the identity is just the norm being multiplicative, written out in real coordinates.

4. **Norm factorisation in $\mathbb{C}[X]$.** *Cue:* sum of two squares of reals. *Circuit:* $P^2 + Q^2 = N(P + iQ)$; factor the target, then impose reality by conjugation. Set $A = P + iQ$, so that the equation reads $A \cdot \sigma(A) = X^{2n} + 1$ where σ conjugates coefficients. Unique factorisation in $\mathbb{C}[X]$ turns the problem into a choice of a subset of the $2n$ roots, and reality turns that into "exactly one root from each conjugate pair". Best: it produces the construction and the completeness proof in the same breath, and it generalises immediately to any real target (see Revolving concepts).

The ideal solution

The number of such pairs is $\boxed{2^{n+1}}$.

Degrees. Suppose $P^2 + Q^2 = X^{2n} + 1$ with $\deg P > \deg Q$. Use the convention $\deg 0 = -\infty$, so a priori $Q = 0$ is not excluded by the degree condition and must be excluded by hand later. Let $d = \deg P$ and let p be the leading coefficient of P. Since $\deg Q^2 < \deg P^2$, the coefficient of X^{2d} in $P^2 + Q^2$ equals $p^2 \neq 0$, so $2d = 2n$ and $p^2 = 1$. Thus

$$\deg P = n, \qquad p = \pm 1, \qquad \deg Q \leq n - 1.$$

The target. The polynomial $X^{2n} + 1$ has the $2n$ roots

$$\zeta_m = \exp\Big(\frac{i\pi(2m+1)}{2n}\Big), \qquad m = 0, 1, \ldots, 2n-1,$$

which are distinct because their arguments $\pi(2m+1)/(2n)$ are distinct in $[0, 2\pi)$. Counting degrees,

$$X^{2n} + 1 = \prod_{m=0}^{2n-1} (X - \zeta_m).$$

None of these roots is real, since $x^{2n} + 1 \geq 1 > 0$ for every real x. Complex conjugation permutes the root set (the coefficients are real) and has no fixed point on it, so it partitions the $2n$ roots into exactly n conjugate pairs $\{\zeta, \bar{\zeta}\}$.

The norm form. Let $\sigma\colon \mathbb{C}[X] \to \mathbb{C}[X]$ be the map that conjugates every coefficient, $\sigma\big(\sum a_k X^k\big) = \sum \overline{a_k} X^k$. It is a ring automorphism, it satisfies $\sigma^2 = \mathrm{id}$, its fixed ring is exactly $\mathbb{R}[X]$, and $\sigma(X - \zeta) = X - \bar{\zeta}$. Put

$$A = P + iQ, \qquad \text{so that} \qquad \sigma(A) = P - iQ, \qquad A\,\sigma(A) = P^2 + Q^2.$$

Conversely, any $A \in \mathbb{C}[X]$ determines the pair

$$P = \tfrac{1}{2}\big(A + \sigma(A)\big), \qquad Q = \tfrac{1}{2i}\big(A - \sigma(A)\big),$$

and both are fixed by σ, hence have real coefficients: $\sigma(P) = \frac{1}{2}(\sigma(A) + A) = P$ and $\sigma(Q) = \frac{1}{-2i}(\sigma(A) - A) = Q$. So real pairs (P, Q) correspond bijectively to elements $A \in \mathbb{C}[X]$, and the equation to be solved becomes

$$A\,\sigma(A) = X^{2n} + 1.$$

Which A occur. $\mathbb{C}[X]$ is a Euclidean domain, hence a unique factorisation domain, its units are the nonzero constants, and the primes dividing $X^{2n}+1$ are the $2n$ distinct monic linear polynomials $X-\zeta_m$. Therefore A, being a divisor of $X^{2n}+1$, has the form

$$A = c\prod_{m\in S}(X-\zeta_m), \qquad c\in\mathbb{C}^\times, \quad S\subseteq\{0,1,\dots,2n-1\},$$

and then $\sigma(A)=\bar{c}\prod_{m\in S}(X-\bar{\zeta}_m)$. Write $Z(S)=\{\zeta_m : m\in S\}$ and let $\overline{Z(S)}$ be its image under conjugation. Comparing $A\,\sigma(A)=X^{2n}+1$ with the factorisation of the target and using uniqueness, we need $c\bar{c}=1$, that is $|c|=1$, together with

$$\overline{Z(S)} = \{\zeta_0,\dots,\zeta_{2n-1}\}\setminus Z(S).$$

This last condition says precisely that S contains exactly one member of each conjugate pair. Indeed, if $Z(S)$ contained both ζ and $\bar{\zeta}$ then $\bar{\zeta}\in\overline{Z(S)}$ would also lie outside $Z(S)$, a contradiction; if it contained neither, then ζ lies outside $Z(S)$, hence in $\overline{Z(S)}$, so $\bar{\zeta}\in Z(S)$, again a contradiction. Conversely, one from each pair clearly gives $\overline{Z(S)}=Z(S)^c$. In particular $|S|=n$ and $\deg A=n$.

The constant. The coefficient of X^n in $A=P+iQ$ is the leading coefficient of P, because $\deg Q\le n-1$; that coefficient is c, so $c=\pm1$. Conversely, take any S with one index from each conjugate pair and any $c\in\{1,-1\}$, and set $A=c\prod_{m\in S}(X-\zeta_m)$. Then $A\,\sigma(A)=c\bar{c}\prod_{m=0}^{2n-1}(X-\zeta_m)=X^{2n}+1$; the associated P and Q are real by the paragraph above; and the coefficient of X^n in A is the real number c, so the coefficient of X^n in Q is 0, giving $\deg Q\le n-1<n=\deg P$. Every such (S,c) is therefore admissible. (This also disposes of the degenerate case: $Q=0$ would force $A=\sigma(A)$, hence $Z(S)=\overline{Z(S)}=Z(S)^c$, which is impossible for a nonempty S.)

The count. The correspondence $(S,c)\mapsto A\mapsto(P,Q)$ is injective, since $A=P+iQ$ recovers c as its leading coefficient and S as its root set. There are n conjugate pairs and two choices in each, so 2^n admissible sets S, and two choices of c. Hence the number of pairs is $2\cdot 2^n=2^{n+1}$. □

Layer 1: WHAT

Block 1. Degree bookkeeping: $\deg P=n$, leading coefficient ±1, $\deg Q\le n-1$.

Block 2. Rewrite the additive equation multiplicatively: $P^2+Q^2=(P+iQ)(P-iQ)$, and name $A=P+iQ$.

Block 3. Name the reality operator: σ conjugates coefficients, its fixed ring is $\mathbb{R}[X]$, and the equation is $A\,\sigma(A)=X^{2n}+1$.

Block 4. Factor the target: $2n$ distinct roots, none real, so n conjugate pairs.

Block 5. Unique factorisation: A is a constant times a subproduct; reality forces the root set of A to meet each conjugate pair exactly once; the degree condition forces the constant to be ±1.

Block 6. Count the free choices: $2^n\cdot 2=2^{n+1}$, and check injectivity so that the choices really are the pairs.

Juxtaposition. The nominal route stays inside $\mathbb{R}[X]$: expand, compare coefficients, or factor into real quadratics and grind the two squares identity. It can manufacture examples but never closes the count, because inside $\mathbb{R}[X]$ the object P^2+Q^2 is irreducible information, whereas inside $\mathbb{C}[X]$ it is a product. The bifurcation point is Block 2, the single line where you write $P^2+Q^2=(P+iQ)(P-iQ)$ and commit to leaving the reals. Everything before that line is common to both routes; everything after it is either a two paragraph proof or a page of algebra with no ending.

Layer 2: HOW

Block 1. Cue. The problem hands you a degree inequality rather than a symmetric condition, which means it is there to remove an ambiguity, not to be used cleverly. **Why natural.** Squares of reals cannot cancel leading terms: if $\deg P>\deg Q$ then the top coefficient of P^2+Q^2 is p^2, which is positive, so no cancellation can occur and the degree of P is forced. Reading a degree condition

as "leading coefficients cannot interfere" is the standard first move with real squares. **Link to the next block.** Now you know the shape of the answer set: P monic up to sign of degree n, Q strictly smaller. That is exactly the data you will later need to pin the unit constant c, so keep it.

Block 2. Cue. The expression $P^2 + Q^2$, with real coefficients, and a question that asks how many. **Why natural.** Counting questions are answered by structure, and the only structure a sum of two squares has is that it is a norm. Over $\mathbb{R}$, $a^2 + b^2$ does not factor; over $\mathbb{C}$ it always does, into $(a + bi)(a - bi)$. Since the ring $\mathbb{C}[X]$ has unique factorisation and you can list the primes of the target explicitly, factoring converts "how many representations" into "how many ways to split a known list of primes", which is a finite, countable choice. Nothing here is a leap: the identity $a^2 + b^2 = (a + ib)(a - ib)$ is the definition of the complex norm, and you were handed a norm. **Link to the next block.** Having introduced i, you have widened the ring, so you must immediately record what distinguishes the polynomials you actually want (real ones) inside the bigger ring. That is Block 3.

Block 3. Cue. You have moved from $\mathbb{R}[X]$ to $\mathbb{C}[X]$ and the problem said "real coefficients". **Why natural.** Whenever you enlarge a ring to gain factorisation, you must carry the symmetry that characterises the smaller ring. Here that symmetry is coefficientwise conjugation σ, whose fixed ring is exactly $\mathbb{R}[X]$. Writing the equation as $A\,\sigma(A) = X^{2n} + 1$ is not a cosmetic rewrite: it records both halves of the problem at once, since the left factor is arbitrary and the right factor is then determined by it. **Link to the next block.** The equation now says that the multiset of primes of the target splits into a part S and the conjugate of that part. To use that you need to know the primes and how conjugation acts on them, which is Block 4.

Block 4. Cue. $X^{2n} + 1$, a binomial with a root of unity flavour. **Why natural.** You know the roots of $z^{2n} = -1$ from de Moivre, so the factorisation is free. Two facts must be checked because the argument depends on them: the roots are distinct (so the target is squarefree, and subsets rather than multisets suffice), and none is real (so conjugation pairs them up without fixed points). Both are one line, and both are load bearing, so both go in the write-up. **Link to the next block.** You now have n conjugate pairs. The equation $\overline{Z(S)} = Z(S)^c$ is a condition on how S meets those pairs, which is Block 5.

Block 5. Cue. A divisor of a squarefree product of known primes. **Why natural.** Unique factorisation says a divisor is a unit times a subproduct, with no other freedom. The reality condition then reads off pairwise, and the two possible failures (both members of a pair chosen, neither chosen) are each contradictory in one line. The unit c is constrained twice: $|c| = 1$ from the norm, and $c \in \mathbb{R}$ from the degree condition, which is where the hypothesis $\deg P > \deg Q$ finally pays for itself. **Link to the next block.** The construction is now reversible, so the last block is a count of choices plus a check that different choices give different pairs.

Block 6. Cue. A bijection has been set up, so count the domain. **Why natural.** Two independent choices: n binary choices for the root set, one binary choice for the sign. Injectivity is not decoration: without it you would be counting factorisations rather than pairs. Say it in one sentence and take the mark.

Layer 3: WHY

The mathematical truth under this route is that $\mathbb{R}[X] \subset \mathbb{C}[X]$ is a degree two extension of unique factorisation domains, with the nontrivial automorphism σ, and $P^2 + Q^2$ is its norm form $N(A) = A\sigma(A)$. Counting the ways to write a fixed element as a norm is counting the ways to split its prime

factorisation into a part and the conjugate of the complementary part. That is the same sentence that governs sums of two squares in $\mathbb{Z}$: the number of representations of N is controlled by how the primes of N split in $\mathbb{Z}[i]$, and the primes that split contribute a factor to the count while the inert ones contribute nothing. Here every prime splits, because $\mathbb{C}[X]$ has no inert primes over $\mathbb{R}[X]$ except the ones coming from real roots, and $X^{2n}+1$ has none.

The discernment mechanism to install is a dictionary between quadratic expressions and rings: a^2+b^2 means $\mathbb{Z}[i]$ or $\mathbb{C}$ over $\mathbb{R}$; a^2-db^2 means $\mathbb{Z}[\sqrt{d}]$; a^2+ab+b^2 means the Eisenstein integers; $a^2+b^2+c^2+d^2$ means the quaternions and Lagrange. When one of these forms is set equal to something and you are asked which values occur or how many representations there are, the answer is always obtained by factoring in the corresponding ring, never by manipulating the sum. Train it by rewriting every sum of two squares you meet as a norm for a month, even the ones where you do not need it.

There is one more thing to extract here, and it is worth more than the problem itself. The published solution factors $X^{2n}+1$ as $\prod_{j=0}^{n-1}(X-\omega_j)(X+\omega_j)$ with $\omega_j=\exp(i\pi(2j+1)/(2n))$, and then asserts that you must choose exactly one factor from each pair $\{X-\omega_j, X+\omega_j\}$ in order to make $P+iQ$ and $P-iQ$ conjugate. The count that comes out, 2^n subsets, is correct, but the criterion is not: negation and conjugation are different fixed point free involutions of the root set, and they pair the roots differently as soon as $n\geq 2$. Take $n=2$ and the pair $\{X-e^{i\pi/4},\ X+e^{i\pi/4}\}$: choosing $X-e^{i\pi/4}$ and $X+e^{3i\pi/4}=X-e^{-i\pi/4}$ is legal under that criterion and gives $A=X^2-\sqrt{2}X+1$, which is real, hence $Q=0$ and $P^2=(X^2-\sqrt{2}X+1)^2\neq X^4+1$. The correct criterion is one root from each *conjugate* pair, which for $n=2$ selects the four sets $\{e^{i\pi/4},e^{3i\pi/4}\}$, $\{e^{i\pi/4},e^{-3i\pi/4}\}$, $\{e^{-i\pi/4},e^{3i\pi/4}\}$, $\{e^{-i\pi/4},e^{-3i\pi/4}\}$ and yields the eight genuine pairs. Both involutions have n orbits of size 2, which is why the final number survives the slip. The lesson is not that the authors were careless; it is that a counting argument must name the exact equivalence it is counting orbits of, and that you should verify any such pairing on the first case where two candidate pairings differ.

What the examiners nudged toward: they chose $X^{2n}+1$ rather than a general target precisely so that the target is squarefree with no real roots, which makes the orbit structure uniform and the answer a clean power of two. The degree condition $\deg P>\deg Q$ is the nudge that kills the unit circle of constants c down to $\{1,-1\}$; without it the problem would have infinitely many solutions, since A could be multiplied by any unimodular constant.

Revolving concepts

Sum of two squares as a norm. For a ring R with $\mathbb{C}$ style extension $R[i]$, $N(a+bi)=a^2+b^2$ is multiplicative: $N(uv)=N(u)N(v)$. Written out in coordinates this multiplicativity is the Brahmagupta and Fibonacci identity $(a^2+b^2)(c^2+d^2)=(ac-bd)^2+(ad+bc)^2$, and the second expression $(ac+bd)^2+(ad-bc)^2$ comes from conjugating one factor. See Book 1, field: Complex numbers, topic: norms and the two squares identity.

Unique factorisation in $\mathbb{C}[X]$. $\mathbb{C}[X]$ is Euclidean under the degree function, hence a principal ideal domain, hence a unique factorisation domain; its units are the nonzero constants and its primes are the monic linear polynomials. A polynomial is squarefree exactly when it shares no root with its derivative, which for $X^{2n}+1$ is immediate since the derivative $2nX^{2n-1}$ vanishes only at 0. See Book 1, field: Polynomials, topic: factorisation and squarefreeness.

The conjugation automorphism. σ acting coefficientwise on $\mathbb{C}[X]$ fixes exactly $\mathbb{R}[X]$; for a real polynomial the root multiset is stable under conjugation; a real polynomial of odd degree has a real root; and a real root of P^2+Q^2 with P,Q real must be a common root of P and Q, hence a root of the sum of even multiplicity. See Book 1, field: Polynomials, topic: real versus complex factorisation.

The generalisation, which is where the recursion lives. The count $c_n=2^{n+1}$ satisfies $c_{n+1}=2c_n$, and the reason is structural rather than numerical: each new conjugate pair of roots contributes an independent binary choice. Generalise: let $T\in\mathbb{R}[X]$ be nonconstant with positive leading coefficient, and suppose every real root of T has even multiplicity (otherwise no representation

exists at all, since $T = P^2 + Q^2$ forces every real root of T to be a common root of P and Q). Write the nonreal roots as conjugate pairs $\{\zeta_j, \bar{\zeta}_j\}$, $j = 1, \ldots, r$, with ζ_j of multiplicity e_j. Then the number of pairs (P, Q) of real polynomials with $P^2 + Q^2 = T$ and $\deg P > \deg Q$ is

$$2\prod_{j=1}^{r}(e_j + 1),$$

provided the leading coefficient of T is a square in $\mathbb{R}$, which it is. The proof is the one above verbatim: A takes a_j copies of ζ_j and the condition $\overline{Z(S)} = Z(S)^c$ forces the multiplicity of $\bar{\zeta}_j$ in A to be $e_j - a_j$, leaving $a_j \in \{0, 1, \ldots, e_j\}$ free, while real roots are forced to be split evenly and contribute a factor 1. Our problem is the case $r = n$, all $e_j = 1$. This is the exact analogue of the divisor formula for $r_2(N)$ in $\mathbb{Z}[i]$, where a prime $p \equiv 1 \pmod 4$ appearing to the power e contributes $e + 1$. See Book 1, field: Number theory, topic: sums of two squares and $r_2(N)$.

Circuit Bank

- **WHEN** you see $a^2 + b^2$ set equal to something, with a counting or existence question attached **DO** write $a^2 + b^2 = (a + ib)(a - ib)$ and move to the ring where i lives **BECAUSE** a sum of two squares is a norm, and norms are studied by factorisation, never by addition
- **WHEN** you widen a ring to gain factorisation **DO** immediately name the automorphism whose fixed ring is the original one, and rewrite the equation as $A\,\sigma(A) = T$ **BECAUSE** the reality or rationality condition is the only thing keeping the count finite, and it must be carried explicitly, not remembered
- **WHEN** you must count divisors of a squarefree element in a unique factorisation domain subject to a symmetry **DO** count orbits of the symmetry on the prime list, then count one choice per orbit **BECAUSE** unique factorisation converts a divisor into a subset of the primes, so a symmetry constraint becomes a pairing constraint
- **WHEN** a problem gives a degree or size inequality that seems only to break a tie **DO** use it at the very end to pin down the unit or constant **BECAUSE** units are exactly the freedom that unique factorisation leaves behind, and inequalities of this kind are the examiners handing you the tool to remove them
- **WHEN** two candidate pairings of a set both give the same orbit count **DO** test them on the smallest case where they differ before trusting either **BECAUSE** equinumerous pairings can give different answers to everything except the count, and a counting proof must name the correct equivalence

Backtesting

1. First useful cue: the expression $P^2 + Q^2$ with real coefficients and a counting command term. That is a norm form, so the first line written is $(P + iQ)(P - iQ)$.
2. Method the expression suggested: factor the target completely in $\mathbb{C}[X]$, then impose reality through coefficientwise conjugation, converting the equation into a subset choice on the $2n$ roots.
3. Where you would hesitate, and the thought to reinforce: at the moment of deciding which subsets S are legal. Reinforce this: the condition is $\sigma(A)$ equals the complementary factor, so the root set of A conjugates onto its own complement, which is exactly one root from each conjugate pair. Do not reason about which factors "look paired"; compute the involution.

4. The trap the question sets: the degree condition. It looks like a tiebreaker to prevent double counting (P, Q) and (Q, P), and it is really the constraint that reduces the unit constant from the whole unit circle to $\{1, -1\}$. Miss that and you either report 2^n or claim infinitely many.
5. What makes you recognise it faster next time: the shape "fixed real object equals a norm form, count the representations". That shape has one answer in every ring: split the primes.
6. The reusable decision rule: WHEN a real quadratic form equals a fixed element and you are asked how many representations, DO factor in the corresponding quadratic ring and count prime splittings subject to the conjugation constraint, BECAUSE representation counts are divisor counts in disguise.

Mirror drills

1. Write down all pairs (P, Q) of real polynomials with $P^2 + Q^2 = X^4 + 1$ and $\deg P > \deg Q$. *Answer:* the eight pairs $(\pm X^2, \pm 1)$ and $\big(\pm(X^2 - 1), \pm\sqrt{2}X\big)$; check $(X^2 - 1)^2 + 2X^2 = X^4 + 1$.
2. How many pairs (P, Q) of real polynomials satisfy $P^2 + Q^2 = (X^2 + 1)^2$ with $\deg P > \deg Q$? *Answer:* six, by the generalisation with one conjugate pair of multiplicity 2, giving $2(2 + 1)$; explicitly $\pm(X^2 + 1)$ with $Q = 0$, and $\pm(X^2 - 1)$ with $Q = \pm 2X$. The lesson is that squarefreeness was doing real work in the original problem.
3. Prove that there are no real polynomials with $P^2 + Q^2 = X^{2n} - 1$. *Answer:* substituting $X = 1$ gives $P(1)^2 + Q(1)^2 = 0$, so $P(1) = Q(1) = 0$, so $(X - 1)^2$ divides $P^2 + Q^2$; but 1 is a simple root of $X^{2n} - 1$.

19.11 B5. Reducing powers of a floor function

Let k be a positive integer. Prove that there exist polynomials $P_0(n), P_1(n), \ldots, P_{k-1}(n)$ (which may depend on k) such that for any integer n,

$$\left\lfloor \frac{n}{k} \right\rfloor^k = P_0(n) + P_1(n) \left\lfloor \frac{n}{k} \right\rfloor + \cdots + P_{k-1}(n) \left\lfloor \frac{n}{k} \right\rfloor^{k-1}.$$

($\lfloor a \rfloor$ means the largest integer $\leq a$.)

Read it out loud

Read the shape, not the symbols. Something of the form u^k is to be written as a combination of $1, u, u^2, \ldots, u^{k-1}$ with coefficients that are polynomials in n. That sentence has one meaning in mathematics and only one: u satisfies a monic polynomial equation of degree k over the ring $\mathbb{Q}[n]$. This is not an existence question about mysterious polynomials P_i; it is the assertion that $u = \lfloor n/k \rfloor$ is integral of degree at most k over $\mathbb{Q}[n]$, and the only way to prove such an assertion is to write the monic degree k equation down.

Now look at the two k's. The modulus is k and the exponent is k. That coincidence is the guiding light the proposers planted. Why would the exponent be tied to the modulus? Because $\lfloor n/k \rfloor$, for integer n, is not one mysterious quantity: it is one of exactly k explicit quantities. If $n \equiv j \pmod{k}$ then $\lfloor n/k \rfloor = (n-j)/k$, and j ranges over $\{0, 1, \ldots, k-1\}$. So u always equals one of the k known rational functions $(n-0)/k, (n-1)/k, \ldots, (n-k+1)/k$. A quantity that is always one of k known values is always a root of the monic degree k polynomial whose roots are those k values. There is the equation, and the problem is finished before it starts.

The fields embedded: the division algorithm and the definition of the floor (that is all the number theory there is here), Vieta and elementary symmetric functions to expand the product, and the algebraic idea of an annihilating polynomial, which is the same idea as a minimal polynomial of an algebraic number and as Cayley and Hamilton for a matrix. What is being tested is whether you can convert a case analysis into a single algebraic identity, because a k way case split is unusable when k is a variable, while a product over k cases is one line.

Within thirty seconds you should have written: $n = kq + r$ with $q = \lfloor n/k \rfloor$ and $r \in \{0, 1, \ldots, k-1\}$, and then $\prod_{j=0}^{k-1} \left(kq - n + j\right) = 0$. Everything else is expansion.

Approaches, ranked worst to best

1. **Compute small k and hope for an induction on k.** *Cue:* the statement is indexed by k. *Circuit:* do $k = 2$, do $k = 3$, look for a pattern. You get $k = 2$ in three lines, $k = 3$ with effort, and then you stall, because the statement for k says nothing whatever about the statement for $k+1$: the objects $\lfloor n/2 \rfloor$ and $\lfloor n/3 \rfloor$ are unrelated. There is no induction available in the variable that indexes the problem. Worst, and worth recognising quickly: when the induction variable changes the object rather than extending it, induction is not a candidate.

2. **Split into residue classes and interpolate.** *Cue:* the floor is piecewise linear in n on each residue class. *Circuit:* Lagrange interpolation across the k classes. On $n = km + r$ the required identity becomes a polynomial identity in m, so you try to build P_i class by class and then interpolate in r to glue. It can be made to work, but it fights itself: the P_i must be polynomials in n alone, while the natural data is indexed by r, and r is not a polynomial function of n. You end up reintroducing the very case analysis you are trying to remove. More ink, more places to be wrong.

3. **Vandermonde system with Cramer.** *Cue:* for each fixed n there are k equations and k unknowns $P_0, \ldots, P_{k-1}$. *Circuit:* invert a Vandermonde matrix. For fixed n, the requirement is $\sum_{i=0}^{k-1} P_i(n) q_r^i = q_r^k$ for each r, where $q_r = (n-r)/k$. The q_r are distinct, so the Vandermonde

matrix is invertible and Cramer gives each $P_i(n)$ as a ratio of determinants. This actually works cleanly, and there is a pleasant detail: $q_s - q_r = (r-s)/k$ is a constant, so the Vandermonde determinant is a nonzero constant independent of n, hence Cramer returns polynomials rather than rational functions with denominators to worry about. It ranks third only because it costs a page of determinant bookkeeping and returns the coefficients in a form you cannot read.

4. **Annihilating polynomial from the division algorithm.** *Cue:* $\lfloor n/k \rfloor$ is always one of k explicit values. *Circuit:* multiply the k cases together into a single vanishing product. Write $\prod_{j=0}^{k-1} \left(q - (n-j)/k\right) = 0$, which is true because one factor is zero, expand by Vieta, and read off the P_i. Best by a distance: it is three lines, it is uniform in k, it gives the coefficients in closed form, and it proves as a bonus that the P_i are unique.

The ideal solution

Write $q = \lfloor n/k \rfloor$ throughout, and recall that polynomials here are allowed rational coefficients; the problem asks only for polynomials, and rational coefficients will turn out to be unavoidable.

Step 1: the k possible values of q. Let n be any integer. By definition of the floor, $q \le n/k < q+1$, so $0 \le n - kq < k$; since $r := n - kq$ is an integer, $r \in \{0, 1, \ldots, k-1\}$. In other words, for every integer n there exists $j \in \{0, 1, \ldots, k-1\}$ with

$$q = \frac{n-j}{k}.$$

This holds for negative n as well as positive; the floor is defined by the inequality above and nothing in the argument used a sign.

Step 2: the annihilating product. Consider the polynomial in one variable t, with coefficients in $\mathbb{Q}[n]$,

$$F(t) \;=\; \prod_{j=0}^{k-1} \left(t - \frac{n-j}{k} \right).$$

It is monic of degree k in t. By Step 1, for every integer n one of the k factors of $F(q)$ vanishes, hence

$$F(q) = \prod_{j=0}^{k-1} \left(\left\lfloor \frac{n}{k} \right\rfloor - \frac{n-j}{k} \right) = 0.$$

Step 3: expand. By Vieta, for indeterminates $v_0, \ldots, v_{k-1}$,

$$\prod_{j=0}^{k-1} (t - v_j) \;=\; \sum_{i=0}^{k} (-1)^{k-i} e_{k-i}(v_0, \ldots, v_{k-1})\, t^i,$$

where e_m denotes the mth elementary symmetric polynomial and $e_0 = 1$. Substituting $v_j = (n-j)/k$ and $t = q$, and using $e_m\left(\frac{n}{k}, \frac{n-1}{k}, \ldots, \frac{n-k+1}{k}\right) = k^{-m} e_m(n, n-1, \ldots, n-k+1)$, the identity $F(q) = 0$ reads

$$q^k + \sum_{i=0}^{k-1} \frac{(-1)^{k-i}}{k^{k-i}}\, e_{k-i}(n, n-1, \ldots, n-k+1)\, q^i \;=\; 0.$$

Therefore, defining

$$P_i(n) \;=\; \frac{(-1)^{k-i-1}}{k^{k-i}}\, e_{k-i}\big(n,\, n-1,\, \ldots,\, n-k+1\big), \qquad i = 0, 1, \ldots, k-1,$$

we have $q^k = \sum_{i=0}^{k-1} P_i(n) q^i$ for every integer n, as required. Each P_i is a polynomial in n with rational coefficients, of degree exactly $k-i$, since e_{k-i} of k monic linear expressions in n is a monic multiple of n^{k-i} up to the constant k^{i-k}. $\square$

Worked instance. For $k = 2$: $F(t) = (t - \frac{n}{2})(t - \frac{n-1}{2})$, so

$$\left\lfloor \frac{n}{2} \right\rfloor^2 = \frac{2n-1}{2} \left\lfloor \frac{n}{2} \right\rfloor - \frac{n(n-1)}{4}.$$

Check $n = -3$: the left side is $(-2)^2 = 4$, the right side is $\frac{-7}{2} \cdot (-2) - \frac{(-3)(-4)}{4} = 7 - 3 = 4$.

Proposition (the P_i are unique). Suppose $P_0, \ldots, P_{k-1} \in \mathbb{Q}[n]$ satisfy the identity for every integer n. Set $R(n,t) = t^k - \sum_{i=0}^{k-1} P_i(n) t^i$. Fix $r \in \{0, \ldots, k-1\}$ and substitute $n = km + r$, so that $q = m$ for every integer m: the identity gives $R(km + r, m) = 0$ for all integers m. A one variable polynomial vanishing at infinitely many points is the zero polynomial, so $R(km + r, m)$ is identically zero in m; since $m \mapsto km + r$ is an invertible affine substitution, this is the same as saying that $R\big(n, (n-r)/k\big)$ is identically zero in n. Thus, over the field $\mathbb{Q}(n)$, the monic degree k polynomial $R(n,t)$ has the k distinct roots $(n-r)/k$ for $r = 0, \ldots, k-1$, so $R(n,t) = F(t)$ and the P_i are exactly the ones constructed. $\square$

Corollary. The P_i cannot in general be taken with integer coefficients: for $k = 2$ uniqueness forces $P_1(n) = (2n-1)/2$. So the word "polynomials" in the statement must be read over $\mathbb{Q}$, and the denominator k^{k-i} is not an artefact of the method.

Layer 1: WHAT

Block 1. Read the target shape: u^k in terms of $1, u, \ldots, u^{k-1}$ means u is a root of a monic degree k polynomial over $\mathbb{Q}[n]$.

Block 2. Ask what $u = \lfloor n/k \rfloor$ actually is for integer n: by the division algorithm it is one of the k explicit values $(n-j)/k$, $j = 0, \ldots, k-1$.

Block 3. Convert the k way case split into one identity: the product of the k differences vanishes, since one factor is zero.

Block 4. Expand the product by Vieta; the coefficient of q^k is 1, so solving for q^k requires no division by anything that could vanish.

Block 5. Read off P_i in closed form and record the degree and the denominator.

Block 6 (the extra mark). Prove uniqueness, which turns "here is a construction" into "this is the only construction", and explains why rational coefficients are necessary.

Juxtaposition. The nominal route is: split into residue classes, do the algebra in each, then try to glue the pieces into polynomials in n. It is a route through k separate worlds, and k is a variable, so it can never terminate on the page. The ideal route never leaves the single world of $\mathbb{Q}[n][t]$. The bifurcation point is Block 3: the moment you decide that "one of these k things holds" should be written as a product equal to zero rather than as a case analysis. Everything before that line is shared; after it the nominal route is still writing and the ideal route is finished.

Layer 2: HOW

Block 1. Cue. The exponent on the left is k and the highest exponent on the right is $k-1$, with k coefficient functions. **Why natural.** Reducing the kth power to lower powers is the definition of satisfying a monic degree k equation. This is not an analogy; it is a restatement. Recognising it converts an unfamiliar existence claim into a familiar target: produce the monic degree k equation. **Link to the next block.** A monic equation must have roots, so the next question is forced: what are the possible values of $\lfloor n/k \rfloor$?

Block 2. Cue. The modulus k inside the floor and the exponent k outside agree. **Why natural.** The floor of n/k is not an opaque object for integer n. The division algorithm says $n = kq + r$ with $r \in \{0, \ldots, k-1\}$, so $q = (n-r)/k$, and there are exactly k candidates because there are exactly k residues. The matching of the two k's is the examiners telling you where the degree k comes from. **Link to the next block.** You now have k candidate values and a quantity known to equal one of them. That is the standard input to the product move.

Block 3. **Cue.** A statement of the form "$u = v_0$ or $u = v_1$ or ... or $u = v_{k-1}$". **Why natural.** A disjunction of equalities is exactly a single product equalling zero: $\prod_j (u - v_j) = 0$. This is the cleanest way to hold a variable length case analysis in one hand, and it is the reason the argument does not care that k is a variable. Note that you never need to know which case holds, only that some case holds, which is precisely what makes the move legitimate here where r depends on n in a non polynomial way. **Link to the next block.** The product is a polynomial identity, so the remaining work is expansion.

Block 4. **Cue.** A product of k linear factors in t to be expanded. **Why natural.** Vieta is the expansion, and elementary symmetric functions are its output; you do not need to know them explicitly for the existence proof, only that they are polynomials in n. The important structural check is that the leading coefficient in t is 1, so the highest power can be isolated without dividing by anything that might be zero. Had you written the product as $\prod(kq - n + j) = 0$ instead, the leading coefficient would be k^k, which is still harmless because $k \geq 1$, but writing the monic version keeps the statement in the exact shape the problem asks for. **Link to the next block.** Expansion complete, the coefficients can be named, and then the only thing left worth having is uniqueness.

Block 5. **Cue.** The problem said "polynomials", without specifying the coefficient field. **Why natural.** Your P_i carry a denominator k^{k-i}, so you should say explicitly that rational coefficients are intended, and then earn the point by showing that this is forced rather than sloppy. **Link to the next block.** That forcing is exactly the uniqueness statement.

Block 6. **Cue.** An existence proof that produced a canonical looking answer. **Why natural.** If a construction is forced, saying so is cheap and it upgrades the write-up. The mechanism is the standard one: an identity holding for infinitely many integers is a polynomial identity, and a monic degree k polynomial with k distinct roots in a field equals the product of the corresponding linear factors.

Layer 3: WHY

The mathematical truth underneath is a statement about integrality. The ring $\mathbb{Q}[n]$ acts on the set of functions from $\mathbb{Z}$ to $\mathbb{Q}$, and the function $n \mapsto \lfloor n/k \rfloor$, which is not itself a polynomial and not even continuous as a function of a real variable, nevertheless satisfies a monic polynomial equation of degree k over $\mathbb{Q}[n]$. Consequently the $\mathbb{Q}[n]$ algebra generated by $\lfloor n/k \rfloor$ is spanned as a module by $1, \lfloor n/k \rfloor, \ldots, \lfloor n/k \rfloor^{k-1}$, and every polynomial expression in n and $\lfloor n/k \rfloor$ can be reduced to that basis. The problem asks you to prove exactly the generating relation of that module. Seen this way it belongs to the same family as: an algebraic number of degree k has $\mathbb{Q}(\alpha) = \mathbb{Q} \oplus \mathbb{Q}\alpha \oplus \cdots \oplus \mathbb{Q}\alpha^{k-1}$; a square matrix satisfies its own characteristic polynomial, so every power reduces to the first n; an eigenvalue satisfies the characteristic polynomial even though you do not know which eigenvalue you have.

That last phrase is the discernment mechanism, and it is the transferable content of this problem. You do not know which residue class n lies in, and you must never find out, because the answer would not be a polynomial in n. What you do know is the finite list of possibilities. The rule is: when an object is known to belong to a finite explicit list, do not case split, multiply. The product over the list is a single algebraic identity that is valid uniformly and is insensitive to which case actually occurs. This is why the same move solves apparently unrelated problems: quantities defined by "the nearest integer", "the remainder", "the sign", "whichever root is real", "the eigenvalue in this region". Train it by rewriting every case analysis you meet as a product or a symmetric function and asking whether the case labels ever needed to be known.

How the examiners nudged. First, they matched the exponent to the modulus, which is the only structural hint and it points directly at "degree k relation". Second, they wrote "which may depend

on k", which sounds like a permission but is really a warning that the coefficients are objects of the ambient parameter, not universal constants. Third, they wrote "for any integer n", not "for any positive integer n", so negative n must be covered; the division algorithm formulation covers it without comment, whereas a solution that reasons about "how many multiples of k are below n" has to stop and think.

The honest knowledge gap to name: nothing here is beyond a well trained A level student except the vocabulary. The reason this is a Putnam B5 rather than a school exercise is that the move "disjunction becomes product" is not taught anywhere in the A level syllabus, and without it you are left staring at a case analysis of variable length. That single move is the entire problem.

Revolving concepts

Floor and the division algorithm. For integers n and $k \geq 1$ there are unique integers q, r with $n = kq + r$ and $0 \leq r < k$, and then $q = \lfloor n/k \rfloor$. The defining inequality $\lfloor x \rfloor \leq x < \lfloor x \rfloor + 1$ is the only property used, and it makes no sign assumption. Related standard facts worth having installed: $\lfloor x + m \rfloor = \lfloor x \rfloor + m$ for integer m; Hermite's identity $\sum_{i=0}^{k-1} \lfloor x + i/k \rfloor = \lfloor kx \rfloor$; and $\lfloor \lfloor x/a \rfloor / b \rfloor = \lfloor x/(ab) \rfloor$ for positive integers a, b. See Book 1, field: Number theory, topic: floor function and division.

Annihilating polynomials, and the recursion they generate. General statement: let u be any quantity depending on a parameter, and suppose that for each value of the parameter u equals one of the k expressions $v_0, \ldots, v_{k-1}$. Then $\prod_j (u - v_j) = 0$ identically, hence

$$u^k = \sum_{i=0}^{k-1} (-1)^{k-i-1} e_{k-i}(v_0, \ldots, v_{k-1})\, u^i.$$

This is a recursion in disguise and it must be generalised as such: it says the sequence of powers $u^0, u^1, u^2, \ldots$ satisfies a linear recurrence of order k with coefficients $(-1)^{k-i-1} e_{k-i}$, so every power u^N with $N \geq k$ reduces to the span of $1, u, \ldots, u^{k-1}$, and the reduction is computed by repeatedly applying that recurrence. The general solution method for such a reduction is the same as for any linear recurrence with constant coefficients relative to the base ring: the characteristic polynomial is F itself, and the closed form of the coefficients of u^N in the reduced basis is obtained from the power sums or, equivalently, from Lagrange interpolation at the v_j. The identical structure appears as Cayley and Hamilton for matrices (every power of an m by m matrix reduces to the span of $I, A, \ldots, A^{m-1}$), as reduction modulo the minimal polynomial of an algebraic number, and as the reduction of $\lfloor n/k \rfloor^N$ for any $N \geq k$ in this problem. See Book 1, field: Abstract algebra, topic: minimal polynomials and integrality.

Elementary symmetric functions and Vieta. $\prod_{j=0}^{k-1} (t - v_j) = \sum_{i=0}^{k} (-1)^{k-i} e_{k-i}(v) t^i$, with e_m the sum of all products of m distinct v_j. In this problem $e_m(n, n-1, \ldots, n-k+1)$ appears; expanding instead in powers of $kq - n$ gives the alternative closed form

$$P_a(n) = -\frac{1}{k^{k-a}} \sum_{i=a}^{k} \begin{bmatrix} k \\ i \end{bmatrix} \binom{i}{a} (-n)^{i-a},$$

where $\begin{bmatrix} k \\ i \end{bmatrix}$ are the unsigned Stirling numbers of the first kind, defined by the rising factorial expansion $\prod_{j=0}^{k-1} (x + j) = \sum_i \begin{bmatrix} k \\ i \end{bmatrix} x^i$ and satisfying the recursion $\begin{bmatrix} k+1 \\ i \end{bmatrix} = k \begin{bmatrix} k \\ i \end{bmatrix} + \begin{bmatrix} k \\ i-1 \end{bmatrix}$. Generalised, that recursion is the statement that multiplying the rising factorial by $(x + k)$ shifts and scales the coefficient list, which is how every table of Stirling numbers is generated. See Book 1, field: Combinatorics, topic: Stirling numbers and factorial bases.

Uniqueness and the vanishing principle. A polynomial over an infinite integral domain that vanishes at infinitely many points is the zero polynomial; a monic degree k polynomial over a field with k distinct roots factors completely. Both are used in the uniqueness proposition, and together they are the standard machine for upgrading a pointwise identity to a formal one. See Book 1, field: Polynomials, topic: identity theorem for polynomials.

Circuit Bank

- **WHEN** a quantity is known to be one of k explicit values but you cannot tell which **DO** write $\prod_j (u - v_j) = 0$ and expand **BECAUSE** a disjunction of equalities is a single vanishing product, and the product does not need to know which case occurred
- **WHEN** you are asked to express u^k in terms of $1, u, \ldots, u^{k-1}$ with coefficients from a ring **DO** prove u satisfies a monic degree k polynomial over that ring, then rearrange **BECAUSE** that request is the definition of integrality of degree k, so producing the monic relation is the entire task
- **WHEN** a floor, a remainder or a nearest integer appears with integer input **DO** immediately write the division algorithm form $n = kq + r$, $0 \le r < k$ **BECAUSE** it removes the floor from the problem and replaces it by a finite explicit list, which is the only usable form
- **WHEN** you have constructed the objects a problem asks to exist and the construction looks canonical **DO** spend three lines proving uniqueness **BECAUSE** uniqueness converts a construction into a classification, and it usually explains the shape of the coefficients, such as why denominators are unavoidable
- **WHEN** a proposed induction would change the object rather than extend it, such as an induction on a modulus **DO** abandon induction and look for a uniform identity in the parameter **BECAUSE** induction needs the case k to be contained in the case $k + 1$, and a change of modulus destroys that containment

Backtesting

1. First useful cue: the exponent k matches the modulus k, and the right hand side is a combination of the lower powers. That is a monic degree k relation waiting to be written.
2. Method the expression suggested: division algorithm to list the k possible values of $\lfloor n/k \rfloor$, then multiply the k differences to get a single vanishing product, then Vieta.
3. Where you would hesitate, and the thought to reinforce: at the temptation to work residue class by residue class. Reinforce this: you must never learn which class n is in, because the coefficients are required to be polynomials in n alone, and r is not a polynomial in n. The product is the only object that respects that constraint.
4. The trap the question sets: the word "polynomials" with no coefficient field named. Denominators k^{k-i} are unavoidable, so a solver who insists on integer coefficients will conclude the statement is false. State that you work over $\mathbb{Q}$ and prove uniqueness to justify it.
5. What makes you recognise it faster next time: the phrase "express the kth power in terms of the lower powers". That phrase is always integrality, and integrality is always a monic annihilating polynomial.
6. The reusable decision rule: WHEN a quantity ranges over a finite explicit list, DO multiply the case equations into one vanishing product instead of splitting into cases, BECAUSE the product is uniform in the number of cases and eliminates the unknown case label.

Mirror drills

1. Write the identity explicitly for $k = 3$ and verify it at $n = -4$. *Answer:* $F(t) = (t - \frac{n}{3})(t - \frac{n-1}{3})(t - \frac{n-2}{3})$ gives $q^3 = \frac{3n-3}{3} q^2 - \frac{e_2}{9} q + \frac{n(n-1)(n-2)}{27}$ with $e_2 = n(n-1) + n(n-2) + (n-1)(n-2)$; at $n = -4$, $q = -2$ and both sides equal -8.

2. Let $r = n - k\lfloor n/k \rfloor$ be the remainder. Show that r^k is an integer coefficient combination of $1, r, \ldots, r^{k-1}$. *Answer:* $r \in \{0, \ldots, k-1\}$, so $\prod_{j=0}^{k-1}(r-j) = 0$; expanding gives $r^k = \sum_{i<k}(-1)^{k-i-1}e_{k-i}(0,1,\ldots,k-1)r^i$, and those elementary symmetric values are integers. Contrast with the main problem, where the corresponding coefficients are genuinely non integral.
3. Let x be a real number with $x^3 = 3x + 1$. Express x^5 in the basis $1, x, x^2$. *Answer:* $x^4 = 3x^2 + x$, so $x^5 = 3x^3 + x^2 = x^2 + 9x + 3$. Same circuit: a monic relation reduces every higher power.

19.12 B6. Counting factorial coin representations asymptotically

For each positive integer n, let $f(n)$ be the number of ways to make $n!$ cents using an unordered collection of coins, each worth $k!$ cents for some k, $1 \le k \le n$. Prove that for some constant C, independent of n,

$$n^{n^2/2-Cn}e^{-n^2/4} \;\le\; f(n) \;\le\; n^{n^2/2+Cn}e^{-n^2/4}.$$

Read it out loud

There are two things in this problem and you must separate them before doing anything. The first is a counting object: $f(n)$ is the number of solutions in nonnegative integers of $a_1 \cdot 1! + a_2 \cdot 2! + \cdots + a_n \cdot n! = n!$, because an unordered collection of coins is exactly a multiset, and a multiset is exactly the vector of multiplicities. The second is an asymptotic target with a free constant C in the exponent, and the free constant is the entire strategic content of the problem.

Take logarithms of the target immediately. The claim is

$$\tfrac{1}{2}n^2 \log n - \tfrac{1}{4}n^2 - Cn \log n \;\le\; \log f(n) \;\le\; \tfrac{1}{2}n^2 \log n - \tfrac{1}{4}n^2 + Cn \log n,$$

since $n^{Cn} = e^{Cn \log n}$. So you are asked for the first two terms of $\log f(n)$, with an error term of size $n \log n$ permitted. The main term is of size $n^2 \log n$. That is a relative precision of order $1/n$, which is an enormous licence: any step that changes $f(n)$ by a factor of $n^{O(n)}$ is free. Multiplying by 2^n is free. Replacing $n!$ by $(n-1)!$ in each of n coordinates is free, since it costs a factor n per coordinate. Throwing away an entire coordinate is free. Once you have read the tolerance, the method chooses itself: bracket the solution set between two boxes, count the boxes, and never think about the actual combinatorics again.

The fields embedded: counting lattice points in a polytope (that is what a coin problem is), and asymptotics of sums of the form $\sum i \log i$, which is Stirling's method applied to the hyperfactorial rather than the factorial. Indeed, recognise the target: $n^{n^2/2}e^{-n^2/4}$ is, up to $n^{O(n)}$, the hyperfactorial $\prod_{j=1}^{n} j^j$. So the shape of the answer is telling you in advance that the count will come out as a product of consecutive integers raised to powers proportional to themselves, which is exactly what a product of factorial ratios $\prod_i n!/i!$ is. Read the answer backwards to find the method.

Within thirty seconds you should have on the page: the tuple formulation $\sum a_i\, i! = n!$; the reduction of the claim to $\left|\log f(n) - \left(\tfrac{1}{2}n^2 \log n - \tfrac{1}{4}n^2\right)\right| \le Cn \log n$; and the observation that $a_i \le n!/i!$ for every i.

Approaches, ranked worst to best

1. **Exact evaluation of $f(n)$.** *Cue:* a coin counting function. *Circuit:* find a recursion or closed form, then estimate it. There is a recursion in principle, since a solution is a factorial base object, but no usable closed form exists and you would be computing an exact quantity in order to throw almost all of it away. Worst, and worst for a reason worth naming: the problem asked for two terms of a logarithm and you would be computing every term. That is consumption, not analysis.

2. **Generating functions and a saddle point.** *Cue:* coin counting means $\prod_{i=1}^{n}(1 - x^{i!})^{-1}$. *Circuit:* extract $[x^{n!}]$ by a contour integral and estimate. $f(n) = [x^{n!}] \prod_{i=1}^{n}(1 - x^{i!})^{-1}$ is correct and is the standard machine for partition asymptotics. Here the number of parts grows with n and the parts are spaced factorially, so the saddle point analysis is a research level computation, and it would deliver an answer far sharper than the one requested. Ranks second from bottom purely on cost: right tool, wrong problem, because the requested precision is crude.

3. **Volume heuristic for the simplex.** *Cue:* the solution set is the lattice points on $\sum x_i\, i! = n!$, $x \ge 0$. *Circuit:* lattice point count is approximately the volume. For fixed weights $w_1, \ldots, w_k$

the number of nonnegative integer solutions of $\sum a_i w_i = N$ is asymptotic to $N^{k-1}/\big((k-1)!\,w_1\cdots w_k\big)$ as $N\to\infty$. Substituting $N=n!$, $k=n$, $w_i=i!$ gives $\log(\text{volume}) = \sum_j (j-2)\log j + O(n\log n)$, which is the correct answer. But the asymptotic is for fixed k and here k grows with N, so this is a compass, not a proof. Use it to know where you are going, then never write it down.

4. **Two boxes and one Stirling type estimate.** *Cue:* the tolerance is a factor $n^{O(n)}$. *Circuit:* bound the solution set above by a product of intervals and below by a sub box in which one coordinate absorbs the remainder. Upper bound: $0\le a_i\le n!/i!$ for each i, so $f(n)$ is at most the product of the interval lengths. Lower bound: fix $a_n=0$, let $a_2,\dots,a_{n-1}$ range freely over intervals chosen small enough that no overshoot is possible, and let a_1 absorb whatever is left, which is legal because the smallest coin is worth one cent. Both counts are products of factorial ratios, and one integral comparison estimates both. Best by a distance: half a page, and the two crude bounds differ by exactly the factor the problem allows.

The ideal solution

Throughout, log is the natural logarithm and

$$G(n) \;=\; \tfrac12 n^2\log n - \tfrac14 n^2.$$

Since $n^{n^2/2\pm Cn}e^{-n^2/4} = \exp\big(G(n)\pm Cn\log n\big)$, the assertion to be proved is exactly

$$\big|\log f(n) - G(n)\big| \;\le\; C\,n\log n.$$

Assume $n\ge 2$. This is necessary: $f(1)=1$ while both sides of the required inequality equal $e^{-1/4}<1$ when $n=1$, and no choice of C repairs this because $1^{Cn}=1$. For $n\ge 2$ the factor n^{Cn} is unbounded in C, so any finite set of remaining small cases can be absorbed by enlarging C.

Step 1: the counting model. An unordered collection of coins of denominations $1!,2!,\dots,n!$ is determined by the multiplicities, so

$$f(n) \;=\; \#\Big\{(a_1,\dots,a_n)\in\mathbb{Z}^n_{\ge 0} \;:\; \sum_{i=1}^{n} a_i\,i! \;=\; n!\Big\}.$$

Step 2: an estimate for the sums that will appear.

Lemma 19.12.1. *Let c be a real number and $n\ge 2$. Then*

$$\Big|\sum_{i=1}^{n}(i+c)\log i \;-\; G(n)\Big| \;\le\; (2+|c|)\,n\log n.$$

Proof. The function $g(x)=x\log x$ is nonnegative and nondecreasing on $[1,\infty)$. For a nonnegative nondecreasing g we have $\int_{i-1}^{i} g \le g(i) \le \int_i^{i+1} g$; summing the left inequality for $i=2,\dots,n$ gives $\sum_{i=1}^n g(i)\ge \int_1^n g$, and summing the right inequality for $i=1,\dots,n-1$ gives $\sum_{i=1}^n g(i)\le \int_1^n g + g(n)$. Since

$$\int_1^n x\log x\,dx \;=\; \tfrac12 n^2\log n - \tfrac14 n^2 + \tfrac14 \;=\; G(n)+\tfrac14,$$

we obtain $\big|\sum_{i=1}^n i\log i - G(n)\big| \le n\log n + \frac14$. Also $\big|c\sum_{i=1}^n \log i\big| \le |c|\,n\log n$. Adding, and using $\frac14 \le n\log n$ for $n\ge 2$, gives the claim. □

Step 3: the upper bound. If $(a_1,\dots,a_n)$ is a solution then $a_i\,i!\le n!$ for each i, so a_i lies in $\{0,1,\dots,n!/i!\}$, a set of $n!/i!+1\le 2\,(n!/i!)$ elements, the inequality because $n!/i!\ge 1$. Hence

$$f(n) \;\le\; \prod_{i=1}^{n} 2\,\frac{n!}{i!} \;=\; 2^n \prod_{i=1}^{n}\frac{n!}{i!} \;=\; 2^n\prod_{j=2}^{n} j^{j-1},$$

where the last equality holds because $n!/i! = \prod_{j=i+1}^{n} j$, and a given j occurs in this product for exactly the $j-1$ indices $i = 1, \dots, j-1$. Taking logarithms and applying the Lemma with $c = -1$,

$$\log f(n) \;\le\; n\log 2 + \sum_{j=1}^{n}(j-1)\log j \;\le\; n\log n + G(n) + 3n\log n \;=\; G(n) + 4n\log n,$$

using $\log 2 \le \log n$ for $n \ge 2$.

Step 4: the lower bound. Consider the tuples with $a_n = 0$ and

$$a_i \in \Big\{0, 1, \dots, \tfrac{(n-1)!}{i!} - 1\Big\} \qquad (i = 2, 3, \dots, n-1),$$

which is a legitimate range because $(n-1)!/i!$ is a positive integer for $i \le n-1$. For any such choice,

$$\sum_{i=2}^{n-1} a_i\, i! \;\le\; \sum_{i=2}^{n-1}\Big(\frac{(n-1)!}{i!} - 1\Big) i! \;=\; \sum_{i=2}^{n-1}\big((n-1)! - i!\big) \;\le\; (n-2)\,(n-1)! \;\le\; n!,$$

so setting

$$a_1 \;=\; n! - \sum_{i=2}^{n-1} a_i\, i! \;\ge\; 0$$

produces a solution, because the smallest coin is worth exactly one cent and therefore absorbs any nonnegative remainder. Distinct choices of $(a_2, \dots, a_{n-1})$ give distinct solutions, so

$$f(n) \;\ge\; \prod_{i=2}^{n-1} \frac{(n-1)!}{i!} \;=\; \prod_{j=3}^{n-1} j^{\,j-2},$$

by the same regrouping as before: $(n-1)!/i! = \prod_{j=i+1}^{n-1} j$ and a given j occurs for the $j-2$ indices $i = 2, \dots, j-1$. Since the terms $j = 1$ and $j = 2$ of $\sum_{j=1}^{n}(j-2)\log j$ both vanish,

$$\sum_{j=3}^{n-1}(j-2)\log j \;=\; \sum_{j=1}^{n}(j-2)\log j \;-\; (n-2)\log n,$$

so by the Lemma with $c = -2$,

$$\log f(n) \;\ge\; G(n) - 4n\log n - (n-2)\log n \;\ge\; G(n) - 5n\log n.$$

Step 5: conclusion. For every $n \ge 2$,

$$\big|\log f(n) - G(n)\big| \;\le\; 5\, n\log n,$$

that is, $n^{n^2/2 - 5n} e^{-n^2/4} \le f(n) \le n^{n^2/2 + 5n} e^{-n^2/4}$. So $C = 5$ works for all $n \ge 2$, and the statement is false for $n = 1$. $\square$

Remark 19.12.2. The two bounds differ by a factor $n^{\Theta(n)}$, so this method cannot prove anything sharper than the stated form, and it does not need to. The volume heuristic indicates that $\log f(n) - G(n)$ is genuinely of order $n\log n$ and negative, so the tolerance $n^{\pm Cn}$ in the problem is matched to the truth rather than generous: the same statement with $e^{\pm Cn}$ in place of $n^{\pm Cn}$ would not be provable, being false.

Layer 1: WHAT

Block 1. Convert the coin language into the tuple equation $\sum a_i\, i! = n!$ with $a_i \geq 0$ integers.

Block 2. Take logarithms of the target and read the tolerance: the claim is $|\log f(n) - G(n)| \leq Cn \log n$, so any factor of size $n^{O(n)}$ is free.

Block 3. Upper bound by the box: each coordinate is confined to an interval of length $n!/i!$, so $f(n) \leq 2^n \prod_i n!/i!$, and regroup into $\prod_j j^{j-1}$.

Block 4. Lower bound by a sub box: shrink each range from $n!/i!$ to $(n-1)!/i!$ so that overshoot is impossible, discard the top coordinate, and let a_1 absorb the remainder. Regroup into $\prod_j j^{j-2}$.

Block 5. Estimate $\sum_i (i+c) \log i$ once, by comparing with $\int x \log x\, dx$, and apply it to both products.

Block 6. Assemble, and dispose of $n = 1$ honestly.

Juxtaposition. The nominal route treats this as a partition asymptotics problem: generating function, saddle point, sharp constants. It is not wrong, it is disproportionate, and in the arena it does not finish. The ideal route never computes anything about $f(n)$ beyond two inclusions of sets. The bifurcation point is Block 2, the line where you take logarithms and measure the permitted error before choosing a method. Everything upstream of that line is shared; downstream, one route is doing complex analysis and the other is counting boxes.

Layer 2: HOW

Block 1. **Cue.** "Unordered collection of coins" and a fixed total. **Why natural.** An unordered collection is a multiset, and a multiset over a finite denomination set is exactly its multiplicity vector. Nothing is lost and the object becomes a lattice point set defined by one linear equation. Do this translation before reading the rest of the problem, because you cannot estimate what you have not written as a set. **Link to the next block.** You now have a lattice point count in a simplex, and you next need to know how accurately it must be counted.

Block 2. **Cue.** A free constant C sitting in the exponent, on both sides, with the same main term. **Why natural.** A two sided bound with a free constant is never a request for a value; it is a request for the first terms of an asymptotic expansion, and the position of the constant tells you exactly how many terms. Taking logarithms turns the product form into $G(n) \pm Cn \log n$, and comparing $n \log n$ with the main term $\frac{1}{2} n^2 \log n$ shows the error budget is a factor $n^{O(n)}$ on $f(n)$ itself. This measurement is the single most valuable act in the whole solution, and it takes one line. **Link to the next block.** Knowing that a factor $n^{O(n)}$ is free, you may now use the crudest bounds available, so long as each is crude by only that much.

Block 3. **Cue.** A linear equation with positive coefficients and nonnegative unknowns. **Why natural.** Each coordinate is immediately bounded: $a_i\, i! \leq n!$ because all other terms are nonnegative. So the solution set sits inside a box, and the number of lattice points in a box is the product of the side lengths. The wasteful step, replacing $n!/i! + 1$ by $2 \cdot n!/i!$, costs a factor 2^n, which is far inside the budget; noticing that you are allowed to be wasteful here is the reason this step is written in one line rather than fussed over. **Link to the next block.** An upper bound alone proves nothing about a two sided claim, so you now need a lower bound of the same shape, which means a box that consists entirely of solutions.

Block 4. **Cue.** The denomination $1! = 1$ is present. **Why natural.** A unit coin means every nonnegative remainder can be completed. So to build solutions in bulk, choose all the other coordinates freely subject only to not overshooting $n!$, and let a_1 take up the slack. To guarantee no overshoot with room to spare, shrink each range from $n!/i!$ to $(n-1)!/i!$, which costs a factor of about n per coordinate, that is $n^{O(n)}$ in total, which the budget already told you was free. Dropping

a_n costs a factor 2. The resulting map from partial tuples to solutions is injective because a_1 is determined by the others. **Link to the next block.** Both bounds are now products of factorial ratios, so one estimate serves both.

Block 5. Cue. Products of the form $\prod_j j^{j+c}$, that is, sums $\sum_j (j+c)\log j$. **Why natural.** This is Stirling's method one level up. Stirling estimates $\sum \log i$ by comparing with $\int \log x\,dx$; here you compare $\sum i \log i$ with $\int x \log x\,dx$, and the monotone comparison gives an error at most one term, namely $n \log n$, which is exactly the size of the permitted error. Do not reach for a sharp Euler and Maclaurin expansion: the crude monotone bound is already inside budget, and a sharp expansion would cost ink for nothing. **Link to the next block.** Substituting $c = -1$ and $c = -2$ into the same lemma finishes both sides.

Block 6. Cue. The problem says "for some constant C independent of n". **Why natural.** That phrasing permits finitely many small cases to be absorbed, provided the bound is nontrivial there, which it is for $n \geq 2$ since $n^{Cn} \to \infty$ as C grows. It does not permit $n = 1$, where $n^{Cn} = 1$; there the statement is false, and saying so plainly is worth more than pretending otherwise. A grader who has read the problem knows this.

Layer 3: WHY

The mathematical truth beneath the route is that counting lattice points in a polytope is, to first order, computing a volume, and that both of the crude bounds used here are really volume computations in disguise. The solution set is the set of lattice points on the simplex $\Sigma = \{x \in \mathbb{R}^n_{\geq 0} : \sum x_i\, i! = n!\}$. The upper box is the bounding box of Σ, and the lower sub box is an inscribed box. For a fixed number of weights the count is asymptotic to the volume, $N^{k-1}/\big((k-1)!\,w_1 \cdots w_k\big)$, and substituting $N = n!$, $k = n$, $w_i = i!$ reproduces $\sum_j (j-2)\log j$ after taking logarithms, which is the same main term the rigorous bounds give. That is why the two crude boxes could possibly have agreed to the required precision: in high dimension the ratio of the bounding box to the inscribed box is exponential in the dimension, $n^{O(n)}$ here, and the problem's tolerance was written to be exactly that size. The proposers chose the tolerance to make box counting sufficient. Recognising that a stated error term has been calibrated to a specific method is a skill in itself, and it is usually the fastest way into an asymptotic problem.

The discernment mechanism: before choosing a method for an estimate, compute the ratio between the permitted error and the main term, in logarithmic form. If the permitted relative error is a constant factor, you need sharp constants and probably a saddle point or a precise Stirling expansion. If the permitted error is $e^{O(n)}$ on a quantity of size $e^{\Theta(n^2)}$, you may be exponentially wasteful per dimension but not more. If, as here, the permitted error is $e^{O(n \log n)}$, you may lose a factor of order n per coordinate, which is precisely what "replace $n!$ by $(n-1)!$" does. Train this by writing the tolerance as a factor per coordinate before starting: budget first, method second.

The second transferable truth is the role of the unit coin. Lower bounds for counting problems are usually harder than upper bounds, because you must exhibit solutions rather than merely constrain them. The presence of a denomination equal to 1 converts the lower bound into a triviality: any conservative choice of the other coordinates extends uniquely to a solution. The general principle: if the weights $w_1 \mid w_2 \mid \cdots$ or merely $w_1 = 1$, then the solution set of $\sum a_i w_i = N$ contains a full box of dimension one less, obtained by bounding the other coordinates so that their total cannot exceed N. Here the factorials are even better than coprime, they are a divisibility chain, which is also why the exact count has a factorial base flavour.

Knowledge gaps to name, because this problem is not approachable without them. First, the integral comparison estimate for monotone sums, which is Euler and Maclaurin at its crudest and is the engine behind Stirling. Second, comfort with the identity $n^{Cn} = e^{Cn \log n}$ and with reading an exponent as a tolerance, which is not taught at A level at all. Third, the hyperfactorial $H(n) = \prod_{j=1}^{n} j^j$

and its asymptotic $H(n) = A\, n^{n^2/2+n/2+1/12} e^{-n^2/4}$, where A is the Glaisher and Kinkelin constant: you do not need the constant, but you must recognise the shape $n^{n^2/2} e^{-n^2/4}$ as "a product of j^j" or you will not know what kind of product to aim for. Fourth, the fact that a coin counting problem is a lattice point count and that lattice point counts approximate volumes, which is the Ehrhart circle of ideas.

Revolving concepts

Coin counting, multisets and generating functions. The number of multisets of denominations $w_1, \dots, w_k$ with total N is the number of $(a_1, \dots, a_k) \in \mathbb{Z}^k_{\geq 0}$ with $\sum a_i w_i = N$, and it equals $[x^N] \prod_{i=1}^{k} (1 - x^{w_i})^{-1}$. For fixed k this count is a quasi polynomial in N of degree $k-1$ (Ehrhart), with leading term $N^{k-1} / \big((k-1)!\, w_1 \cdots w_k\big)$. See Book 1, field: Combinatorics, topic: coin problems and Ehrhart quasi polynomials.

The recursion behind the count, generalised. Write $f_m(N)$ for the number of representations of N using only the denominations $w_1, \dots, w_m$. Then

$$f_m(N) \;=\; \sum_{a \geq 0} f_{m-1}(N - a w_m) \;=\; f_{m-1}(N) + f_m(N - w_m),$$

with $f_0(N) = [N = 0]$. That two term form is the standard dynamic programming recursion for coin counting and is the general solution method for every problem of this shape: it says the generating function factorises, $\sum_N f_m(N) x^N = \prod_{i \leq m} (1 - x^{w_i})^{-1}$. In this problem the weights satisfy the divisibility chain $i! \mid (i+1)!$, which specialises the recursion further: writing $N = n!$ in the factorial base, the unique representation with digits $c_i \leq i$ is the greedy one, and $f(n)$ counts all representations, greedy or not. The general lesson to carry: a linear Diophantine counting problem always has both a product generating function and a one step recursion, and you choose between them by whether you want exact values or asymptotics. See Book 1, field: Generating functions, topic: partitions with prescribed parts.

Stirling's method and the hyperfactorial. For a nonnegative nondecreasing g on $[1, n]$, $\int_1^n g \leq \sum_{i=1}^{n} g(i) \leq \int_1^n g + g(n)$. With $g = \log x$ this gives $\log n! = n \log n - n + O(\log n)$, and with $g = x \log x$ it gives $\sum_{i \leq n} i \log i = \frac{1}{2} n^2 \log n - \frac{1}{4} n^2 + O(n \log n)$, that is, $\prod_{j \leq n} j^j = n^{n^2/2 + O(n)} e^{-n^2/4}$. The sharp versions are Stirling's series and the Glaisher and Kinkelin asymptotic $H(n) = A n^{n^2/2+n/2+1/12} e^{-n^2/4}$ with $A \approx 1.2824$. See Book 1, field: Real analysis, topic: Euler and Maclaurin comparison and Stirling.

Reading a tolerance. If a claim is $M(n) e^{-E(n)} \leq X(n) \leq M(n) e^{+E(n)}$, then in logarithmic form it is $|\log X - \log M| \leq E$, and the useful quantity is E divided by the number of coordinates, which is the permitted loss per coordinate. Here $E = Cn \log n$ over n coordinates, so a factor n^C per coordinate is free. See Book 1, field: Real analysis, topic: asymptotic bookkeeping.

Circuit Bank

- **WHEN** a bound is stated with a free constant in an exponent, on both sides of the quantity **DO** take logarithms first and compute the permitted error divided by the number of coordinates **BECAUSE** the position of the free constant tells you how crude you are allowed to be, and that determines the method before any mathematics is done
- **WHEN** you must count solutions of a linear equation in nonnegative integers **DO** bound above by the bounding box of the simplex and below by an inscribed box, and only sharpen if the tolerance demands it **BECAUSE** lattice point counts are volumes to first order, and in high dimension the bounding box and an inscribed box differ by a factor exponential in the dimension, which is often exactly the permitted error
- **WHEN** one of the weights in a linear Diophantine problem equals 1 or divides all the others **DO** build a lower bound by choosing every other coordinate conservatively and letting that

coordinate absorb the remainder **BECAUSE** a unit weight makes completion automatic, which converts the hard direction of a counting bound into an injection from a box

- **WHEN** you meet $\prod_j j^{j+c}$ or the shape $n^{n^2/2}e^{-n^2/4}$ **DO** recognise the hyperfactorial and estimate $\sum(j+c)\log j$ by comparison with $\int x \log x\, dx$ **BECAUSE** the same monotone comparison that proves Stirling proves this, and the error is one term, which is almost always inside the tolerance of such problems
- **WHEN** a stated asymptotic claim fails at the smallest index **DO** say so explicitly, prove the claim for $n \geq n_0$, and note that finitely many cases are absorbed by enlarging the constant when the bound is nontrivial there **BECAUSE** honesty about the edge case costs one sentence and protects the whole write up; concealing it invites a grader to assume the rest is equally careless

Backtesting

1. First useful cue: the free constant C in the exponent on both sides. That is a tolerance statement, so the first line is to take logarithms and measure it.
2. Method the expression suggested: bracket the lattice point set between a bounding box and an inscribed box, both being products of factorial ratios, then estimate the resulting sums by one integral comparison.
3. Where you would hesitate, and the thought to reinforce: at the lower bound, where it feels as though a careful construction is needed. Reinforce this: the coin of value 1 means completion is free, so the only requirement on the other coordinates is that they cannot overshoot; give yourself a factor of n of headroom per coordinate, since the budget already permits it.
4. The trap the question sets: the temptation to be accurate. Every sharp tool here, Stirling's series, saddle point, Ehrhart theory, costs more than the problem pays. The second trap is $n = 1$, where the statement is false; a solution that quietly ignores it is incomplete, and one sentence fixes it.
5. What makes you recognise it faster next time: the pairing of a factorially spaced weight set with an answer of hyperfactorial shape. That pairing says "product of factorial ratios", which says "box count".
6. The reusable decision rule: WHEN an estimate is requested with a free constant in an exponent, DO convert to logarithms, compute the permitted error per coordinate, and select the crudest method that fits inside it, BECAUSE precision beyond the tolerance is wasted ink and the tolerance is usually calibrated to one specific crude method.

Mirror drills

1. Prove that $\prod_{j=1}^{n} j^j = n^{n^2/2+O(n)}e^{-n^2/4}$. *Answer:* take logarithms and compare $\sum j\log j$ with $\int_1^n x\log x\,dx = \frac{1}{2}n^2\log n - \frac{1}{4}n^2 + \frac{1}{4}$; monotonicity gives an error of at most one term, $n\log n$, which is $O(n)$ in the exponent of n.
2. Let $g(n)$ be the number of ways to write 2^n as an unordered sum of powers 2^k with $0 \leq k \leq n$. Show that $\log_2 g(n) = \frac{1}{2}n^2 + O(n\log n)$. *Answer:* same two boxes. Above, $a_k \leq 2^{n-k}$ gives $\log_2 g \leq \sum_k (n-k) + O(n) = \frac{1}{2}n^2 + O(n)$. Below, restrict to $1 \leq k \leq n-1$ with $a_k < 2^{n-k}/(2n)$, so the total is at most $(n-1)2^n/(2n) < 2^n$ and the unit part absorbs the rest, giving $\log_2 g \geq \frac{1}{2}n^2 - O(n\log n)$.
3. Suppose the same problem had been stated with $e^{\pm Cn}$ in place of $n^{\pm Cn}$. Which steps of the solution would still be legal, and which would break? *Answer:* the replacement of $n!/i! + 1$ by

$2\,n!/i!$ survives, since it costs $e^{n \log 2}$; the shrinking of the ranges from $n!/i!$ to $(n-1)!/i!$ does not, since it costs $n^{\Theta(n)} = e^{\Theta(n \log n)}$. The exercise is the point: read what each wasteful step costs in the currency of the stated tolerance.

Chapter 20

Putnam 2006

20.1 A1. Volume of a Torus from a Quartic Inequality

Find the volume of the region of points (x, y, z) such that

$$(x^2 + y^2 + z^2 + 8)^2 \leq 36(x^2 + y^2).$$

Read it out loud

This is a three variable inequality that only ever touches z through z^2 and only ever touches x, y through the combination $x^2 + y^2$; nowhere does it ask about x or y individually, and nowhere does it mix z with x or y except by both appearing squared inside the same bracket. That is the whole grammar of the problem: whatever region this describes is invariant under any rotation about the z axis, and invariant under nothing else in general. The fields wired into the question are solid geometry, specifically the volume of a region defined implicitly by an inequality, and elementary algebra, specifically isolating a familiar shape by completing a square, dressed up to look harder than it is by the stray constant 8 and the outer square on the left.

The first useful cue, the one you should have circled within the first ten seconds, is that x and y never appear separately, only as $x^2 + y^2$. Any time that happens in three dimensions, write $r = \sqrt{x^2 + y^2}$ before doing anything else; you have converted a genuinely three dimensional inequality into a two dimensional one in the pair (r, z), at the cost of remembering that $r \geq 0$.

The second cue is the shape of the inequality itself: something squared on the left, compared against something else squared on the right. That is not a shape you integrate blindly, it is a shape you unsquare, because $A^2 \leq B^2$ with $B \geq 0$ is nothing more than $-B \leq A \leq B$, and once you write that out you will usually find, as you do here, that one of the two resulting inequalities is vacuous and the other is the entire content of the problem. What survives is a single quadratic inequality in r and z; complete the square in r and you are looking at a disc, at which point the question stops being a calculus question and becomes a question about a named theorem for volumes of revolution.

Approaches, ranked worst to best

1. **Spherical coordinates.** *Cue:* seeing $x^2 + y^2 + z^2$ and reflexively reaching for a radius ρ. *Circuit:* sum of three squares to radius. (why it ranks here: the right hand side depends on $x^2 + y^2$ alone, not $x^2 + y^2 + z^2$, so the boundary surface has no constant ρ, and the angle ϕ never decouples from ρ; you end up with a transcendental relation between ρ and ϕ and no clean region to integrate. This costs ink for no return and should be abandoned the moment you write it down and see it does not simplify.)

2. **Cylindrical coordinates with a washer integral.** *Cue:* the inequality is a function of r and z only, so the solid is a solid of revolution. *Circuit:* invariance under rotation about an axis forces cylindrical coordinates. (why it ranks here: this works completely, and is the honest fallback if you forget the next theorem, but it costs an extra integral. Having reduced the boundary to $(r - 3)^2 + z^2 \leq 1$, you would compute, for each $z \in [-1, 1]$, the annulus $3 - \sqrt{1 - z^2} \leq r \leq 3 + \sqrt{1 - z^2}$ of area $12\pi\sqrt{1 - z^2}$, then integrate that over $z \in [-1, 1]$ using $\int_{-1}^{1} \sqrt{1 - z^2}\, dz = \pi/2$. It gives the right answer but re-derives, by hand, a fact that has a name.)

3. **Cylindrical coordinates plus Pappus's centroid theorem.** *Cue:* after completing the square you are rotating a disc that does not touch the axis of revolution. *Circuit:* solid of revolution of a fixed planar region not meeting the axis. (why it ranks here: this is the theorem the washer integral above is secretly proving from scratch every time; once you recognise the disc and check it stays clear of $r = 0$, the volume is one line, $V = 2\pi(\text{centroid distance})(\text{area})$, with no integral left to compute.)

The ideal solution

Write $r = \sqrt{x^2+y^2} \geq 0$. The given inequality is $(r^2+z^2+8)^2 \leq 36r^2 = (6r)^2$. Since $6r \geq 0$, this is equivalent, by the standard fact that $A^2 \leq B^2$ with $B \geq 0$ unpacks to $-B \leq A \leq B$, to

$$-6r \leq r^2+z^2+8 \leq 6r.$$

The left inequality holds for every $r \geq 0$ regardless of z, because $r^2+z^2+8 \geq 8 > 0 \geq -6r$; it carries no information. The right inequality is the entire content of the problem:

$$r^2+z^2+8 \leq 6r \iff r^2-6r+z^2+8 \leq 0 \iff (r-3)^2+z^2 \leq 1.$$

In the half plane $r \geq 0$, this is the closed disc of radius 1 centred at $(r,z) = (3,0)$. Its centre is at distance 3 from the line $r = 0$, which exceeds the radius 1, so the disc lies entirely in $r > 0$: it never touches, let alone crosses, the axis of revolution.

The three dimensional region is exactly the solid obtained by revolving this disc about the z axis, since a point (x,y,z) with $r = \sqrt{x^2+y^2}$ satisfies the original inequality precisely when (r,z) lies in the disc, and this condition is unchanged by rotating (x,y) about the origin at fixed r,z. This is a solid torus. By Pappus's centroid theorem, the volume of a solid of revolution of a planar region of area A, lying entirely on one side of an axis in its own plane at distance d from its centroid, is $V = 2\pi dA$. Here $A = \pi \cdot 1^2 = \pi$ and, by the disc's symmetry, its centroid is its own centre, at distance $d = 3$ from the axis. Hence

$$V = 2\pi \cdot 3 \cdot \pi = \boxed{6\pi^2}.$$

Layer 1: WHAT

Block 1: notice the inequality depends on x,y only through x^2+y^2, and substitute $r = \sqrt{x^2+y^2}$. Block 2: unpack the squared inequality into its two branches, discard the vacuous one, and complete the square in r. Block 3: recognise $(r-3)^2+z^2 \leq 1$ as a disc not touching the axis $r = 0$, hence a solid torus when revolved. Block 4: apply Pappus's centroid theorem to read off the volume in one line.

The nominal route agrees with the ideal route through Block 3, then splits: instead of naming the theorem, it sets up $V = \int_{-1}^{1} \pi\big((3+\sqrt{1-z^2})^2 - (3-\sqrt{1-z^2})^2\big)\,dz$, expands the difference of squares, and integrates $12\pi\sqrt{1-z^2}$ over $z \in [-1,1]$ by recognising it as the area of a semicircle. It reaches the same answer, $6\pi^2$, but by re-deriving Pappus's theorem for this one case instead of citing it. The bifurcation point is the instant you have written $(r-3)^2+z^2 \leq 1$ and identified it as a disc clear of the axis: from that sentence on, the ideal route costs one line and the nominal route costs an integral.

Layer 2: HOW

Block 1. Cue. The right hand side of the inequality, $36(x^2+y^2)$, and the left hand side inside its bracket, $x^2+y^2+z^2+8$, both treat x,y only through x^2+y^2; neither ever isolates x or y. **Why natural.** A region in $\mathbb{R}^3$ is invariant under rotation about the z axis exactly when its defining relation is a function of z and $r = \sqrt{x^2+y^2}$ alone, by definition of what that rotation does to a point (it fixes z and fixes x^2+y^2, and moves nothing else). The substitution is therefore forced by the structure, not chosen for convenience. **Link to the next block.** With the inequality now written purely in r and z, it becomes a two dimensional problem, and the next natural move is to simplify the algebra: unsquare it.

Block 2. **Cue.** The inequality has the shape (something)^2 $\leq$(something else)^2, with the right hand side manifestly non negative. **Why natural.** $A^2 \leq B^2$ for $B \geq 0$ is, by definition of the square root as a monotonic function on non negative reals, equivalent to $-B \leq A \leq B$; you are entitled to write both branches, and checking which is active (rather than guessing) is the only way to be certain nothing was lost. **Link to the next block.** One branch, $-6r \leq r^2 + z^2 + 8$, is seen immediately to be automatic since the right side is at least 8 and the left side is at most 0 for $r \geq 0$; discarding it correctly leaves a single quadratic inequality, which completing the square converts into a geometric statement.

Block 3. **Cue.** Completing the square produced $(r-3)^2 + z^2 \leq 1$, a sum of two squared linear terms bounded above by a constant. **Why natural.** That is, by definition, the set of points within distance 1 of $(3,0)$ in the (r,z) half plane, i.e. a disc of radius 1 and centre $(3,0)$; and since the centre's distance from the line $r = 0$ is 3, which exceeds the radius 1, the whole disc lies strictly in $r > 0$. **Link to the next block.** A disc revolved about an axis it does not meet is precisely the picture a solid of revolution problem wants you to draw, and precisely the hypothesis under which the volume formula for such a solid needs no case analysis.

Block 4. **Cue.** The task is now: find the volume swept out by revolving a known disc, of known area and known centroid, about an axis at a known distance. **Why natural.** Pappus's centroid theorem states this volume is 2π times the distance from the centroid to the axis, times the area; this is itself just the statement that the volume integral $\iiint 2\pi r \, dr \, dz$ over the disc equals 2π times the first moment of the disc about the axis, divided by its area, times the area, i.e. $2\pi \bar{r} A$, which is exactly the definition of the centroid $\bar{r}$. **Link to the next block.** Nothing remains: substitute the known area and distance and the answer follows in one line.

Layer 3: WHY

The mathematical truth underneath the route is that a triple integral over a solid of revolution factors, under Fubini, into an angular integral (which is always 2π, since nothing in the region depends on the angle) times an integral over the meridian region, weighted by r. That weighted integral is, again by definition, the area of the meridian region times its centroid distance. Pappus's theorem is not a separate fact you must independently verify each time; it is this factorisation, packaged with a name so you never have to write the triple integral out again.

The discernment mechanism for choosing this route over direct integration is a habit of asking, the moment you see a rotationally symmetric region, whether the meridian cross section is a shape whose area and centroid you already know without computation: a disc, a rectangle, a triangle. If it is, Pappus finishes the problem in one line. If the meridian region is irregular, or its centroid is unknown, or it touches the axis (so that revolving it would double count or degenerate), you fall back to the washer or shell integral, which is always valid but always costs more ink. Training this discernment is a matter of pattern matching the algebra: whenever completing the square in two of your three variables produces "(linear)^2+(linear)^2 $\leq$ constant", you should see a circle before you see anything else, and immediately check where its centre sits relative to any axis of revolution in the problem.

The examiners built the numbers to reward exactly this discernment. The constant 8 is placed so that, after moving to cylindrical coordinates and completing the square, the resulting circle has centre distance 3 and radius 1, comfortably clear of the axis, guaranteeing a genuine, non self intersecting torus rather than a degenerate case; and the coefficient $36 = 6^2$ is chosen so the centre and radius come out as small integers, so that a candidate who reaches Pappus's theorem is rewarded with an immediate, clean numerical answer, while a candidate who does not is still able to finish, at greater cost, by direct integration.

Revolving concepts

Cylindrical coordinates: writing a point in $\mathbb{R}^3$ as (r, θ, z) with $r = \sqrt{x^2 + y^2} \geq 0$. You reach for them whenever a defining relation in a three dimensional geometry problem is manifestly unchanged by rotation about a fixed axis, which you recognise from the relation depending on x, y only through $x^2 + y^2$. See Book 1, field: Geometry, topic: coordinate systems adapted to symmetry.

Pappus's centroid theorem, also called the Pappus-Guldinus theorem: for a plane region of area A lying entirely on one side of a line L in its plane, at distance d from its centroid, the solid formed by revolving the region about L has volume $V = 2\pi dA$. There is a companion first theorem for surface area, that the surface generated by revolving a plane curve of length ℓ about an external axis at distance d from the curve's centroid has area $S = 2\pi d\ell$; both are proved by the same Fubini factorisation argument. See Book 1, field: Geometry, topic: solids and surfaces of revolution.

Completing the square as the standard reroute for recognising a circle or sphere disguised inside a polynomial inequality: whenever an inequality is quadratic in two variables with equal leading coefficients and no cross term, complete the square in each variable in turn and read off centre and radius directly, rather than plotting points or reasoning about the inequality numerically. See Book 1, field: Geometry, topic: conic and quadric recognition.

Washer and shell integration for solids of revolution: the general purpose tools, always available, that Pappus's theorem is a packaged special case of; useful in particular when the meridian region touches the axis, self intersects when revolved, or has no known centroid, none of which occur in this problem but all of which should be checked for before reaching for Pappus. See Book 1, field: Calculus and integrals, topic: volumes of revolution.

Circuit Bank

- **WHEN** an inequality in x, y, z depends on x, y only through $x^2 + y^2$ **DO** substitute $r = \sqrt{x^2 + y^2} \geq 0$ and treat the problem as two dimensional in (r, z) **BECAUSE** the region is then invariant under rotation about the z axis, and cylindrical coordinates are exactly the coordinates adapted to that invariance
- **WHEN** you must take a square root across an inequality of the form $A^2 \leq B^2$ **DO** write it out as $-B \leq A \leq B$ for $B \geq 0$ and check both branches explicitly **BECAUSE** silently keeping only the branch that looks useful is a skipped calculation error, and the discarded branch is often itself informative about the shape of the region
- **WHEN** a known planar shape (disc, rectangle, triangle) is being revolved about an axis it provably does not touch **DO** apply Pappus's centroid theorem, $V = 2\pi dA$, instead of setting up a washer or shell integral **BECAUSE** the theorem is the same integral pre packaged; recomputing it by hand costs ink and invites an arithmetic slip for no extra rigour
- **WHEN** completing the square yields "(linear)^2+(linear)$^2 \leq$ constant" **DO** name it immediately as a disc of that centre and radius, and check whether it meets any axis of symmetry in the problem **BECAUSE** this single check determines the topology of the final solid, torus versus ball versus degenerate case, before any volume is computed

Backtesting

1. First useful cue: the right hand side, $36(x^2 + y^2)$, mentions only x and y, telling you the region is a solid of revolution about the z axis before you write a single further line.
2. Method the expression suggested: substitute $r = \sqrt{x^2 + y^2}$, collapsing a three variable inequality into a two variable one.

3. Where you would hesitate, and the thought to reinforce: deciding which branch of $A^2 \le B^2$ survives after the square root; reinforce with the habit of writing $-B \le A \le B$ in full every time, never trusting instinct on which half to keep.
4. The trap the question sets: the added constant 8 tempts you into expanding and grinding through a washer integral rather than pausing, after completing the square, to notice you are looking at a disc that clears the axis, which is exactly when Pappus's theorem applies for free.
5. What makes you recognise it faster next time: seeing "(sum of squares plus a constant) squared, bounded by a constant times a partial sum of squares" as the fingerprint of a circle hiding inside a norm inequality, to be exposed by completing the square immediately after unsquaring.
6. The reusable decision rule: rotational symmetry in the defining inequality routes you to cylindrical coordinates, completing the square routes you to a named planar shape, and a shape clear of the axis routes you to Pappus before any integral is written.

Mirror drills

1. Find the volume of the region $(x^2+y^2+z^2+3)^2 \le 16(x^2+y^2)$. *Answer:* complete the square exactly as above to get $(r-2)^2+z^2 \le 1$, a disc of radius 1 at distance 2 from the axis, so $V = 2\pi(2)(\pi) = 4\pi^2$.
2. A disc $(x-5)^2+y^2 \le 4$ in the xy plane is revolved about the y axis. Find the swept volume without integrating. *Answer:* Pappus directly, area 4π, centroid distance 5, so $V = 2\pi(5)(4\pi) = 40\pi^2$.
3. Decide, without computing a volume, what kind of solid $(x^2+y^2+z^2+2)^2 \le 4(x^2+y^2)$ describes. *Answer:* the same reduction gives $(r-1)^2+z^2 \le -1$, which has no real solutions, so the region is empty.

20.2 A2. Infinitude of Bob's Winning Heap Sizes

Alice and Bob play a game in which they take turns removing stones from a heap that initially has n stones. The number of stones removed at each turn must be one less than a prime number. The winner is the player who takes the last stone. Alice plays first. Prove that there are infinitely many n such that Bob has a winning strategy. (For example, if $n = 17$, then Alice might take 6 leaving 11; then Bob might take 1 leaving 10; then Alice can take the remaining stones to win.)

Read it out loud

This is a combinatorial game dressed as a stone heap, and the command term is the whole plan: you are asked to *prove there are infinitely many n* with a property, not to *find* them or to *determine* the full set of them. Whenever a Putnam problem asks for infinitude of some implicitly defined set rather than its exact description, that is a nudge toward an indirect argument, because it is telling you the set itself may have no usable closed form, only a property you can exploit. The fields wired into this problem are combinatorial game theory, specifically the standard machinery of positions from which the player to move wins or loses, and number theory, specifically the distribution of primes, since the legal move sizes are exactly the numbers one less than a prime.

The second thing to read off is what those legal move sizes look like: $p - 1$ for p prime gives $1, 2, 4, 6, 10, 12, 16, 18, 22, \ldots$, a set with no arithmetic progression structure and no periodicity, because the primes themselves have none. That single observation should kill, before you write a line of proof, any plan that involves computing the winning and losing heap sizes by hand and spotting a repeating pattern; there is nothing here that is forced to repeat.

The first useful cue to write down within the first thirty seconds is the translation of the English statement into game theory language: define a heap size n to be a losing position for the player about to move, and observe that "Bob has a winning strategy at heap n, with Alice moving first" is exactly the statement "n is a losing position for its first mover". Once that translation is made, the whole problem becomes: show the set of losing positions is infinite, and the recursive structure of losing and winning positions is exactly what the rest of the solution manipulates.

Approaches, ranked worst to best

1. **Direct computation and pattern spotting.** *Cue:* a subtraction game with a small explicit move set often has an eventually periodic set of losing positions. *Circuit:* subtraction game, compute small cases, guess and prove a period. (why it ranks here: the move set here is $\{p - 1 : p \text{ prime}\}$, which is infinite and irregular; there is no reason to expect, and in fact no evidence, that the losing positions are periodic, so this plan either never terminates or leads you to assert an unproven regularity, which the hard rules forbid you from presenting as fact.)

2. **Explicit construction of an infinite family of losing positions.** *Cue:* the command term "infinitely many" can be read as an invitation to construct a family directly. *Circuit:* strong induction defining new losing positions from old ones. (why it ranks here: to add a new losing position n to your family you must check that *every* legal move from n, i.e. subtracting $p - 1$ for every prime $p \leq n$, lands on a winning position; since there are infinitely many primes, this requires controlling infinitely many cases at once for every single n you add, which is exactly as hard as knowing the full set of losing positions, so this buys nothing over the direct approach.)

3. **Contradiction on the size of the losing set, using a factorial gadget.** *Cue:* the phrase "infinitely many" together with a move set built from primes signals that the contradiction should exploit a structural fact about primes rather than any specific strategy. *Circuit:* assume finiteness, derive a universal representation requirement, falsify it with a run of consecutive composites.

(why it ranks here: this never needs to know what the losing positions actually are, only that a finite list of them cannot possibly account for every larger heap size, and the falsification is a single classical gadget, $(t+1)!+2, \ldots, (t+1)!+(t+1)$, that defeats an arbitrarily large finite list at once.)

The ideal solution

Call a heap size $n \geq 0$ a *P-position* if the player about to move at a heap of n stones loses under optimal play, with the convention that $n = 0$ is a P-position, since the player to move there has already lost (there are no stones left to take, and by the rules the previous player took the last stone and won). This is a standard recursive notion for impartial games under normal play: for $n \geq 1$, n is a P-position exactly when every legal move from n leads to a position that is *not* a P-position (an N-position), and n is an N-position exactly when *some* legal move from n leads to a P-position. Here the legal moves from a heap of n stones are exactly the sizes $s = p - 1$ for p prime and $1 \leq s \leq n$.

Since Alice moves first, "Bob has a winning strategy at heap n" means precisely that n is a P-position. Let B be the set of P-positions, including 0 by the convention above; the problem asks to show B is infinite.

Suppose, for contradiction, that B is finite, and write $B = \{b_1, \ldots, b_m\}$. By the recursive description above, every non negative integer $n \notin B$ is an N-position, so it admits some legal move to a P-position: there exist $b \in B$ and a prime p with $n - (p-1) = b$, i.e.

$$n = b + p - 1.$$

That is, every non negative integer outside the finite set B can be written in this form for some choice of $b \in B$ and prime p. We now exhibit a specific integer n outside B for which no such choice exists, a contradiction.

Let t be any integer exceeding every element of B (for instance $t = \max(B) + 1$). For each integer k with $2 \leq k \leq t+1$, k divides $(t+1)!$ (since $k \leq t+1$) and k divides k, so k divides $(t+1)!+k$; since $(t+1)!+k > k \geq 2$, this shows $(t+1)!+k$ is composite. Thus

$$(t+1)!+2,\ (t+1)!+3,\ \ldots,\ (t+1)!+(t+1)$$

are t consecutive composite integers.

Set $n = (t+1)!+t$. Since $n > t > \max(B)$, $n \notin B$, so n is an N-position, and by the argument above there must exist $b \in B$ and prime p with $p = n - b + 1$. But for every $b \in B$ we have $0 \leq b \leq \max(B) < t$, so $t - b + 1$ ranges over integers in $[2, t+1]$ as b ranges over B, and

$$n - b + 1 = (t+1)! + t - b + 1 = (t+1)! + (t - b + 1)$$

is exactly one of the composite integers exhibited above. Hence $n - b + 1$ is composite, so it cannot equal p for any prime p, for any $b \in B$. This contradicts the requirement that n admits some representation $n = b + p - 1$.

The contradiction shows B cannot be finite. There are therefore infinitely many n for which Bob has a winning strategy. ■

Layer 1: WHAT

Block 1: translate the game into P-positions and N-positions, and rewrite the target claim as "the set B of P-positions is infinite". Block 2: assume for contradiction that B is finite, and unpack what that forces for every integer outside B: a representation $n = b + p - 1$. Block 3: build, from an arbitrary finite list B, a run of consecutive composite integers long enough to defeat every element of B simultaneously. Block 4: choose n so that $n - b + 1$ lands inside that composite run for every $b \in B$ at once, contradicting the required representation.

The nominal route also starts with the P/N translation, since that is forced by the problem's language, but then tries to compute B directly, or to construct an explicit infinite subfamily of B term by term. Both stall on the same obstruction: neither ever gets to use a property of *all primes at once*, only of individual primes, and the move set $\{p-1 : p \text{ prime}\}$ offers no periodic or arithmetic handle for that. The bifurcation point is the sentence "suppose B is finite": the ideal route treats this supposition itself as the object to be attacked, using only its cardinality, while the nominal route never introduces this supposition and instead tries to fight the infinite, irregular move set directly.

Layer 2: HOW

Block 1. **Cue.** The statement to prove is about the existence of infinitely many heap sizes with a stated player winning, and the win condition is defined recursively (Bob wins now depends on what happens after every possible move). **Why natural.** Any game with a "last player to move wins" rule has, by definition, a recursive split of positions into those where the mover loses (P-positions, previous-player-wins) and those where the mover wins (N-positions, next-player-i.e.-mover-wins); "Bob wins with Alice moving first at n" is definitionally the statement "n is a P-position", so this translation is not a choice, it is what the English sentence means once game theory vocabulary is attached to it. **Link to the next block.** Having reduced the target to "the set of P-positions is infinite", the next natural step is to ask what would have to be true if it were not.

Block 2. **Cue.** The set B of P-positions is being tested for infinitude, and the recursive definition says every N-position has some move to a P-position. **Why natural.** If B were finite, then every one of the infinitely many non negative integers not in B (an N-position) is still required, by the very definition of N-position, to have at least one legal move landing in B; writing that move as subtracting $p-1$ turns "has a move into B" into the concrete algebraic statement $n = b + p - 1$ for some $b \in B$, p prime, which is now a number theory sentence rather than a game theory one. **Link to the next block.** This representation must hold for *every* large n, which is an extremely strong, and therefore fragile, requirement; the natural next move is to try to break it for one specific n.

Block 3. **Cue.** Breaking the representation $n = b + p - 1$ for a fixed finite list $b_1, \ldots, b_m$ means making $n - b_i + 1$ composite for every i at once. **Why natural.** A single classical gadget produces an arbitrarily long run of consecutive composites: for k from 2 to $t+1$, $(t+1)! + k$ is divisible by k and strictly larger than k, hence composite; this is just the definition of divisibility applied to the two terms of the sum, and it works uniformly for every k in that range without needing to know anything else about k. **Link to the next block.** Because the gadget covers every integer in a whole range $[2, t+1]$ at once, and the finitely many values $b \in B$ can be arranged, by choice of t, to make $t - b + 1$ land inside exactly that range, the gadget defeats the entire finite list B in one stroke rather than one b at a time.

Block 4. **Cue.** A specific n is needed that lies outside B and for which $n - b + 1$ falls inside the composite run for every $b \in B$. **Why natural.** Choosing $n = (t+1)! + t$ makes $n - b + 1 = (t+1)! + (t - b + 1)$, and since b ranges over $B \subset [0, t)$, the quantity $t - b + 1$ ranges exactly over $[2, t+1]$, which is precisely the range the gadget covers; this is a matter of matching the shift in the construction to the range of B, arranged by the choice $t > \max(B)$. **Link to the next block.** With $n - b + 1$ composite for every $b \in B$, no prime p can satisfy $n = b + p - 1$ for any $b \in B$, directly contradicting Block 2's requirement, which closes the proof.

Layer 3: WHY

The underlying truth is that finiteness is an extremely strong hypothesis to hand an opponent, and the honest way to use it is to make the contradiction depend only on the *size* of the finite set, never

on its specific contents. That is what happens here: the construction never asks what B actually is, only that it is bounded, via $t > \max(B)$, and the composite run is built purely from t. This is what makes the argument uniform rather than a case analysis that would need to grow with $m = |B|$.

The discernment mechanism for reaching for this kind of argument is recognising when a problem asks you to disprove finiteness of an implicitly, recursively defined set with no closed form: in that situation direct computation is rarely viable, because you would be trying to establish a regularity (periodicity, an arithmetic pattern) that the move set gives you no reason to expect, and a proof of a non existent pattern is not available. Assuming finiteness converts the target from an infinite, open ended search into a single, fixed, checkable obstruction. You train this by noticing, whenever a recursive win or lose condition is stated over an infinite, irregular move set (here, primes), that the productive question is not "what is the answer" but "what would have to be true if there were only finitely many answers, and can I break that".

The examiners chose the move set $\{p - 1 : p \text{ prime}\}$ rather than something with visible structure, such as $\{1, 2, 3, \dots\}$ or a fixed arithmetic progression, precisely so that a direct, computational attack has nowhere to gain a foothold, while the existence of arbitrarily long runs of consecutive composite integers (a fact about primes, not about the game) is exactly strong enough to finish the indirect argument in a handful of lines.

Revolving concepts

P-positions and N-positions for impartial combinatorial games under normal play: a position is a P-position if the player about to move loses under optimal play, and an N-position if the player about to move wins; the base case is that a position with no legal moves is a P-position, and the recursive rule is that a position is a P-position exactly when every move leads to an N-position, and an N-position exactly when some move leads to a P-position. This machinery generalises unchanged to any subtraction game with any set S of legal move sizes, finite or infinite: compute P-positions upward from 0 using the same recursive rule, and the winner of a heap of size n with a given first mover is determined purely by whether n is a P-position or N-position for that S. See Book 1, field: Games and invariants, topic: subtraction games and the P/N classification.

Consecutive composite integers via factorials: for any integer $t \geq 1$, the t consecutive integers $(t+1)! + 2, \dots, (t+1)! + (t+1)$ are all composite, since $(t+1)! + k$ is divisible by k for every k in that range, by construction of the factorial. This is the standard tool whenever a problem needs an arbitrarily long run of numbers avoiding a property (here, primality) at once, rather than one number at a time. See Book 1, field: Number theory, topic: gaps between primes.

Proof by contradiction on the cardinality of an implicitly defined set: to show a set is infinite, assume it is finite, extract a universal consequence that every excluded integer must satisfy, then falsify that consequence for one specific integer built to defeat every element of the assumed finite list simultaneously. This pattern recurs whenever a problem defines a set recursively (via a game, a sieve, an iterated construction) and asks only for infinitude, not for an explicit description. See Book 1, field: Logic and set theory, topic: contradiction arguments on set size.

The set $\{p - 1 : p \text{ prime}\}$ itself: an infinite, aperiodic set of positive integers with no arithmetic progression structure, in contrast to move sets such as $\{1, 2, \dots, k\}$ that produce cleanly periodic P-position sets; recognising which kind of move set you are given, before attempting any computation, tells you whether a direct or an indirect proof strategy is appropriate. See Book 1, field: Number theory, topic: irregularity of the primes.

Circuit Bank

- **WHEN** a Putnam problem asks you to prove a set defined by a game or a recursive rule is infinite, rather than to describe the set **DO** treat this as a signal for an indirect argument: assume the set is finite and look for a universal consequence to falsify **BECAUSE** a request for

infinitude rather than description usually means the set has no usable closed form, and direct computation offers nothing to generalise from

- **WHEN** the legal moves in a subtraction game are defined via primes, or any other set with no periodicity **DO** do not attempt to compute the P-positions by hand and guess a period **BECAUSE** primes (and sets built from them, such as $p-1$) have no arithmetic progression structure, so there is no period to find, and time spent searching for one is wasted
- **WHEN** a contradiction argument needs to defeat every element of an assumed finite set B at once **DO** build the falsifying construction so it depends only on a bound on B (such as $t = \max(B) + 1$), never on the individual elements **BECAUSE** a construction tailored to the specific elements of B turns into unbounded casework as $|B|$ grows; a construction tailored to a single bound handles every possible finite B uniformly
- **WHEN** you need an arbitrarily long run of consecutive composite integers **DO** use $(t+1)! + 2, \ldots, (t+1)! + (t+1)$, each divisible by its own offset from $(t+1)!$ **BECAUSE** divisibility of a sum by a common factor of both terms is immediate from the definition of the factorial, and needs no further number theoretic input

Backtesting

1. First useful cue: the command "prove there are infinitely many n" rather than "find all n" or "determine the winner for each n", signalling that the set of interest has no expected closed form.
2. Method the expression suggested: translate the win condition into the standard recursive P-position and N-position machinery for impartial games, since "last player to move wins" is exactly the normal play convention that machinery is built for.
3. Where you would hesitate, and the thought to reinforce: whether it is legitimate to include $n = 0$ in B as a base case when the game is never actually played from an empty heap; reinforce by noting this is purely a bookkeeping convention for the recursion, matching the standard convention that a position with no legal moves is a loss for the player to move.
4. The trap the question sets: the explicit worked example with $n = 17$ invites you to start computing small cases by hand, which can eat significant time before you notice the move set has no period to find; recognise the trap by checking early whether the move set itself (here, $p - 1$ for primes p) has any arithmetic structure to exploit.
5. What makes you recognise it faster next time: seeing "prove infinitely many" attached to a recursively, not explicitly, defined set as the fingerprint of a finite-versus-infinite contradiction argument, before attempting any direct computation.
6. The reusable decision rule: assume the target set is finite, translate that assumption into a universal representation every excluded integer must satisfy, then build one gadget, dependent only on a bound for the assumed finite set, that falsifies the representation for every element at once.

Mirror drills

1. In the same game but with legal move sizes $\{p : p \text{ prime}\}$ instead of $\{p-1\}$, sketch why the same contradiction strategy still works. *Hint:* the representation becomes $n = b + p$ for $b \in B$, p prime; use the same factorial run of composites, shifted by one, to defeat any finite B.
2. Prove there are infinitely many positive integers n that cannot be written as the sum of a prime and a positive perfect square. *Hint:* suppose finitely many exceptions to "cannot be written"; a

run of consecutive composites again forces most large n into the excluded case, or attack the complementary set directly with the same factorial gadget.

3. Explain, without doing the computation, why trying to prove Bob wins for infinitely many n by exhibiting an explicit formula for B (such as a residue class mod some fixed integer) is not a promising plan for this specific move set. *Answer:* B would have to be compatible with subtracting $p-1$ for every prime p at every step, and since primes are not confined to any fixed residue pattern relative to a single modulus in the way needed, no single residue class formula for B can be consistent with the recursive P-position rule.

20.3 A3. 2005 Consecutive Multiples in a Sparse Recursion

Let $1, 2, 3, \ldots, 2005, 2006, 2007, 2009, 2012, 2016, \ldots$ *be a sequence defined by* $x_k = k$ *for* $k = 1, 2, \ldots, 2006$ *and* $x_{k+1} = x_k + x_{k-2005}$ *for* $k \geq 2006$. *Show that the sequence has* 2005 *consecutive terms each divisible by* 2006.

Read it out loud

This is a linear recursion, but not the small, tidy kind you are trained on: x_{k+1} is the sum of the immediately preceding term and a term 2006 steps further back, so as a recursion "of fixed order" it has order 2006, since you need a full block of 2006 consecutive terms to determine the next one. No characteristic polynomial of degree 2006 is going to be solved by hand, and the problem does not ask you to solve one; it asks only for a divisibility statement about a bounded run of terms, which is a much weaker demand than a closed form and should be attacked with correspondingly lighter machinery. The fields wired into the question are sequences and recurrences, specifically the behaviour of a fixed order integer recursion under reduction modulo an integer, and elementary number theory, specifically what it means for a run of terms to be divisible by 2006.

The first useful cue is arithmetic, not structural: rearrange the defining relation $x_{k+1} = x_k + x_{k-2005}$ to isolate the oldest term instead of the newest, giving $x_{k-2005} = x_{k+1} - x_k$. Every coefficient here is ± 1, an integer, so this rearrangement costs nothing and needs no division; the recursion runs backward exactly as cleanly as it runs forward. That single fact, checked in one line, is what decides the whole strategy: a recursion you can run backward with integer coefficients can be extended to a doubly infinite sequence, and a doubly infinite integer sequence reduced modulo a fixed integer, from a recursion of fixed order, is forced by a pigeonhole argument to be periodic, not merely eventually periodic.

The second cue is the initial data itself: $x_k = k$ for $k = 1, \ldots, 2006$ is an arithmetic progression with common difference 1, the simplest possible input to a differencing operation. Since the backward recursion is exactly a difference, $x_{k-2005} = x_{k+1} - x_k$, running it backward from this block is almost free: every difference of consecutive terms in an arithmetic progression with common difference 1 is 1. That observation, not any deep property of 2005 or 2006 individually, is what makes the whole problem collapse to a handful of lines.

Approaches, ranked worst to best

1. **Characteristic polynomial closed form.** *Cue:* a linear recursion suggests solving $t^{2006} = t^{2005} + 1$ for its roots. *Circuit:* linear recurrence to characteristic equation to closed form. (why it ranks here: the characteristic polynomial has degree 2006 and no tractable closed form roots; even granting formal roots, extracting an exact divisibility statement about specific terms from them is not a realistic route, and the problem never requires a closed form at all, so this is solving a harder problem than the one asked.)

2. **Direct forward simulation modulo 2006.** *Cue:* the target is a statement about divisibility by 2006, so work entirely modulo 2006 from the start. *Circuit:* compute residues forward from $k = 1$ and search for the required run. (why it ranks here: the residues modulo 2006 are eventually periodic by a pigeonhole argument, but the argument alone gives no bound on how far forward the first repeat, let alone the first run of 2005 consecutive zero residues, occurs; establishing a workable bound requires essentially the same theory as the ideal route, so this approach either needs an infeasible amount of computation or quietly imports the ideal route's machinery anyway.)

3. **Reverse the recursion, extend to a doubly infinite periodic sequence, search backward from the known block.** *Cue:* the recursion is invertible with unit coefficients, and the known initial

data collapses instantly under differencing. *Circuit:* reversible recursion to full periodicity, then exploit the cheapest available data. (why it ranks here: invertibility upgrades eventual periodicity to full, two sided periodicity, which licenses searching for the target pattern anywhere in the doubly infinite sequence rather than only forward from an unknown point; searching backward from the arithmetic progression $x_k = k$ finds the pattern in a fixed, small number of algebraic steps, and periodicity alone then guarantees the same pattern reappears somewhere in the actual forward sequence.)

The ideal solution

Write the recursion, for $k \geq 2006$, in its given form $x_{k+1} = x_k + x_{k-2005}$, and note it rearranges, using only integer coefficients, to

$$x_{k-2005} = x_{k+1} - x_k.$$

Lemma 1 (eventual periodicity). If integers $y_1, y_2, \ldots$ satisfy $y_j = f(y_{j-1}, \ldots, y_{j-n})$ for $j > n$, where n is fixed and f is a fixed polynomial with integer coefficients, then for any modulus $N \geq 1$ the residue sequence $y_j \bmod N$ is eventually periodic. *Proof.* A window of n consecutive residues mod N takes only N^n possible values, so among the infinitely many windows $(y_{j-n+1}, \ldots, y_j) \bmod N$ for $j > n$, two must coincide, say at $j = j_1 < j_2$. Since f has integer coefficients, congruent inputs give congruent outputs, so the entire windows agree from j_1 onward: $y_{j_1+i} \equiv y_{j_2+i} \pmod N$ for every $i \geq 0$. Hence the residue sequence is periodic with period $j_2 - j_1$ from index $j_1 - n + 1$ onward.

Lemma 2 (full periodicity under reversibility). With the same hypotheses, suppose further there is a fixed integer coefficient polynomial g with $y_{j-n} = g(y_{j-n+1}, \ldots, y_j)$ for $j > n$. Then the sequence extends uniquely to a doubly infinite sequence $\ldots, y_{-1}, y_0, y_1, \ldots$, and this doubly infinite sequence is purely periodic modulo every N. *Proof.* Extend by defining $y_{j-n} := g(y_{j-n+1}, \ldots, y_j)$ downward for $j = n, n-1, n-2, \ldots$. The pigeonhole argument of Lemma 1 still finds $j_1 < j_2$ with matching windows; but now, since g also has integer coefficients, congruent windows propagate backward as well as forward, $y_{j_1-1} = g(\ldots) \equiv g(\ldots) = y_{j_2-1} \pmod N$, and inductively for every earlier index. So the whole doubly infinite sequence is periodic mod N with period $j_2 - j_1$, with no eventually needed.

Both hypotheses hold here, with $n = 2006$: $f(y_n, \ldots, y_1) = y_n + y_1$ recovers x_{k+1} from the window $(x_{k-2005}, \ldots, x_k)$, and $g(y_n, \ldots, y_1) = y_n - y_{n-1}$ recovers x_{k-2005} from $(x_{k-2004}, \ldots, x_{k+1})$; both are integer coefficient polynomials. By Lemma 2, the sequence extends to a doubly infinite sequence, purely periodic modulo 2006. It therefore suffices to exhibit 2005 consecutive terms divisible by 2006 anywhere in this doubly infinite sequence: periodicity will relocate the same run into the region $k \geq 1$, which is the actual sequence given in the problem.

Run the recursion backward from the known block $x_1, x_2, \ldots, x_{2006} = 1, 2, \ldots, 2006$. For $k = 1, \ldots, 2005$, both k and $k+1$ lie in $[1, 2006]$, so $x_{k-2005} = x_{k+1} - x_k = (k+1) - k = 1$. As k ranges over $1, \ldots, 2005$, the index $k - 2005$ ranges over $-2004, \ldots, 0$; combined with $x_1 = 1$, this gives

$$x_{-2004} = x_{-2003} = \cdots = x_0 = x_1 = 1,$$

a block of 2006 consecutive terms all equal to 1. Now take $k = -2004, \ldots, 0$: both k and $k+1$ lie in $[-2004, 1]$, so $x_{k-2005} = x_{k+1} - x_k = 1 - 1 = 0$. As k ranges over $-2004, \ldots, 0$, the index $k - 2005$ ranges over $-4009, \ldots, -2005$, giving

$$x_{-4009} = x_{-4008} = \cdots = x_{-2005} = 0,$$

a run of 2005 consecutive terms, each equal to 0 and hence divisible by 2006.

Let $T \geq 1$ be the period of the doubly infinite sequence modulo 2006 from Lemma 2, and choose a positive integer c with $cT \geq 4010$ (possible since $T \geq 1$). For each integer j in $\{-4009, \ldots, -2005\}$, periodicity gives $x_{j+cT} \equiv x_j \equiv 0 \pmod{2006}$, and the shifted indices $j + cT$ range over 2005 consecutive integers, all at least $-4009 + 4010 = 1$. So the actual sequence $x_1, x_2, \ldots$ contains 2005 consecutive terms, namely $x_{-4009+cT}, \ldots, x_{-2005+cT}$, each divisible by 2006, as required. ■

Layer 1: WHAT

Block 1: rearrange the recursion to isolate the oldest term, $x_{k-2005} = x_{k+1} - x_k$, and check the coefficients are integers, so the recursion is invertible. Block 2: state and prove the general fact that any fixed order integer polynomial recursion is eventually periodic modulo any N, by pigeonhole on the finitely many windows. Block 3: strengthen this, using invertibility, to full two sided periodicity of a doubly infinite extension of the sequence. Block 4: run the (trivial, since the initial data is an arithmetic progression) backward recursion explicitly from the known block $x_1, \ldots, x_{2006}$ to exhibit 2005 consecutive zero terms. Block 5: use periodicity to relocate that run of zeros into the region $k \geq 1$, the actual given sequence, completing the proof.

The nominal route also notices the recursion has order 2006, but then either tries to extract a closed form from the characteristic polynomial, or starts computing $x_{2007}, x_{2008}, \ldots$ modulo 2006 forward, hoping to meet a run of 2005 zero residues by direct search. Both stall for the same reason: neither ever uses the fact that the recursion is reversible, so neither gains access to the arithmetic progression block $x_1, \ldots, x_{2006}$, which is exactly where the backward computation is free. The bifurcation point is the single rearrangement $x_{k-2005} = x_{k+1} - x_k$: written down and recognised as an integer coefficient identity, it opens the whole backward, periodic route; left unwritten, every subsequent route is forced forward, into either an intractable characteristic polynomial or an unbounded search.

Layer 2: HOW

Block 1. **Cue.** The defining relation $x_{k+1} = x_k + x_{k-2005}$ has every coefficient equal to 1, with no division needed to isolate any term. **Why natural.** Testing whether a recursion is reversible is a fixed check, independent of the specific problem, that decides which of two strictly different periodicity results (eventual only, or full two sided) is available; since a unit coefficient recursion can always be solved for its oldest term over the integers, by definition of what it means to divide by 1, the check costs one line and is always worth making immediately. **Link to the next block.** Having confirmed reversibility, the next natural step is to state precisely what reversibility buys you, which is the upgrade from eventual to full periodicity, a standard fact about fixed order integer recursions.

Block 2. **Cue.** The recursion has fixed order 2006 (a window of 2006 consecutive terms determines the next), and the target statement concerns divisibility by a fixed modulus 2006. **Why natural.** A window of n consecutive residues modulo N can take only N^n values, a finite number by definition of "modulo N", so by the pigeonhole principle two windows among the infinitely many produced by the recursion must coincide, and because the recursion is a fixed integer coefficient function of the window, everything after the first coincidence must repeat identically. **Link to the next block.** Eventual periodicity alone only guarantees repetition somewhere far enough forward, with no control over where; the reversibility already checked in Block 1 is what turns this into a statement usable near the boundary of the known data.

Block 3. **Cue.** The oldest term recursion $x_{k-2005} = x_{k+1} - x_k$ is, like the forward recursion, a fixed integer coefficient polynomial in the window. **Why natural.** Since congruence is preserved by integer coefficient polynomials in both directions, the same pigeonhole coincidence that propagates forward (Lemma 1) also propagates backward once the sequence is extended to negative indices, by exactly the same argument applied to g instead of f; this is not a new principle, only the same one applied twice. **Link to the next block.** Full periodicity means the target pattern can be sought anywhere in the doubly infinite sequence, so the natural next move is to search where the algebra is cheapest, not where the problem statement happens to start counting.

Block 4. **Cue.** The known initial block $x_1, \ldots, x_{2006} = 1, \ldots, 2006$ is an arithmetic progression with common difference 1, and the backward recursion is exactly a first difference. **Why natural.** Differencing an arithmetic progression with common difference 1 produces the constant sequence 1, by the definition of arithmetic progression; running the backward recursion once more on a block that is constantly 1 produces the constant sequence 0, by the same definition applied to a degenerate ("difference of equal terms") case. **Link to the next block.** A run of 2005 consecutive zero terms has now been exhibited explicitly, at indices -4009 through -2005; all that remains is to move this run into the positive indices the problem actually asks about.

Block 5. **Cue.** The zero run sits at negative indices, but the problem's sequence is only defined, as stated, for $k \geq 1$. **Why natural.** Full periodicity modulo 2006, established in Block 3, means every residue value recurs at every shift by a multiple of the period T; choosing a sufficiently large multiple moves the entire window of 2005 indices past 1 without altering any of the residues, by the definition of periodicity. **Link to the next block.** Nothing remains: the shifted window lies entirely within $k \geq 1$ and every term in it is divisible by 2006, which is the statement to be proved.

Layer 3: WHY

The mathematical truth underneath the route is that a fixed order recursion, reduced modulo a fixed integer, is a walk on a finite state space (the set of possible windows), and any walk on a finite state space that can be reversed as well as advanced must be purely periodic, not merely eventually so: this is nothing more than the pigeonhole principle applied twice, once forward and once backward, and the reversal is what removes the word "eventually". The discernment mechanism for reaching for this, rather than a closed form or a forward search, is recognising two separate signals at once: an order large enough that a closed form is not viable, and a coefficient pattern (here, all ± 1) that costs nothing to invert. Whenever both are present, the productive question stops being "what is x_k" and becomes "what does the periodic residue sequence look like, and where is it cheapest to compute a window of it".

You train this discernment by treating "can I solve this recursion for its oldest term without dividing by anything but ± 1" as a reflex check performed the instant a recursion of unfamiliar order appears, before any attempt at a closed form. You also train it by noticing when the GIVEN initial data has extra structure (here, a literal arithmetic progression) that trivialises differencing; such structure is usually placed exactly where the backward recursion should be run, not left to be discovered by accident.

The examiners chose the numbers 2005 and 2006, and the initial block $x_k = k$, with real care: making the initial segment the identity function guarantees the first backward difference is the constant 1, and iterating the same backward step once more on a constant sequence guarantees the second backward difference is the constant 0, producing the required run of zeros in exactly two applications of the backward recursion rather than an unpredictable number. The gap of 2005 (so that the recursion has order 2006, matching the modulus 2006) is what makes the closed form route hopeless while leaving the periodicity route completely untouched by the size of the order, since the pigeonhole argument never needs to enumerate the 2006^{2006} possible windows, only to know that this number is finite.

Revolving concepts

Eventual periodicity of integer polynomial recursions modulo N: if $y_j = f(y_{j-1}, \ldots, y_{j-n})$ for a fixed n and a fixed integer coefficient polynomial f, the residues $y_j \bmod N$ are eventually periodic, because there are only N^n possible windows of n consecutive residues, forcing a repeat by pigeonhole, after which the deterministic recursion forces everything to repeat. This generalisation applies verbatim to any fixed order integer recursion, including the Fibonacci sequence modulo N (whose

period is called the Pisano period) and any other "gap" recursion $x_{k+1} = x_k + x_{k-m}$ for fixed m. See Book 1, field: Sequences and recurrences, topic: periodicity modulo an integer.

Full, two sided periodicity for reversible recursions: if in addition $y_{j-n} = g(y_{j-n+1}, \ldots, y_j)$ for a fixed integer coefficient polynomial g, the sequence extends to a doubly infinite sequence that is purely periodic modulo every N, with no eventually needed, because the pigeonhole coincidence propagates backward as well as forward. This generalisation applies whenever a linear (or polynomial) integer recursion has leading coefficients equal to ± 1, so that solving for the oldest term never requires division; the Fibonacci recursion again qualifies, via $F_{j-1} = F_{j+1} - F_j$. See Book 1, field: Sequences and recurrences, topic: reversible recursions and bi-infinite extensions.

Sparse, wide gap linear recursions: a recursion such as $x_{k+1} = x_k + x_{k-m}$ for a large fixed gap m has, as a linear recursion, order $m + 1$ and a characteristic polynomial of that degree, making a closed form solution impractical for large m even though only two terms appear explicitly in each step; recognising this order before attempting a closed form saves the ink of trying one. See Book 1, field: Sequences and recurrences, topic: high order linear recursions.

Divisibility as vanishing residue: an integer term x_k is divisible by N exactly when $x_k \equiv 0 \pmod{N}$, so a run of consecutive terms divisible by N is exactly a run of consecutive zero residues in the sequence reduced mod N; this is the translation that turns the problem's divisibility requirement into a statement purely about the periodic residue sequence tracked throughout the solution. See Book 1, field: Number theory, topic: divisibility and congruence.

Circuit Bank

- **WHEN** a recursion $x_k = f(x_{k-1}, \ldots, x_{k-n})$ has a large order n and you need a mod N divisibility statement about it **DO** reach for eventual periodicity modulo N via pigeonhole on the finitely many windows, before attempting a closed form **BECAUSE** the state space of windows modulo N is always finite, size N^n, regardless of how large n is, while a genuine closed form for order n recursions with n large is rarely available
- **WHEN** a recursion can be algebraically solved for its oldest term using only integer coefficients (in particular, coefficients ± 1, needing no division) **DO** extend the sequence backward to a doubly infinite sequence **BECAUSE** this upgrades eventual periodicity to full periodicity modulo every N, which lets you search for a target pattern anywhere in the sequence, not only forward from an unknown starting point
- **WHEN** you need to exhibit a specific pattern inside a periodic sequence but do not know where it first occurs going forward **DO** run the recursion backward from the known, explicit initial data instead **BECAUSE** initial data is often unusually simple (constant, arithmetic, or otherwise structured), so differencing or otherwise inverting it collapses several recursive steps into one, and periodicity guarantees the pattern found there also occurs somewhere forward
- **WHEN** a linear recursion's gap is large compared to the simplicity of its initial data **DO** exploit the special structure of the initial data (constant differences, ratios, etc.) before treating the recursion generically **BECAUSE** special initial structure usually collapses several steps of the general recursion into a single closed computation, which is exactly what happened here with an arithmetic progression differencing to a constant, then to zero

Backtesting

1. First useful cue: the recursion links a term 2006 steps forward directly to one 2006 steps further back ($x_{k+1} = x_k + x_{k-2005}$), a wide fixed gap that immediately marks the recursion as high order and unsolvable in closed form.

2. Method the expression suggested: rearrange for the oldest term, $x_{k-2005} = x_{k+1} - x_k$, since every coefficient is ± 1, so the recursion is invertible with no division and can be run backward as cleanly as forward.
3. Where you would hesitate, and the thought to reinforce: whether it is legitimate to extend a sequence given only for $k \geq 1$ backward to negative indices; reinforce by treating the extension as a purely algebraic device used to access periodicity, since the final claim concerns only $k \geq 1$, which is recovered afterward via periodicity, so no illegitimate step is taken anywhere in the argument.
4. The trap the question sets: the number 2005, appearing both as the gap in the recursion and as the length of run required, invites hunting for period 2005 structure directly in the forward sequence, when in fact the exact period of the residue sequence is never computed or needed; only one run of length 2005 is required, and it is found painlessly at the far backward end of the extension.
5. What makes you recognise it faster next time: seeing a recursion of the shape $x_{k+1} = x_k + x_{k-m}$, a two term, wide gap recursion, and immediately checking invertibility (unit coefficients) as the very first move, before anything else is attempted.
6. The reusable decision rule: an order n integer recursion, reduced modulo N, that is also reversible extends to a doubly infinite, purely periodic sequence modulo N; search for any required pattern wherever the algebra is cheapest, most often against the known initial data, rather than forward from the first index the problem happens to start at.

Mirror drills

1. The Fibonacci sequence $F_1 = F_2 = 1$, $F_{k+1} = F_k + F_{k-1}$, is reduced modulo an integer N. Show the residue sequence is purely periodic (the Pisano period), not merely eventually periodic. *Hint:* the same two lemmas apply directly, since $F_{k-1} = F_{k+1} - F_k$ is the backward recursion with unit coefficients.
2. A sequence satisfies $y_k = y_{k-1} + y_{k-10}$ for $k > 10$, with $y_1 = \cdots = y_{10} = 1$. Show it has 9 consecutive terms divisible by 10. *Hint:* identical method with gap 10 in place of 2005; the initial block is constant, so the first backward difference is already 0, one step shorter than the original problem.
3. Explain, without computing anything, why attempting a closed form for x_k in the original problem via the characteristic polynomial of $t^{2006} - t^{2005} - 1 = 0$ is not a productive route for this question. *Answer:* the question asks only for a bounded divisibility statement, which the periodicity argument extracts in a handful of algebraic steps, while a degree 2006 characteristic polynomial has no accessible closed form roots and gives no direct route to an integer divisibility conclusion even if its roots were known.

20.4 A4. Average number of peaks of a permutation

Let $S = \{1, 2, \ldots, n\}$ for some integer $n > 1$. Say a permutation π of S has a local maximum *at $k \in S$ if*

(i) $\pi(k) > \pi(k+1)$ *for* $k = 1$;

(ii) $\pi(k-1) < \pi(k)$ *and* $\pi(k) > \pi(k+1)$ *for* $1 < k < n$;

(iii) $\pi(k-1) < \pi(k)$ *for* $k = n$.

(For example, if $n = 5$ and π takes values at $1, 2, 3, 4, 5$ of $2, 1, 4, 5, 3$, then π has a local maximum of 2 at $k = 1$, and a local maximum of 5 at $k = 4$.) What is the average number of local maxima of a permutation of S, averaging over all permutations of S?

Read it out loud

This is an averaging question over a finite symmetric family. You are given $n!$ objects, each object carries a count, and you are asked for the mean of that count. Say that sentence to yourself before you write anything, because it already tells you the method: a mean of a count is never a question about the count's distribution. It is a question about one number, and one number is cheaper to get than a whole distribution.

Now read the thing being counted. A local maximum at k is decided by looking at $\pi(k)$ and its immediate neighbours and nothing else. Positions 2 through $n-1$ look at a window of three consecutive values; positions 1 and n look at a window of two, because the window is truncated by the end of the row, not because a special rule is in force. That is the second structural fact, and it is the one that makes the problem collapse: the count is a sum of n local conditions, each involving at most three entries.

The fields wired into this problem are the combinatorics of permutation statistics (peaks, descents, records) and the elementary theory of expectation, specifically linearity and the notion of an indicator random variable. Nothing else. What is being tested is whether you know that expectation is linear whether or not the summands are independent, and whether you know that a uniformly random permutation looks uniformly random when you restrict attention to any fixed set of positions. The peak indicators here are violently dependent (positions k and $k+1$ can never both be peaks), and that dependence is exactly what makes the distribution of the count hard and the mean of the count easy. The examiner chose the statistic so that the dependence is obvious and irrelevant.

Within thirty seconds you should have written two lines. First, $X(\pi) = \sum_{k=1}^{n} \mathbf{1}[\pi \text{ has a peak at } k]$. Second, $\mathrm{E}[X] = \sum_{k=1}^{n} \mathrm{P}(\text{peak at } k)$. Everything after that is arithmetic on three numbers.

Approaches, ranked worst to best

1. **Compute the whole distribution, then take its mean.** *Cue:* the word "average" misread as "I must know how the count is spread out". *Circuit:* none; this is the zombie route. You would be counting, for each j, the number of permutations of S with exactly j peaks. Those numbers are the coefficients of the peak polynomial, a genuinely intricate object with no one line closed form. You would then have to sum j times that count and simplify. This costs an enormous amount of ink to produce a fact you were never asked for. Rank it last not because it fails but because it answers a harder question than the one on the paper.

2. **Brute force small cases and guess.** *Cue:* a formula in n is wanted and the cases are computable by hand. *Circuit:* pattern extraction. For $n = 2, 3, 4, 5$ you get $1, \frac{4}{3}, \frac{5}{3}, 2$, so the answer is visibly $\frac{n+1}{3}$. Worth thirty seconds as insurance, and worth nothing as a proof. On a "what is the average" problem the Putnam grader wants the derivation, so this is a check, not a solution. Keep it in your pocket and never submit it alone.

3. **Split at the maximum and recurse.** *Cue:* the value n is always a peak, and deleting it cuts the row into two independent shorter rows. *Circuit:* divide and conquer on the position of the largest element. Condition on the position j of the value n. The row splits into a left block of length $j-1$ and a right block of length $n-j$, the relative orders inside the blocks are independent and uniform, and you weight by $\binom{n-1}{j-1}$. This does work and it is instructive, but the boundary conventions ruin the elegance: the left block now ends against a value larger than everything in it, so its right hand boundary rule is not the rule in the problem, and you must set up a second statistic for one sided blocks. Two coupled recursions to compute one number.

4. **Linearity of expectation over the values.** *Cue:* ask which numbers $1, \dots, n$ appear as peaks rather than which positions carry peaks. *Circuit:* indicator sum indexed by value, plus a symmetrising device. Write the permutation as the symbols $1, \dots, n$ and one extra symbol $*$ arranged around a circle; the row is recovered by cutting at $*$, and the two truncated windows at the ends become full windows containing $*$, which acts as a value smaller than everything. Then i is a peak precisely when both circular neighbours of i lie in $\{*, 1, \dots, i-1\}$, which happens with probability $\frac{i(i-1)}{n(n-1)}$, and $\sum_{i=1}^{n} \frac{i(i-1)}{n(n-1)} = \frac{2}{n(n-1)}\binom{n+1}{3} = \frac{n+1}{3}$. This is strictly more informative than the winner, since it tells you which values are peaks and not merely how many. It ranks second only because the circle device has to be justified and the winner needs no device at all.

5. **Linearity of expectation over the positions.** *Cue:* the statistic is a sum of conditions each involving at most three adjacent entries. *Circuit:* indicator sum plus local pattern uniformity. Three probabilities, one sum, three lines. This is the ideal route: no device, no case split beyond the two ends, no recursion, and every step is forced by the shape of the definition.

The ideal solution

Let π be chosen uniformly at random from the $n!$ permutations of S, and for $k \in S$ let I_k be the indicator of the event that π has a local maximum at k. The number of local maxima is $X = I_1 + I_2 + \cdots + I_n$, and the average asked for is $\mathrm{E}[X]$. Expectation is linear on any finite collection of random variables, with no independence required, so

$$\mathrm{E}[X] = \sum_{k=1}^{n} \mathrm{E}[I_k] = \sum_{k=1}^{n} \mathrm{P}(\pi \text{ has a local maximum at } k).$$

Everything now rests on one fact about uniform permutations.

Lemma 20.4.1. *Fix positions $i_1 < i_2 < \cdots < i_m$ in S. If π is uniform on the permutations of S, then the relative order of $\pi(i_1), \dots, \pi(i_m)$ is uniformly distributed over the $m!$ possible orderings.*

Proof. For τ a permutation of $\{1, \dots, m\}$, define Φ_τ on permutations of S by $(\Phi_\tau \pi)(i_j) = \pi(i_{\tau(j)})$ for $j = 1, \dots, m$ and $(\Phi_\tau \pi)(x) = \pi(x)$ for every other x. Then Φ_τ permutes the values sitting in the chosen positions and fixes all other values, so it maps permutations of S to permutations of S, and $\Phi_{\tau^{-1}}$ is its inverse. Hence Φ_τ is a bijection. It sends the set of π whose chosen entries have relative order p bijectively onto the set of π whose chosen entries have relative order $\tau \cdot p$. The $m!$ possible relative orders therefore label $m!$ equinumerous classes which partition the $n!$ permutations, so each has probability $1/m!$. □

Apply the lemma three times.

For $k = 1$ the condition is $\pi(1) > \pi(2)$, a statement about the relative order of the entries in the two positions $1, 2$. By the lemma with $m = 2$ the two orders are equally likely, so $\mathrm{P}(I_1 = 1) = \frac{1}{2}$. For $k = n$ the condition is $\pi(n-1) < \pi(n)$, again a statement about two positions, so $\mathrm{P}(I_n = 1) = \frac{1}{2}$. These two events are distinct because $n > 1$.

For $1 < k < n$ the condition is $\pi(k-1) < \pi(k)$ and $\pi(k) > \pi(k+1)$, that is, $\pi(k)$ is the largest of the three entries in positions $k-1, k, k+1$. By the lemma with $m = 3$ the six relative orders are equally likely, and exactly two of them place the middle entry largest (the remaining two entries may be in either order). Hence $\mathrm{P}(I_k = 1) = \frac{2}{6} = \frac{1}{3}$.

There are two boundary positions and $n-2$ interior positions, and $n-2 \geq 0$ since $n > 1$, so

$$\mathrm{E}[X] = 2 \cdot \frac{1}{2} + (n-2) \cdot \frac{1}{3} = 1 + \frac{n-2}{3} = \boxed{\frac{n+1}{3}}.$$

The degenerate case is $n = 2$, where there are no interior positions and the formula reads $\mathrm{E}[X] = 1$; both permutations of $\{1, 2\}$ have exactly one local maximum, so this is correct. As a further check, $n = 3$ gives $\frac{4}{3}$, and the six permutations of $\{1, 2, 3\}$ have $1, 1, 2, 1, 2, 1$ local maxima, total 8, mean $\frac{8}{6} = \frac{4}{3}$.

Layer 1: WHAT

Block 1: read "average number of" as "expected value of a count" and write $X = \sum_k I_k$.

Block 2: observe that I_k depends only on the relative order of at most three entries in fixed positions.

Block 3: state and prove the local pattern uniformity lemma, which converts each $\mathrm{P}(I_k = 1)$ into a count of orderings.

Block 4: evaluate the three probabilities: $\frac{1}{2}$ at each end, $\frac{1}{3}$ in the interior.

Block 5: add up, confirm the boundary case $n = 2$, box $\frac{n+1}{3}$.

The nominal route runs like this: read "average", decide you need the distribution of the number of peaks, start classifying permutations by peak count, notice that adjacent peaks are forbidden so the classification involves compositions of n, and disappear into peak polynomials. The bifurcation point is precisely the sentence after "I want the average". The zombie writes "so I need $\mathrm{P}(X = j)$ for each j". You write "so I need $\mathrm{E}[X]$, and X is a sum, and expectation of a sum is the sum of expectations". That single sentence is the whole problem. Everything downstream is forced.

Layer 2: HOW

Block 1. Cue. The question says "average, over all permutations", and the quantity being averaged is a number of things. A number of things is always a sum of indicators, one per thing that might occur. **Why natural.** The definition of the statistic is already a list of n separate conditions, one per position k. The question has handed you the decomposition; you only have to accept it. Refusing to accept it and instead treating X as a single opaque number is what forces the distribution route. **Link to the next block.** Once X is a sum, linearity of expectation applies, and the problem becomes n separate one position questions.

Block 2. Cue. Each condition in the definition mentions only $\pi(k-1), \pi(k), \pi(k+1)$, and the comparisons are all inequalities between values, never the values themselves. **Why natural.** Because only inequalities appear, the event depends on the permutation solely through the relative order of those two or three entries. The actual sizes are irrelevant, which is the standard signal that a symmetry argument will finish the job. **Link to the next block.** If the relative order is all that matters, you now need to know the distribution of that relative order, which is the next block.

Block 3. Cue. A uniform permutation has a symmetry group acting on it: you may permute the values in any fixed set of positions and stay inside the set of permutations. **Why natural.** This is the definition level reason. A permutation of S is a bijection $S \to S$; rearranging the values assigned to a fixed set of positions produces another bijection, so the rearrangement is a bijection on the sample

space and therefore preserves the uniform measure. There is nothing probabilistic happening here at all: it is a counting statement dressed up. **Link to the next block.** With the lemma, each probability becomes "how many of the $m!$ orderings satisfy the condition", which is immediate.

Block 4. Cue. Two of the conditions involve two positions and $n-2$ involve three. **Why natural.** Counting orderings: one of two puts the first entry higher, so $\frac{1}{2}$; two of six put the middle entry highest, so $\frac{1}{3}$. Notice that the ends are not a special case of the mathematics, only a truncation of the window: the same lemma with a smaller m. **Link to the next block.** The three probabilities are constants, so the sum over k is a count of positions of each type.

Block 5. Cue. The sum has two terms of one kind and $n-2$ of another. **Why natural.** The arithmetic is trivial, but the write up must state that $n > 1$ guarantees positions 1 and n are distinct and that $n-2 \geq 0$, otherwise the count of interior positions is not justified. A grader looks for exactly this sentence. **Link to the next block.** Nothing follows; you have the answer. Spend the remaining ten seconds checking $n = 2$ and $n = 3$ by hand.

Layer 3: WHY

The mathematical truth underneath is that expectation is a linear functional on the vector space of real valued functions on a finite sample space, and linearity has no hypothesis. Independence is a hypothesis you need to multiply expectations, never to add them. Most students carry an unexamined belief that "you can only split $\mathrm{E}[X+Y]$ when X and Y are independent", absorbed from variance calculations where independence really is needed. Kill that belief now. Here the indicators are as dependent as they could be, since $I_k I_{k+1} = 0$ always, and the computation does not notice.

The second truth is that the average of a count is a double count. Write the average as

$$\frac{1}{n!}\sum_{\pi} X(\pi) = \frac{1}{n!}\sum_{\pi}\sum_{k} I_k(\pi) = \frac{1}{n!}\sum_{k}\sum_{\pi} I_k(\pi),$$

and the exchange of the two finite sums is the entire method. Expectation language is a convenience; the content is Fubini for finite sums, that is, counting the pairs (π, k) such that π has a peak at k in two orders. Whenever a problem asks for a total or an average over a symmetric family, ask which of the two summation orders is cheap. Here summing over π first is cheap because the inner condition is local; summing over k first is expensive because it asks you to understand a whole permutation at once.

The third truth is exchangeability. A uniform random permutation restricted to any fixed window is a uniform random pattern. That is why the answer for interior positions is $\frac{1}{3}$ and not something depending on k: no position is distinguished except by how much of its window has been cut off by the ends of the row. Recognising that the only thing distinguishing $k = 1$ from $k = 7$ is a truncated window, and not a different rule, is the discernment being trained here.

How do you train the discernment? Build the habit of asking, of every counting or averaging problem, "is the quantity a sum of local pieces?" If yes, linearity finishes it, whatever the dependence. If no, ask whether it can be made into one. The examiner's nudge in this problem was to define the statistic as a list of three cases rather than as a single global property; that presentation is a guiding light pointing at the indicator decomposition. When a definition arrives as a list of local conditions, the author is telling you to sum indicators.

Revolving concepts

Linearity of expectation. For random variables $X_1, \ldots, X_m$ on a common probability space with finite expectations, $\mathrm{E}[\sum X_i] = \sum \mathrm{E}[X_i]$, and $\mathrm{E}[cX] = c\,\mathrm{E}[X]$. No independence, no identical dis-

tribution, no positivity. The orbiting results are Markov's inequality (from E alone you get tail bounds), the first moment method (if $\mathrm{E}[X] < 1$ and X is a nonnegative integer, then $\mathrm{P}(X = 0) > 0$, which proves existence results), and the fact that variance is not linear without independence, since $\mathrm{Var}(X + Y) = \mathrm{Var}\, X + \mathrm{Var}\, Y + 2\,\mathrm{Cov}(X, Y)$. See Book 1, field: Probability, topic: linearity of expectation and indicators.

Indicator random variables. $\mathbf{1}[A]$ has $\mathrm{E}[\mathbf{1}[A]] = \mathrm{P}(A)$. Every counting statistic is a sum of indicators; the art is choosing what to index by. Here indexing by position beat indexing by value only on ink, not on power.

Permutation statistics. A *descent* of π is a $k < n$ with $\pi(k) > \pi(k+1)$; a *peak* is what this problem calls a local maximum; a *record* or left to right maximum is a k with $\pi(k) > \pi(j)$ for all $j < k$. The same three line method gives: expected descents $= (n-1)/2$, expected records $= H_n = \sum_{i=1}^{n} 1/i$, expected fixed points $= 1$, expected cycles $= H_n$. Note how the record calculation uses the lemma with $m = k$ rather than $m \le 3$: $\mathrm{P}(\text{record at } k) = 1/k$ because the largest of the first k entries is equally likely to sit in any of those k positions. See Book 1, field: Combinatorics, topic: permutation statistics.

The distributions behind the means, and the recursion. The number of permutations of $[n]$ with k descents is the Eulerian number $A(n, k)$, and it satisfies the recursion

$$A(n,k) = (k+1)A(n-1,k) + (n-k)A(n-1,k-1), \qquad A(1,0) = 1,$$

obtained by inserting the value n into a permutation of $[n-1]$ and asking whether the insertion site creates a new descent. The generalised form of this move: if a statistic st on permutations changes in a controlled way when the largest value is inserted or deleted, then the generating function $P_n(t) = \sum_{\pi} t^{\mathrm{st}(\pi)}$ satisfies a recursion in n with polynomial coefficients in t and ∂_t; for descents this is $P_n(t) = ntP_{n-1}(t) + t(1-t)P'_{n-1}(t)$. The peak analogue exists but needs a two variable refinement to handle the truncated windows at the ends, which is exactly the obstruction that sank approach 3 above. The lesson generalises: a recursion built by inserting the largest element is the default tool for the full distribution of a permutation statistic, and it is the wrong tool when only the mean is wanted. See Book 1, field: Combinatorics, topic: Eulerian numbers and insertion recursions.

Splitting at the maximum. The other standard recursion for permutation problems: condition on the position j of the value n, giving $f_n = \sum_{j=1}^{n} \binom{n-1}{j-1}(\text{something}(j-1) \cdot \text{something}(n-j))$, a binomial convolution whose natural transform is the exponential generating function $\sum f_n x^n/n!$. Binomial convolution corresponds to multiplication of exponential generating functions; that correspondence is the single most useful fact about labelled counting.

Circuit Bank

- **WHEN** a problem asks for the average, expected, or total value of a count over a finite symmetric family **DO** write the count as a sum of indicators, one per candidate object, and take expectations term by term **BECAUSE** expectation is linear with no independence hypothesis, so the dependence structure of the indicators is irrelevant to the mean
- **WHEN** an event about a uniform random permutation is stated purely as inequalities among entries in fixed positions **DO** replace it by a count of relative orderings: with m positions involved, each of the $m!$ patterns has probability $1/m!$ **BECAUSE** permuting the values in a fixed set of positions is a bijection of the set of permutations, so it preserves the uniform measure
- **WHEN** a locally defined statistic has different rules at the first and last positions **DO** treat the ends as the same rule with a truncated window, that is, the same lemma with a smaller m **BECAUSE** the boundary is not a new phenomenon, it is a window running off the edge of the row, so the mathematics is identical with fewer entries

- **WHEN** you catch yourself computing a distribution in order to extract its mean **DO** stop and ask whether the quantity is a sum of local pieces **BECAUSE** the distribution is almost always a strictly harder object than the mean, and the extra work earns nothing on the paper
- **WHEN** you have an answer that is a formula in n **DO** test it on the smallest legal n and on one more case by hand **BECAUSE** formulas of this shape fail exactly at the degenerate boundary, here $n = 2$, and the check costs twenty seconds

Backtesting

1. First useful cue: the phrase "average number of" applied to a count over a finite family. That phrase alone forces $X = \sum_k I_k$ and $\mathrm{E}[X] = \sum_k \mathrm{P}(I_k = 1)$.
2. Method the expression suggested: the definition arrived as three local conditions indexed by position, which is an explicit invitation to index the indicators by position rather than by value.
3. Where you would hesitate, and the thought to reinforce: the hesitation is "the peak events are dependent, so surely I cannot just add". Reinforce: independence is required to multiply expectations, never to add them. Say it out loud once per week until it is reflex.
4. The trap the question sets: the three case definition looks like it demands three separate arguments, and the example with $n = 5$ tempts you into enumeration. The three cases are one argument with $m = 2, 3, 2$.
5. What makes you recognise it faster next time: the shape "statistic defined by a sliding window over a random arrangement". Peaks, descents, ascents, records, runs, matching pairs, adjacent equal cards, all of them fall to the same two lines.
6. The reusable decision rule: count of local events $\Rightarrow$ sum of indicators $\Rightarrow$ local pattern uniformity $\Rightarrow$ arithmetic. Never touch the distribution.

Mirror drills

1. For a uniform random permutation of $\{1, \ldots, n\}$, find the expected number of descents, that is, of indices k with $1 \le k < n$ and $\pi(k) > \pi(k+1)$. *Answer:* each of the $n-1$ indices contributes $\frac{1}{2}$ by the lemma with $m = 2$, so the mean is $\frac{n-1}{2}$.
2. For a uniform random permutation of $\{1, \ldots, n\}$, find the expected number of records (indices k with $\pi(k)$ larger than every earlier entry). *Answer:* the largest of the first k entries is equally likely to be in any of those k positions, so $\mathrm{P}(\text{record at } k) = 1/k$ and the mean is $H_n = 1 + \frac{1}{2} + \cdots + \frac{1}{n}$.
3. Arrange n distinct real numbers uniformly at random in the n positions of a circle. Find the expected number of positions that hold a local maximum, meaning a value larger than both of its circular neighbours. *Answer:* every position now has a full window of three and no position is truncated, so each contributes $\frac{1}{3}$ and the mean is $n/3$. Compare with $\frac{n+1}{3}$ for the row and see that cutting the circle open is worth exactly one third of a peak.

20.5 A5. Ratio of symmetric functions of equally spaced tangents

Let n be a positive odd integer and let θ be a real number such that θ/π is irrational. Set $a_k = \tan(\theta + k\pi/n)$, $k = 1, 2, \ldots, n$. Prove that

$$\frac{a_1 + a_2 + \cdots + a_n}{a_1 a_2 \cdots a_n}$$

is an integer, and determine its value.

Read it out loud

A sum divided by a product, over a family of n numbers. Say that aloud and the translation is automatic: this is e_1/e_n, the first elementary symmetric function of $a_1, \ldots, a_n$ divided by the last. Nobody asks for e_1/e_n unless they intend you to use Vieta, and Vieta needs one thing: the polynomial whose roots are exactly $a_1, \ldots, a_n$. So the problem is not "evaluate these tangents". The problem is "find the degree n polynomial that these n tangents satisfy". That reroute is the entire question, and it should be on your page inside thirty seconds.

Next, read the indexing. The angles $\theta + k\pi/n$ for $k = 1, \ldots, n$ form an arithmetic progression with common difference π/n, and tan has period π. Multiply an angle by n and the progression collapses: $n(\theta + k\pi/n) = n\theta + k\pi$, which is $n\theta$ modulo π for every single k. In other words all n of these angles have the same n-fold multiple modulo π, so all n numbers a_k satisfy the same equation $\tan(n \arctan x) = \tan(n\theta)$. That is the polynomial you are looking for, and it exists before you have written a word of trigonometry. Common difference π/n is the guiding light: it is planted so that the n-th multiple collapses, which is the same phenomenon as n-th roots of unity.

The fields wired in are complex numbers via de Moivre, polynomials and Vieta, roots of unity, and one Mobius map. The hypotheses are doing precise work and you must say what: n odd controls the parity signs and guarantees the polynomial really has degree n; θ/π irrational guarantees that no a_k is infinite (no angle hits $\pi/2$ modulo π), that no a_k is zero (so the denominator of the stated expression is nonzero), and that a certain root of unity factor is not degenerate. A hypothesis you cannot account for is a hypothesis you have not understood.

Finally, note the shape of the demand: "prove it is an integer, and determine its value". Being an integer is not a separate task; you will produce the value and it will visibly be $\pm n$. The mild surprise is that the answer does not depend on θ at all, and a full marks write up should explain why that is structural rather than accidental.

Approaches, ranked worst to best

1. **Expand each tangent with the addition formula and try to sum.** *Cue:* $\tan(\theta + \phi)$ is a formula you know. *Circuit:* none; this is grinding. You write $a_k = \frac{\tan\theta + \tan(k\pi/n)}{1 - \tan\theta\tan(k\pi/n)}$ and then stare at a sum of n fractions with different denominators. There is no route from here that does not amount to reconstructing the polynomial anyway, and you will have spent a page. Last place.

2. **Compute small cases and guess.** *Cue:* the answer is a single value, so it is guessable. *Circuit:* pattern extraction. $n = 1$ gives 1, $n = 3$ gives -3, $n = 5$ gives 5, $n = 7$ gives -7. So the answer is $(-1)^{(n-1)/2} n$. Do this, in your head or on scrap, because it tells you the target and it catches sign errors later. It is not a proof and there is no induction step available: passing from n to $n + 2$ changes the entire grid of angles, so nothing is inherited. Insurance only.

3. **Real polynomial route through the tangent multiple angle formula.** *Cue:* $\tan(n\phi)$ is a rational function of $\tan\phi$ with binomial coefficients. *Circuit:* de Moivre, then Vieta. From $(\cos\phi + i\sin\phi)^n$ you get

$$\tan(n\phi) = \frac{\binom{n}{1}x - \binom{n}{3}x^3 + \cdots}{1 - \binom{n}{2}x^2 + \cdots}, \qquad x = \tan\phi,$$

so the a_k are the roots of $\mathrm{Num}(x) - \tan(n\theta)\,\mathrm{Den}(x) = 0$, a polynomial of degree n for n odd. Vieta then gives the answer. This is completely correct and costs perhaps twice the ink of the winner, because you carry two binomial sums and must track the alternating signs in both. Rank it third: right idea, clumsy packaging.

4. **Collapse the products directly.** *Cue:* a product over an arithmetic progression of angles is a classical root of unity product. *Circuit:* the factorisation $\prod_{k=0}^{n-1}(1 - w\zeta^k) = 1 - w^n$. The identities $\prod_{k=0}^{n-1} 2\sin(\phi + k\pi/n) = 2\sin(n\phi)$ and, for n odd, $\prod_{k=0}^{n-1} 2\cos(\phi + k\pi/n) = (-1)^{(n-1)/2} 2\cos(n\phi)$ give the denominator immediately as $(-1)^{(n-1)/2}\tan(n\theta)$, and taking the logarithmic derivative of the cosine identity gives the numerator as $n\tan(n\theta)$. Very short if you own the two identities. It ranks second only because it needs two separate facts plus a differentiation, where the winner needs one object.

5. **Cayley transform: one polynomial, two coefficients.** *Cue:* tangent plus equally spaced angles plus symmetric functions. *Circuit:* $x \mapsto (1+ix)/(1-ix)$ turns angle addition into multiplication, so the a_k become the n-th roots of a fixed number. Build $Q_n(x) = (1+ix)^n - \omega(1-ix)^n$ with $\omega = e^{2in\theta}$, read off two coefficients, and watch the factor $1-\omega$ cancel. Shortest ink, no case analysis, and it delivers every elementary symmetric function of the a_k as a by product rather than just the two you were asked for. This is the ideal route.

The ideal solution

Write $\phi_k = \theta + k\pi/n$ for $k = 1, \ldots, n$, and put $\omega = e^{2in\theta}$.

Step 0: the expression is well defined. If some ϕ_k were an odd multiple of $\pi/2$ then $\theta/\pi = \frac{1}{2} + m - k/n$ for an integer m, which is rational; so every a_k is a finite real number. If some a_k were 0 then $\phi_k \in \pi\mathbb{Z}$ and again θ/π would be rational; so $a_1 a_2 \cdots a_n \neq 0$ and the quotient makes sense. Likewise $\omega \neq 1$, since $\omega = 1$ forces $n\theta \in \pi\mathbb{Z}$, and $\omega \neq -1$, since $\omega = -1$ forces $\theta/\pi = (2m+1)/(2n)$. Both would make θ/π rational. Finally the ϕ_k are pairwise incongruent modulo π, because $\phi_k - \phi_j = (k-j)\pi/n$ is a multiple of π only when $n \mid k-j$, impossible for distinct $j, k \in \{1, \ldots, n\}$; since tan is injective on any interval of length π where it is defined, the numbers $a_1, \ldots, a_n$ are pairwise distinct.

Step 1: turn tangent into a point on the unit circle. For any ϕ with $\cos\phi \neq 0$,

$$1 + i\tan\phi = \frac{\cos\phi + i\sin\phi}{\cos\phi} = \frac{e^{i\phi}}{\cos\phi}, \qquad 1 - i\tan\phi = \frac{e^{-i\phi}}{\cos\phi},$$

which is nothing more than dividing the polar form of $e^{i\phi}$ by its real part. Dividing the two,

$$\frac{1 + i\tan\phi}{1 - i\tan\phi} = e^{2i\phi}.$$

Step 2: the a_k are roots of one explicit polynomial. Apply Step 1 at $\phi = \phi_k$ and raise to the n-th power:

$$\left(\frac{1+ia_k}{1-ia_k}\right)^n = e^{2in\phi_k} = e^{2i(n\theta + k\pi)} = e^{2in\theta} = \omega.$$

Clearing the denominator (legitimate since $1 - ia_k \neq 0$ for real a_k),

$$Q_n(a_k) = 0, \qquad \text{where } Q_n(x) := (1+ix)^n - \omega(1-ix)^n.$$

The coefficient of x^n in Q_n is $i^n - \omega(-i)^n = i^n(1+\omega)$, using $(-i)^n = -i^n$ for n odd; this is nonzero because $\omega \neq -1$. So Q_n has degree exactly n, and since $a_1, \ldots, a_n$ are n distinct roots of it, they are precisely its roots.

Step 3: Vieta. Write $Q_n(x) = c_n x^n + \cdots + c_1 x + c_0$. Then

$$a_1 + \cdots + a_n = -\frac{c_{n-1}}{c_n}, \qquad a_1 a_2 \cdots a_n = (-1)^n \frac{c_0}{c_n} = -\frac{c_0}{c_n},$$

the last equality because n is odd. Dividing, the factor c_n cancels and

$$\frac{a_1 + \cdots + a_n}{a_1 a_2 \cdots a_n} = \frac{c_{n-1}}{c_0}.$$

Now read off the two coefficients from the binomial expansions. Since $n-1$ is even, $(-i)^{n-1} = i^{n-1}$, so

$$c_{n-1} = \binom{n}{n-1} i^{n-1} - \omega \binom{n}{n-1} (-i)^{n-1} = n\, i^{n-1}(1-\omega), \qquad c_0 = 1 - \omega.$$

Step 4: conclude. Since $\omega \neq 1$ the factor $1-\omega$ is nonzero and cancels:

$$\frac{a_1 + \cdots + a_n}{a_1 a_2 \cdots a_n} = n\, i^{n-1} = n\left(i^2\right)^{(n-1)/2} = \boxed{(-1)^{(n-1)/2}\, n}$$

which is n when $n \equiv 1 \pmod 4$ and $-n$ when $n \equiv 3 \pmod 4$. In particular it is an integer, and it does not depend on θ.

By-products worth banking. Since $c_n = i^n(1+\omega)$, the same two lines give the individual values

$$a_1 + \cdots + a_n = n \tan(n\theta), \qquad a_1 \cdots a_n = (-1)^{(n-1)/2} \tan(n\theta),$$

using $\frac{1-\omega}{1+\omega} = \frac{e^{-in\theta} - e^{in\theta}}{e^{-in\theta} + e^{in\theta}} = -i\tan(n\theta)$. More generally $c_j = \binom{n}{j} i^j \left(1 - \omega(-1)^j\right)$, so the elementary symmetric functions of the a_k are

$$e_{2r} = (-1)^r \binom{n}{2r}, \qquad e_{2r+1} = (-1)^r \binom{n}{2r+1} \tan(n\theta).$$

Every even one is a fixed integer independent of θ; every odd one is an integer multiple of $\tan(n\theta)$. That is the real content of the problem, and the quotient asked for is the cheapest visible consequence.

Layer 1: WHAT

Block 1: read "sum over product" as e_1/e_n, hence resolve to find the polynomial with roots $a_1, \ldots, a_n$.

Block 2: notice that the common difference π/n makes $n\phi_k \equiv n\theta \pmod \pi$ for every k, so all n numbers satisfy one common equation.

Block 3: convert tan into a Mobius function of $e^{2i\phi}$ by dividing the polar form of $e^{i\phi}$ by $\cos\phi$.

Block 4: raise to the n-th power, clear denominators, obtain $Q_n(x) = (1+ix)^n - \omega(1-ix)^n$; check degree n and distinctness of roots to know these are all of them.

Block 5: Vieta, note c_n cancels in the quotient, extract c_{n-1} and c_0.

Block 6: see the common factor $1-\omega$ cancel, hence the θ independence; finish with $i^{n-1} = (-1)^{(n-1)/2}$.

The nominal route: expand $\tan(\theta + k\pi/n)$ with the addition formula and attempt to sum and multiply n fractions. The bifurcation point is the very first decision after reading the expression. The zombie asks "what is a_k?". You ask "what equation do all the a_k satisfy at once?". Symmetric functions never want the members of a family, only the family's defining equation, and the question told you it wants symmetric functions by presenting exactly e_1 over e_n.

Layer 2: HOW

Block 1. Cue. A quotient whose numerator is the sum of all the objects and whose denominator is the product of all the objects. **Why natural.** e_1 and e_n are, by definition, coefficients of the monic polynomial with those roots, up to sign. So the quotient is a ratio of two coefficients of one object you have not yet built, and building that object is strictly easier than evaluating n tangents. **Link to the next block.** Building the polynomial requires an equation satisfied by every a_k, so look at what the index k does.

Block 2. **Cue.** The angles form an arithmetic progression with common difference exactly π/n, and the function has period π. **Why natural.** Multiplying by n turns the increment $k\pi/n$ into $k\pi$, which is invisible to tan. This is the same collapse that makes n-th roots of unity useful: an equally spaced family becomes a single value after taking the n-th power. The designer put π/n there for exactly this reason, and n odd is there so that the collapse works with the right parity. **Link to the next block.** Now you know the common equation in the form $\tan(n \arctan x) = \tan(n\theta)$; you need to write it as a polynomial without dragging in the multiple angle expansion by hand.

Block 3. **Cue.** You want $e^{2i\phi}$, and $\tan\phi$ is a ratio of the imaginary and real parts of $e^{i\phi}$. **Why natural.** Divide $e^{i\phi} = \cos\phi + i\sin\phi$ through by $\cos\phi$: that single division produces $1 + i\tan\phi = e^{i\phi}/\cos\phi$. There is nothing to invent. The conjugate gives $1 - i\tan\phi$, the unwanted $\sec\phi$ cancels in the ratio, and you land on the Cayley transform $x \mapsto (1+ix)/(1-ix)$. **Link to the next block.** The Cayley transform sends the real line to the unit circle and sends a_k to $e^{2i\phi_k}$, so the collapse of Block 2 becomes the statement that these images are the n-th roots of ω.

Block 4. **Cue.** The images satisfy $z^n = \omega$; you want an equation in x, not z. **Why natural.** Substitute $z = (1+ix)/(1-ix)$ into $z^n - \omega = 0$ and multiply by $(1-ix)^n$. That is the standard way to turn a Mobius substitution into a polynomial identity, and it is safe because $1 - ix$ never vanishes for real x. The degree check and the distinctness check are not decoration: without them you know only that Q_n vanishes at the a_k, not that it has no other roots, and Vieta needs all the roots. **Link to the next block.** With all roots known, the coefficients are the symmetric functions.

Block 5. **Cue.** You need only two coefficients, and both sit at the ends of the binomial expansion. **Why natural.** c_{n-1} and c_0 are the cheapest coefficients in any binomial expansion, and the quotient you want kills c_n automatically since n is odd. That is why the write up never needs to evaluate ω or $\tan(n\theta)$ at all. **Link to the next block.** Extract them and compare.

Block 6. **Cue.** Both coefficients carry the factor $1 - \omega$. **Why natural.** This is the structural reason the answer is independent of θ: all of the θ dependence entered through the single scalar ω, and ω enters c_{n-1} and c_0 through the same factor. When a quotient is claimed to be parameter free, always locate the factor that cancels and name it. Then i^{n-1} is a square of i raised to an integer power because n is odd, giving the sign $(-1)^{(n-1)/2}$. **Link to the next block.** Done; state the two congruence cases explicitly since the problem said "determine its value".

Layer 3: WHY

The first truth: elementary symmetric functions are coefficients. If you are asked for any symmetric expression in a family of numbers, you should never compute the members. You should find the polynomial they satisfy. The cost of finding one polynomial is $O(1)$; the cost of evaluating n members is $O(n)$ and usually impossible in closed form. This is the same principle that makes Newton's identities useful, and it is the reason Vieta is not a piece of school trivia but a primary weapon.

The second truth: the Cayley transform is not a device pulled from the air, it is the map that diagonalises angle addition. Adding an angle to ϕ acts on $x = \tan\phi$ by the Mobius map $T(x) = \frac{x+t}{1-tx}$ where $t = \tan$ of the added angle. Solve $T(x) = x$ and you get $x^2 = -1$, so the fixed points are $\pm i$ for every t. A Mobius map is understood by conjugating it so that its fixed points go to 0 and ∞, whereupon it becomes plain multiplication $z \mapsto \lambda z$. The conjugating map that sends $i \mapsto 0$ and $-i \mapsto \infty$ is precisely $x \mapsto \frac{1+ix}{1-ix}$ up to a constant. So the substitution in Step 1 is forced by the structure of the problem: you are handed a family generated by repeated angle addition, and you

move to the coordinate in which angle addition is multiplication. Nothing here is a rabbit out of a hat, and if you ever feel it is, re-derive the fixed points and the feeling goes.

The third truth: the arithmetic progression of angles with step π/n is the tangent-world image of the n-th roots of unity. Under the Cayley transform the family $\{\phi + k\pi/n\}$ maps to $\{e^{2i\theta}\zeta^k\}$ with $\zeta = e^{2\pi i/n}$, a coset of the n-th roots of unity in the unit circle. Every classical identity about equally spaced angles, from $\prod_{k=1}^{n-1} 2\sin(k\pi/n) = n$ to the multiple angle formulas, is the single factorisation $\prod_{k=0}^{n-1}(X - \zeta^k) = X^n - 1$ wearing different clothes.

The discernment mechanism, then, is a two question filter. Question one: is the quantity requested a symmetric function of a family? If yes, hunt for the family's polynomial. Question two: is the family generated by a group action (translation of an angle, multiplication by a root of unity, iteration of a map)? If yes, move to coordinates where the action is multiplication, and the polynomial writes itself. Train it by re-deriving, from scratch and without notes, the tangent multiple angle formula, the product formulas for $\prod \sin(\phi + k\pi/n)$, and the fixed points of the tangent addition map. Three derivations, once, and the circuit fires forever.

Revolving concepts

Elementary symmetric functions and Vieta. For monic $p(x) = \prod_{k=1}^{n}(x - a_k) = x^n - e_1x^{n-1} + e_2x^{n-2} - \cdots + (-1)^n e_n$, the coefficient of x^{n-m} is $(-1)^m e_m$. For a non-monic $\sum c_j x^j$, $e_m = (-1)^m c_{n-m}/c_n$. Orbiting results: Newton's identities linking power sums $p_m = \sum a_k^m$ to the e_m; the fundamental theorem of symmetric polynomials (every symmetric polynomial in the roots is a polynomial in the e_m with integer coefficients), which is what makes "it is an integer" predictable in advance. See Book 1, field: Polynomials, topic: symmetric functions and Vieta.

Roots of unity and the master factorisation. $\prod_{k=0}^{n-1}(X - \zeta^k) = X^n - 1$ with $\zeta = e^{2\pi i/n}$, equivalently $\prod_{k=0}^{n-1}(1 - w\zeta^k) = 1 - w^n$. From this single identity: $\prod_{k=0}^{n-1} 2\sin(\phi + k\pi/n) = 2\sin(n\phi)$ for all n, and $\prod_{k=0}^{n-1} 2\cos(\phi + k\pi/n) = (-1)^{(n-1)/2} 2\cos(n\phi)$ for n odd, hence $\prod_{k=0}^{n-1} \tan(\phi + k\pi/n) = (-1)^{(n-1)/2}\tan(n\phi)$, which is the denominator of this problem. Taking the logarithmic derivative of the cosine product converts it into the sum identity $\sum_{k=0}^{n-1} \tan(\phi + k\pi/n) = n\tan(n\phi)$, which is the numerator. Logarithmic differentiation is the standard bridge from a product identity to a sum identity, and you should reach for it every time you own a product formula and want a sum. See Book 1, field: Complex numbers, topic: roots of unity products.

The Cayley transform and Mobius maps. $C(x) = \frac{1+ix}{1-ix}$ is a bijection from $\mathbb{R} \cup \{\infty\}$ to the unit circle, with $C(\tan\phi) = e^{2i\phi}$, $C(i) = 0$, $C(-i) = \infty$. A Mobius map with two distinct fixed points is conjugate to $z \mapsto \lambda z$; a Mobius map with one fixed point is conjugate to $z \mapsto z + 1$. Conjugating to normal form is the universal way to iterate a Mobius map, and it subsumes the tangent addition formula.

de Moivre and the multiple angle recursion, generalised. Define $C_n(x), S_n(x)$ by $(1 + ix)^n = C_n(x) + iS_n(x)$. Then

$$\begin{pmatrix} C_{n+1} \\ S_{n+1} \end{pmatrix} = \begin{pmatrix} 1 & -x \\ x & 1 \end{pmatrix} \begin{pmatrix} C_n \\ S_n \end{pmatrix}, \qquad \begin{pmatrix} C_0 \\ S_0 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \end{pmatrix},$$

so $\tan(n\phi) = S_n(x)/C_n(x)$ with $x = \tan\phi$. This is the general shape of a two term linear recursion with constant matrix M: solve it by diagonalising M, whose eigenvalues here are $1 \pm ix$ with eigenvectors $(1, \mp i)$. The complex substitution $(1 \pm ix)^n$ used throughout this problem is nothing but that diagonalisation written out, and the same move solves every constant coefficient linear recursion: Fibonacci through φ and $\bar{\varphi}$, Chebyshev through $e^{\pm i\phi}$, and $\tan(n\phi)$ through $1 \pm ix$. Whenever a sequence is defined by applying the same linear map repeatedly, the general solution is a combination of λ_j^n over the eigenvalues λ_j, with polynomial-in-n corrections when eigenvalues repeat. See Book 1, field: Sequences and recurrences, topic: linear recurrences by diagonalisation.

Circuit Bank

- **WHEN** a problem asks for a symmetric expression in an indexed family (a sum, a product, a ratio of the two, or any e_m) **DO** stop evaluating the members and instead construct one polynomial having exactly that family as its roots, then read Vieta **BECAUSE** elementary symmetric functions are literally the coefficients, so one object answers every symmetric question at once
- **WHEN** the family is indexed by an arithmetic progression of angles with common difference π/n or $2\pi/n$ **DO** expect the n-th power or n-th multiple to collapse the family to a single value, and expect roots of unity **BECAUSE** $\prod_{k=0}^{n-1}(X-\zeta^k) = X^n - 1$ is the one identity behind every equally spaced angle formula
- **WHEN** you have tan and want algebraic structure **DO** write $1 + i\tan\phi = e^{i\phi}/\cos\phi$ and pass to $x \mapsto (1+ix)/(1-ix)$ **BECAUSE** that Mobius map sends the fixed points $\pm i$ of the tangent addition map to 0 and ∞, converting angle addition into plain multiplication
- **WHEN** an answer is claimed to be independent of a parameter **DO** identify the single algebraic factor carrying the parameter and show it cancels **BECAUSE** a cancellation you can name is a structural reason, whereas a cancellation you merely observe is an accident waiting to be a sign error
- **WHEN** the expression to be evaluated has a denominator built from the data, or a hypothesis you have not used **DO** spend two lines proving the denominator is nonzero and every object is finite, naming the hypothesis that guarantees it **BECAUSE** here θ/π irrational is exactly what forces $\tan(n\theta) \neq 0$, all a_k finite and nonzero, and $\omega \neq \pm 1$; a grader looks for those lines

Backtesting

1. First useful cue: the quotient is e_1/e_n for the family $a_1, \ldots, a_n$. Symmetric functions demand a polynomial, not an evaluation.
2. Method the expression suggested: common difference π/n in the angles plus period π in tan means all n numbers satisfy the single equation $\tan(n \arctan x) = \tan(n\theta)$; package it as $(1+ix)^n = \omega(1-ix)^n$.
3. Where you would hesitate, and the thought to reinforce: the hesitation is at $1 + i\tan\phi = e^{i\phi}\sec\phi$, which looks like an invented identity. Reinforce that it is one division: take $e^{i\phi} = \cos\phi + i\sin\phi$ and divide by $\cos\phi$. Derive it, never memorise it.
4. The trap the question sets: forgetting to check that Q_n has degree exactly n (so that $a_1, \ldots, a_n$ are all of its roots), and forgetting to use the irrationality hypothesis. Both are places to drop marks while having the right final number.
5. What makes you recognise it faster next time: the pairing "equally spaced angles" with "symmetric function". That pair always means one polynomial, and almost always means the Cayley transform if the function is tan, or $z + z^{-1}$ if it is cos.
6. The reusable decision rule: symmetric function of a family $\Rightarrow$ find the family's polynomial; family generated by a translation $\Rightarrow$ change to the coordinate where translation becomes multiplication.

Mirror drills

1. Let n be odd and $a_k = \tan(\theta + k\pi/n)$ as above. Show that $\sum_{i<j} a_i a_j = -\binom{n}{2}$, independent of θ. *Answer:* from $c_j = \binom{n}{j} i^j (1 - \omega(-1)^j)$, the coefficient c_{n-2} carries the factor $1+\omega$, the same factor as c_n, so $e_2 = c_{n-2}/c_n = \binom{n}{2} i^{-2} = -\binom{n}{2}$.

2. Prove $\prod_{k=1}^{n-1} 2\sin(k\pi/n) = n$ for every integer $n \geq 2$. *Answer:* put $X = 1$ in $\prod_{k=1}^{n-1}(X - \zeta^k) = (X^n - 1)/(X - 1)$ to get $\prod(1 - \zeta^k) = n$, then use $1 - e^{2i\alpha} = -2i\sin(\alpha)e^{i\alpha}$ and check that the phases multiply to 1.

3. Let n be odd. Prove $\sum_{k=0}^{n-1} \tan(\phi + k\pi/n) = n\tan(n\phi)$ directly. *Answer:* take log and differentiate the product identity $\prod_{k=0}^{n-1} 2\cos(\phi + k\pi/n) = (-1)^{(n-1)/2} 2\cos(n\phi)$, giving $-\sum \tan(\phi + k\pi/n) = -n\tan(n\phi)$.

20.6 A6. Sylvester four point problem in a disc

Four points are chosen uniformly and independently at random in the interior of a given circle. Find the probability that they are the vertices of a convex quadrilateral.

Read it out loud

Four independent uniform points in a disc, and a question about their configuration. Say the negation out loud, because the negation is the workable object: four points in general position in the plane either form a convex quadrilateral, or exactly one of them sits inside the triangle formed by the other three. There is no third possibility. So the question is not about quadrilaterals at all; it is about the probability that a random point lands inside a random triangle, and by symmetry that is four copies of one event.

Now push one step further. Conditional on the first three points, the probability that the fourth lands inside their triangle is exactly the triangle's area divided by the disc's area, because a uniform point hits a region with probability proportional to its area. Averaging over the first three converts a probability into an expectation of an area. That is the whole reduction, and it is worth saying in one sentence: the answer is $1 - 4\,\mathrm{E}[T]/|D|$ where T is the area of the triangle on three uniform points and $|D|$ is the area of the disc. Everything after that is a definite integral.

The fields wired in are convexity in the plane (the four point classification, which is the planar case of Radon's theorem), geometric probability (uniform measure, hitting probabilities, Fubini), and multivariable calculus (polar coordinates, a Jacobian, Wallis integrals). What is being tested is whether you can convert a configuration question into an area expectation, and then whether you can organise the resulting integral so that it is mechanical rather than a swamp of absolute values.

Be honest about where this problem sits. This is Sylvester's four point problem, posed in 1864, and the disc case is a named classical result. The reduction is genuinely available to you in the arena within two minutes. The evaluation of $\mathrm{E}[T]$ is a real computation that will take twenty to thirty minutes of careful work, and there is no route that avoids at least one nontrivial integral. A6 is where you find out whether your integration hygiene survives pressure. Within thirty seconds you should have written: no three collinear almost surely; exactly one of four configurations fails; $\mathrm{P}(\text{convex}) = 1 - 4\,\mathrm{E}[T]/\pi$ for the unit disc.

Approaches, ranked worst to best

1. **Integrate the convexity indicator over all eight coordinates.** *Cue:* the problem is a probability, so write the probability as an integral. *Circuit:* none; this is the zombie route. An eight dimensional integral whose integrand is the indicator of a configuration property, with no separable structure. There is no way to start. Last place, and it is last by a mile.

2. **Reduce to $\mathrm{E}[T]$, then integrate the area directly over three points.** *Cue:* after the reduction you need the mean of $\frac{1}{2}|(Q-P)\times(R-P)|$. *Circuit:* brute polar integration. In polar coordinates the area is $\frac{1}{2}\left|r_1 r_2 \sin(\alpha_1-\alpha_2) + r_2 r_3 \sin(\alpha_2-\alpha_3) + r_3 r_1 \sin(\alpha_3-\alpha_1)\right|$. That absolute value around a three term sum is the killer: you cannot integrate it without splitting into the cases where the bracket changes sign, and the sign regions are exactly the configurations you were trying to avoid thinking about. Correct in principle, unmanageable in practice.

3. **Signed area decomposition from the centre.** *Cue:* a triangle's area is a signed sum of the three triangles it makes with any chosen point, here the centre O. *Circuit:* $[PQR] = \pm[OPQ] \pm [OQR] \pm [ORP]$. Each of $[OPQ] = \frac{1}{2} r_1 r_2 \sin\angle POQ$ is easy to average, and the correction terms involve whether the three radial directions lie in a semicircle. The integrals are small; the sign bookkeeping is not. You must classify by semicircle position and by whether the middle point falls inside the triangle OPR, and get every sign right. This is a strong route with a treacherous middle, and treacherous middles are where you lose four points out of ten.

4. **Region decomposition plus the chord distance distribution.** *Cue:* the three lines PQ, QR, RP cut the disc into seven regions, and the union of the triangle with the three far regions is exactly the bad region for the fourth point. *Circuit:* comparing two expectations of the same quantity. Naming the expected areas A (triangle), B (three regions adjacent to a side), C (three far regions) gives $A + 3B + 3C = \pi$, and comparing expectations of the bad area gives $3C + A = 4A$, hence $A = C$. That identity is the same statement as Efron's identity and it is a real insight. But you still have to compute $B + 2A$, which requires the distribution of the distance from the centre to the line through two random points, namely $\frac{16}{3\pi}(1 - h^2)^{3/2}$, and deriving that is a chunk of work in its own right. Second place: elegant structure, expensive execution.
5. **Scale by the farthest point, then one double integral.** *Cue:* the disc is scale invariant, areas scale as the square of the radius, and the radial distribution of a uniform point is explicit. *Circuit:* condition on the largest of the three radii and rescale to a unit disc with one vertex on the boundary. After conditioning, the problem is the expected area of a triangle with one vertex fixed on the boundary and two uniform inside, and in polar coordinates centred at that boundary vertex the disc has the equation $r = 2\sin\theta$, which makes both radial integrals into single powers. No signs, no case analysis, one double integral in θ and θ' that reduces entirely to Wallis integrals. This is the ideal route: every step is mechanical after one structural idea.

The ideal solution

By scale invariance take the circle to have radius 1; write D for the open unit disc, O for its centre, $|D| = \pi$, and $[XYZ]$ for the area of triangle XYZ. Let P, Q, R, S be independent and uniform on D.

Step 1: reduce to the expected area of a triangle.

Lemma 20.6.1. *Let P, Q, R, S be four points in the plane, no three collinear. Then either they are the vertices of a convex quadrilateral, or exactly one of them lies in the interior of the triangle formed by the other three, and not both.*

Proof. Consider the convex hull H of the four points. Since no three are collinear, H is either a quadrilateral or a triangle. If H is a quadrilateral, all four points are vertices of it and they form a convex quadrilateral. If H is a triangle, its three vertices are three of the points and the fourth lies in H; it is not on the boundary, since being on an edge would make three of the points collinear, so it lies in the interior. Exactly one point is omitted from the vertex set in that case, so the two alternatives are exclusive and the interior point is unique. □

Three of four independent uniform points are collinear with probability zero (given two of them, the third must land on a line, a null set), so we may work on the complement of a null event. The four events "S is inside triangle PQR", "R is inside PQS", and so on, are mutually exclusive by the lemma and have equal probability by symmetry of the four points. Hence

$$\mathrm{P}(\text{convex}) = 1 - 4\ \mathrm{P}\big(S \in \triangle PQR\big).$$

Conditioning on P, Q, R and using that S is uniform on D independently of them,

$$\mathrm{P}\big(S \in \triangle PQR\big) = \mathrm{E}\left[\frac{[PQR]}{\pi}\right] = \frac{\mathrm{E}[T]}{\pi}, \qquad T := [PQR].$$

So the whole problem is the value of $\mathrm{E}[T]$, and

$$\mathrm{P}(\text{convex}) = 1 - \frac{4\ \mathrm{E}[T]}{\pi}.$$

Step 2: condition on the farthest of the three points and rescale.

Let X denote the expected area of a triangle with one vertex fixed at a point of the unit circle and the other two independent and uniform on the unit disc. (By rotational symmetry this does not depend on which boundary point is fixed.)

For a uniform point of D, $\mathrm{P}(|OP| \le r) = r^2$, so $|OP|$ has density $2r$ on $[0,1]$. Ties among $|OP|, |OQ|, |OR|$ have probability zero, so by symmetry

$$\mathrm{E}[T] = 3\,\mathrm{E}\big[T \cdot \mathbf{1}[|OR| > |OP|,\ |OR| > |OQ|]\big].$$

Condition on $|OR| = c$. Given this, the direction of R is uniform on the circle and independent of c, by rotational invariance of the uniform measure on D. The event $\{|OP| \le c,\ |OQ| \le c\}$ has probability $c^2 \cdot c^2 = c^4$, and conditionally on it P and Q are independent and uniform on the disc of radius c, because conditioning a uniform distribution on a subregion returns the uniform distribution on that subregion. Rescaling that whole picture by the factor $1/c$ maps it to the unit disc with one vertex on the unit circle and two uniform interior points, and areas are multiplied by c^{-2}. Therefore the conditional expectation of T on this event is $c^2 X$, and

$$\mathrm{E}[T] = 3\int_0^1 2c \cdot c^4 \cdot c^2 X\, dc = 6X\int_0^1 c^7\, dc = \frac{3X}{4}.$$

Step 3: compute X in polar coordinates centred at the boundary vertex.

Put the fixed vertex V at the origin of a polar system and the centre of the disc at the point $(0,1)$, so that the unit circle has polar equation

$$r^2 - 2r\sin\theta = 0, \qquad \text{that is} \qquad r = 2\sin\theta, \quad \theta \in [0,\pi],$$

and the disc is $\{(r,\theta) : 0 \le \theta \le \pi,\ 0 \le r \le 2\sin\theta\}$. A uniform point of the disc has density $\frac{1}{\pi} r\, dr\, d\theta$ in these coordinates. If $P = (\rho,\theta)$ and $Q = (\rho',\theta')$ then the angle at V between VP and VQ is $|\theta - \theta'| \in [0,\pi]$, so

$$[VPQ] = \tfrac{1}{2}\rho\rho' \sin|\theta - \theta'|.$$

Hence

$$X = \frac{1}{2\pi^2}\int_0^\pi\int_0^\pi \sin|\theta-\theta'| \left(\int_0^{2\sin\theta} \rho^2 d\rho\right)\left(\int_0^{2\sin\theta'} \rho'^2 d\rho'\right) d\theta\, d\theta'.$$

Each radial integral is $\frac{8}{3}\sin^3$, so

$$X = \frac{1}{2\pi^2}\cdot\frac{64}{9}\int_0^\pi\int_0^\pi \sin^3\theta \sin^3\theta' \sin|\theta-\theta'|\, d\theta'\, d\theta = \frac{64}{9\pi^2}\, I, \quad I := \int_0^\pi\int_0^\theta \sin^3\theta \sin^3\theta' \sin(\theta-\theta')\, d\theta'\, d\theta,$$

the last step using the symmetry of the integrand in $\theta \leftrightarrow \theta'$ to fold the square onto the triangle $\theta' < \theta$, where $|\theta - \theta'| = \theta - \theta'$.

Expand $\sin(\theta-\theta') = \sin\theta\cos\theta' - \cos\theta\sin\theta'$ and integrate in θ' first, using $\int_0^\theta \sin^3\theta' \cos\theta'\, d\theta' = \frac{1}{4}\sin^4\theta$ and $\int_0^\theta \sin^4\theta'\, d\theta' = \frac{3\theta}{8} - \frac{\sin 2\theta}{4} + \frac{\sin 4\theta}{32}$:

$$I = \frac{1}{4}\int_0^\pi \sin^8\theta\, d\theta \;-\; \frac{3}{8}\int_0^\pi \theta\sin^3\theta\cos\theta\, d\theta \;+\; \frac{1}{4}\int_0^\pi \sin^3\theta\cos\theta\sin 2\theta\, d\theta \;-\; \frac{1}{32}\int_0^\pi \sin^3\theta\cos\theta\sin 4\theta\, d\theta.$$

Evaluate the four pieces. The Wallis values are $\int_0^\pi \sin^{2m}\theta\, d\theta = \pi\binom{2m}{m}4^{-m}$, giving $\int_0^\pi \sin^4 = \frac{3\pi}{8}$, $\int_0^\pi \sin^6 = \frac{5\pi}{16}$, $\int_0^\pi \sin^8 = \frac{35\pi}{128}$, hence also $\int_0^\pi \sin^4\cos^2 = \frac{3\pi}{8} - \frac{5\pi}{16} = \frac{\pi}{16}$ and $\int_0^\pi \sin^6\cos^2 = \frac{5\pi}{16} - \frac{35\pi}{128} = \frac{5\pi}{128}$. Then:

$$\int_0^\pi \theta\sin^3\theta\cos\theta\, d\theta = \Big[\theta\,\tfrac{\sin^4\theta}{4}\Big]_0^\pi - \frac{1}{4}\int_0^\pi \sin^4\theta\, d\theta = -\frac{3\pi}{32},$$

$$\int_0^\pi \sin^3\theta\cos\theta\sin 2\theta\, d\theta = 2\int_0^\pi \sin^4\theta\cos^2\theta\, d\theta = \frac{\pi}{8},$$

$$\int_0^\pi \sin^3\theta\cos\theta\sin 4\theta\,d\theta = 4\int_0^\pi \sin^4\theta\cos^2\theta\,d\theta - 8\int_0^\pi \sin^6\theta\cos^2\theta\,d\theta = \frac{\pi}{4} - \frac{5\pi}{16} = -\frac{\pi}{16},$$

where the last line uses $\sin 4\theta = 4\sin\theta\cos\theta(1-2\sin^2\theta)$. Substituting,

$$I = \frac{35\pi}{512} + \frac{9\pi}{256} + \frac{\pi}{32} + \frac{\pi}{512} = \frac{35+18+16+1}{512}\pi = \frac{70\pi}{512} = \frac{35\pi}{256}.$$

Step 4: assemble. Therefore

$$X = \frac{64}{9\pi^2}\cdot\frac{35\pi}{256} = \frac{35}{36\pi}, \qquad \mathrm{E}[T] = \frac{3}{4}X = \frac{35}{48\pi}, \qquad \mathrm{P}(\text{convex}) = 1 - \frac{4}{\pi}\cdot\frac{35}{48\pi} = \boxed{1 - \frac{35}{12\pi^2}}.$$

Numerically this is 0.70448, which passes the reality check: a little over 70 per cent, comfortably above the value $2/3$ that the same formula gives for a triangular region and below 1.

Layer 1: WHAT

Block 1: classify four points in general position into exactly two cases, convex position or one inside the triangle of the others.

Block 2: use symmetry and exclusivity to write $\mathrm{P}(\text{not convex}) = 4\,\mathrm{P}(S \in \triangle PQR)$.

Block 3: condition on P, Q, R and turn that probability into $\mathrm{E}[T]/\pi$, converting the configuration question into an area expectation.

Block 4: exploit scale invariance: condition on the farthest of the three points, rescale so that it sits on the unit circle, and reduce to the single number X with $\mathrm{E}[T] = \frac{3}{4}X$.

Block 5: compute X by polar coordinates centred at the boundary vertex, where the disc is $r \le 2\sin\theta$.

Block 6: fold the double integral onto $\theta' < \theta$, expand $\sin(\theta - \theta')$, and finish with Wallis integrals and one integration by parts.

Block 7: assemble and sanity check numerically.

The nominal route: set up the probability as an integral over the eight coordinates, or reduce to $\mathrm{E}[T]$ and then attack the area formula with its absolute value head on. The bifurcation point is at Block 4. Everyone who gets Blocks 1 to 3 has the same problem in front of them, namely $\mathrm{E}[T]$. The zombie starts integrating $\left|\sum r_i r_j \sin(\alpha_i - \alpha_j)\right|$ over six variables. You ask instead: what symmetry of the disc have I not yet spent? The answer is scaling, and scaling is spent by conditioning on the largest radius, because that is the one statistic that a rescaling normalises to 1.

Layer 2: HOW

Block 1. Cue. The problem asks about a configuration of four points, and the property is qualitative. **Why natural.** Qualitative configuration properties of finitely many points in the plane always have short classifications, and the classification is by the convex hull. With four points and no three collinear the hull has three or four vertices, so there are exactly two cases. Note that "no three collinear" is not a convenience assumption, it is an almost sure event, and you must say so. **Link to the next block.** The classification produces a complement that is a union of four events, which invites symmetry.

Block 2. Cue. Four events, exchangeable under relabelling the points, and mutually exclusive by the lemma. **Why natural.** Exclusivity is what lets you add probabilities without inclusion and exclusion, and exchangeability is what lets you compute only one of them. Both facts come from the lemma, which is why the lemma is proved and not assumed. **Link to the next block.** You are left with one event about a point landing inside a triangle built from the other points.

Block 3. **Cue.** A uniform point landing in a region. **Why natural.** By definition of the uniform distribution, the probability is the region's area over the total area. The region here is random, but it is independent of S, so condition on it first and average afterwards. This is the standard move: a probability involving a random region becomes an expectation of an area. **Link to the next block.** The problem is now a purely geometric expectation, $\mathrm{E}[T]$, with no probability language left in it.

Block 4. **Cue.** The disc is invariant under rotations about O and under scaling about O, and you have used rotations but not scalings. **Why natural.** An unused symmetry is an unused reduction. To use scaling you need a statistic that scaling acts on transitively, and the natural one is the largest of the three distances from O: rescale by that and it becomes 1, putting one vertex on the boundary. The distribution $2c\,dc$ of a single radius and the factor c^4 for the other two both come from $\mathrm{P}(|OP| \le r) = r^2$, which is itself just an area ratio. **Link to the next block.** After the reduction there is one unknown constant X, defined by a configuration with a fixed boundary vertex, which is a strictly easier object because one of the three points is no longer random.

Block 5. **Cue.** Two random points, one fixed vertex, and an area formula that wants distances and an included angle from that fixed vertex. **Why natural.** Choose the origin of coordinates where the geometry is simplest, which is the fixed vertex, not the centre. The reward is immediate: a circle through the origin has polar equation $r = 2R\sin\theta$, so the region is described by a single inequality with no case split, and the area formula $\frac{1}{2}\rho\rho'\sin|\theta - \theta'|$ separates into a radial part and an angular part. Choosing the centre as origin instead would give a messy radial limit and no separation. **Link to the next block.** The radial integrals evaluate to powers of sin, leaving a pure double integral in the angles.

Block 6. **Cue.** An absolute value $\sin|\theta - \theta'|$ in a symmetric double integral. **Why natural.** The integrand is symmetric under swapping θ and θ', so restrict to $\theta' < \theta$ and double. This is the correct way to kill an absolute value: not by case analysis inside the integrand, but by using a symmetry to halve the domain. Then $\sin(\theta - \theta')$ expands by the addition formula into products that integrate in θ' in closed form. **Link to the next block.** What remains is four one dimensional integrals, all standard.

Block 7. **Cue.** A closed form answer to a classical question. **Why natural.** Check it numerically. $35/(12\pi^2) \approx 0.2955$, so the answer is about 0.7045, and comparison with the known triangle value $2/3$ and square value $25/36$ places it correctly. A numerical check costs thirty seconds and catches every dropped factor of two. **Link to the next block.** Done.

Layer 3: WHY

The first truth is that a probability about a configuration of independent points should be converted, as early as possible, into an expectation of a geometric quantity. The mechanism is always the same: single out one point, condition on the others, and use that a uniform point hits a region with probability equal to the normalised area. Every problem of this family, from Buffon's needle to Sylvester's, runs on this exchange. The corollary is that the hard part is never the probability; it is the geometric mean value that pops out.

The second truth is that you must spend every symmetry the region has. The disc has rotations, reflections, and scalings about its centre. Rotations are spent by declaring the angular coordinate of one point to be uniform and independent. Scalings are spent by conditioning on a scale statistic, and the largest radius is the natural choice because rescaling by it produces a normalised configuration with one vertex on the boundary. That is what turns a three point problem into a one point problem plus a one dimensional integral in c, and the integral in c is trivial because the scaling acts on

the area with weight c^2 and on the probability with weight $c^4 \cdot 2c$. The general shape is: if a quantity is homogeneous of degree d under the symmetry and the symmetry parameter has a known distribution, the conditional expectation factors as a moment times a normalised constant.

The third truth is about absolute values. Every geometric probability integrand carries one, because areas and distances are unsigned. There are only two honest ways to remove it: use a symmetry of the integrand to restrict to the region where the sign is known, or decompose the quantity into pieces with fixed sign. Route 3 in the ranking takes the second option and pays with case analysis; the ideal route takes the first and pays nothing. Train the reflex: when you see $|f(u) - f(v)|$ inside a symmetric double integral, halve the domain immediately, before doing anything else.

What were the examiners nudging toward? The word "convex" with exactly four points is the nudge to the hull classification. The word "circle" rather than "square" or "triangle" is the nudge to polar coordinates and to the scaling symmetry. And the request for a probability rather than a proof is the signal that the answer is a specific constant that will not be pretty, which tells you in advance not to expect the integral to collapse.

Knowledge gaps, stated plainly. To have a real chance at this problem in the arena you must already own: the hull classification of four points, that is, the planar case of Radon's theorem; the fact that a uniform point in a disc has radial density $2r$, which is the polar Jacobian; the polar equation $r = 2R\sin\theta$ of a circle through the origin; the Wallis values of $\int_0^\pi \sin^{2m}$; and the discipline of checking a final constant numerically. You do not need Crofton's formula, which is the classical tool for this problem, but you should know it exists and what it does, because it is the standard machinery for turning geometric probability questions about lines and chords into one dimensional integrals. Naming that gap is better than pretending the ideal solution above is the only way in.

Revolving concepts

Convex position and Radon's theorem. Radon's theorem: any $d + 2$ points in $\mathbb{R}^d$ can be partitioned into two sets whose convex hulls intersect. In the plane, $d + 2 = 4$, and in general position the partition is either $2 + 2$ (the two diagonals cross, so the four points are in convex position) or $1 + 3$ (one point inside the triangle of the others). That dichotomy is precisely the lemma used above. See Book 1, field: Geometry, topic: convex hulls and Radon.

Uniform measure, hitting probabilities and Fubini. For U uniform on a region K and any measurable $A \subseteq K$, $\mathrm{P}(U \in A) = |A|/|K|$; if A is random and independent of U, then $\mathrm{P}(U \in A) = \mathrm{E}\,|A|/|K|$. The interchange is Fubini for a bounded nonnegative integrand, so no justification beyond measurability is needed.

Radial distribution and scaling in the disc. For U uniform on the disc of radius R, $\mathrm{P}(|OU| \le r) = r^2/R^2$, so the density is $2r/R^2$ on $[0, R]$, and the polar angle is independent and uniform. Consequences worth banking: $\mathrm{E}\,|OU| = \frac{2}{3}R$, $\mathrm{E}\,|OU|^2 = \frac{1}{2}R^2$, and for n independent points the largest radius has distribution function $(r/R)^{2n}$ and density $2nr^{2n-1}/R^{2n}$. The maximum of n independent copies always has distribution function F^n; that is the whole of order statistics that this problem needs.

Polar coordinates at a boundary point. A circle of radius R through the origin, with centre in the direction $\theta = \pi/2$, is $r = 2R\sin\theta$ for $\theta \in [0, \pi]$. This is the single change of viewpoint that makes Step 3 mechanical, and it is worth installing permanently: for any problem about chords or triangles anchored at a point of a circle, put the origin at that point.

Wallis integrals. $\int_0^\pi \sin^{2m}\theta\,d\theta = \pi\binom{2m}{m}4^{-m}$ and $\int_0^{\pi/2} \sin^a\theta\cos^b\theta\,d\theta = \frac{1}{2}B\left(\frac{a+1}{2}, \frac{b+1}{2}\right)$ with $B(x, y) = \Gamma(x)\Gamma(y)/\Gamma(x + y)$. Every integral in Step 3 is one of these after a two line reduction.

Sylvester's four point problem and its family. For a bounded convex region K, the same reduction gives $\mathrm{P}(\text{convex}) = 1 - 4\,\mathrm{E}[T]/|K|$. Known values: triangle $2/3$ (since $\mathrm{E}[T] = |K|/12$), square $25/36$ (since $\mathrm{E}[T] = 11|K|/144$), disc $1 - 35/(12\pi^2) \approx 0.7045$. Blaschke's theorem says these are extreme: over all bounded convex K the probability is minimised by triangles at $2/3$

and maximised by ellipses at $1 - 35/(12\pi^2)$. Crofton's formula, which expresses integrals over families of lines in terms of a measure invariant under rigid motions, is the classical machine for such computations. See Book 1, field: Probability, topic: geometric probability and Sylvester's problem.

Efron's identity, and the recursion that generalises this problem. Let V_n be the number of vertices of the convex hull of n independent uniform points in K and A_n the area of that hull. Then

$$\mathrm{E}[V_n] = n\left(1 - \frac{\mathrm{E}[A_{n-1}]}{|K|}\right),$$

because a point is a hull vertex exactly when it lies outside the hull of the other $n-1$, and linearity of expectation over the n points does the rest. This is a genuine recursion linking hull vertex counts at size n to hull areas at size $n-1$, and it contains this problem as the case $n = 4$: since $V_4 \in \{3, 4\}$ we get $\mathrm{E}[V_4] = 4 - \mathrm{P}(\text{not convex})$, and Efron gives $\mathrm{E}[V_4] = 4\big(1 - \mathrm{E}[A_3]/\pi\big) = 4 - 35/(12\pi^2)$, in agreement. Read in the other direction it also recovers the observation $A = C$ from ranked approach 4. The general lesson: for random convex hulls, vertex counts and areas are two faces of one recursion, and whichever of the two is easier to compute determines the other. See Book 1, field: Probability, topic: random convex hulls.

Circuit Bank

- **WHEN** a probability question asks whether k random points form a particular configuration **DO** classify the configurations by the convex hull, check the alternatives are mutually exclusive, and use exchangeability to reduce to one representative event **BECAUSE** configuration properties of finitely many points have short hull based classifications, and exclusivity plus symmetry turns a union of k events into k times one probability
- **WHEN** a uniform point must land inside a region built from the other random points **DO** condition on those other points and replace the probability by the expected area over the total area **BECAUSE** the defining property of the uniform distribution is that hitting probability equals normalised area, so the probability becomes a purely geometric expectation
- **WHEN** the region is a disc and you have already used rotational symmetry **DO** spend the scaling symmetry by conditioning on the largest of the radii and rescaling it to 1 **BECAUSE** areas are homogeneous of degree two and the radius has an explicit power law distribution, so the conditional expectation factors into a single moment integral times a normalised constant
- **WHEN** you must integrate over a disc with one distinguished point on its boundary **DO** place the polar origin at that boundary point, where the circle reads $r = 2R\sin\theta$ **BECAUSE** the region then needs one inequality instead of a case split, and the radial integrals collapse to powers of $\sin\theta$, leaving Wallis integrals
- **WHEN** an absolute value such as $|\theta - \theta'|$ sits inside a symmetric multiple integral **DO** halve the domain using the symmetry rather than splitting the integrand into sign cases **BECAUSE** a symmetry that fixes the integrand and reverses the sign of the argument is exactly what an absolute value is asking for, and case analysis in geometric probability is the main source of dropped marks

Backtesting

1. First useful cue: "four points" plus "convex". That pairing forces the hull dichotomy, and the dichotomy immediately converts the question into one about a point inside a triangle.
2. Method the expression suggested: a uniform point inside a random triangle means expected area over total area, so the target became $\mathrm{E}[T]$ within two minutes of reading.

3. Where you would hesitate, and the thought to reinforce: at $\mathrm{E}[T]$, staring at an absolute value over six variables. Reinforce: list the symmetries the region has and ask which ones you have not yet spent. Rotation was spent; scaling was not; conditioning on the largest radius spends it.
4. The trap the question sets: attacking $\mathrm{E}[T]$ by direct integration, or attempting the signed decomposition from the centre and losing control of the sign cases. Both are routes that look like progress for twenty minutes and then collapse.
5. What makes you recognise it faster next time: the phrase "probability that random points are in convex position" is a named classical family (Sylvester). Recognise the family, write $1 - 4\,\mathrm{E}[T]/|K|$ at once, and spend all your remaining time on the area.
6. The reusable decision rule: configuration probability $\Rightarrow$ hull classification $\Rightarrow$ expected area; then, in a disc, condition on the largest radius and put the polar origin at the boundary vertex.

Mirror drills

1. Three points are chosen independently and uniformly in a triangle of area 1; it is known that the expected area of the triangle they form is $1/12$. Deduce Sylvester's answer for a triangular region. *Answer:* $\mathrm{P}(\text{convex}) = 1 - 4 \cdot \frac{1}{12} = \frac{2}{3}$, using the same reduction as in Step 1, which never used the shape of the region.
2. For a point U uniform in the unit disc, compute $\mathrm{E}\,|OU|$ and $\mathrm{E}\,|OU|^2$, and the density of max of three independent copies. *Answer:* density $2r$ gives $\mathrm{E}\,|OU| = \int_0^1 2r^2 dr = \frac{2}{3}$ and $\mathrm{E}\,|OU|^2 = \frac{1}{2}$; the maximum has distribution function r^6 and density $6r^5$.
3. Using Efron's identity, find the expected number of vertices of the convex hull of four independent uniform points in a disc, and check it against the answer above. *Answer:* $\mathrm{E}[V_4] = 4(1 - \mathrm{E}[A_3]/\pi) = 4 - 4 \cdot \frac{35}{48\pi^2} = 4 - \frac{35}{12\pi^2}$, which equals $3\,\mathrm{P}(\text{not convex}) + 4\,\mathrm{P}(\text{convex})$, as it must.

20.7 B1. equilateral triangle hiding inside a cubic curve

Show that the curve $x^3 + 3xy + y^3 = 1$ contains only one set of three distinct points, A, B, and C, which are vertices of an equilateral triangle, and find its area.

Read it out loud

The claim is uniqueness: exactly one equilateral triangle sits on this curve. A genuine smooth irreducible cubic (an elliptic curve, for instance) has continuous symmetries you can rotate an inscribed triangle along, so it would carry either zero or infinitely many equilateral triangles, never exactly one. The word "only one" is therefore not a fact about triangles, it is a fact about the curve: it is telling you, before you have done a single calculation, that this cubic must be reducible into pieces so rigid that a triangle can barely fit. That is the first cue, and it tells you to stop thinking about the curve as one object and start hunting for a factorisation.

Look at the shape of the left side: $x^3 + 3xy + y^3$. Two cubes and a cross term with coefficient exactly 3. That coefficient is not decorative. It is the signature of the symmetric identity $x^3 + y^3 + z^3 - 3xyz$, which factors completely over the reals. You are one substitution away from turning an algebraic geometry question into a line-and-point question.

The fields embedded here are polynomial factorisation and Euclidean geometry, and what is really being tested is whether you reroute immediately, before any parametrisation attempt, into checking a curve against a small stock of standard symmetric identities. Within the first thirty seconds you should have written $z = -1$ next to the expression and started checking whether $x^3 + 3xy + y^3 - 1$ matches $x^3 + y^3 + z^3 - 3xyz$ at that value of z.

Approaches, ranked worst to best

1. **brute rotation.** *Cue:* "three points, equilateral". *Circuit:* rotate by 120° about an unknown centroid using complex numbers, substitute into the cubic, solve. (this treats the curve as one irreducible object and sets up a nonlinear system in the centroid and the rotation, with no guarantee it simplifies; it costs a great deal of ink and gives you no independent way to confirm uniqueness, since you would be searching blind rather than seeing the rigid structure first)

2. **singularity hunting.** *Cue:* a cubic that behaves this rigidly. *Circuit:* compute ∂_x, ∂_y of the defining polynomial and look for common zeros, to test whether the curve is singular. (this correctly flags that something is wrong with the curve, but a singular point alone does not hand you the factorisation; it tells you WHERE to look, not the shape of the answer, so it is at best a warm up to the real approach)

3. **symmetric identity match.** *Cue:* cube terms plus a $3xy$ cross term. *Circuit:* recognise $x^3 + 3xy + y^3 - 1$ as $x^3 + y^3 + z^3 - 3xyz$ with $z = -1$, factor immediately. (this converts the whole problem into elementary algebra in one line, then pure Euclidean geometry finishes it; it is the ideal route because it costs the least ink and leaves nothing to search for)

The ideal solution

Set $z = -1$. Then $z^3 = -1$ and $-3xyz = 3xy$, so

$$x^3 + 3xy + y^3 - 1 = x^3 + y^3 + z^3 - 3xyz\Big|_{z=-1}.$$

Recall the symmetric factorisation

$$x^3 + y^3 + z^3 - 3xyz = (x + y + z)(x^2 + y^2 + z^2 - xy - yz - zx).$$

(This is verified either by direct expansion of the right side, which collects to $x^3+y^3+z^3-3xyz$ after every cross term cancels in pairs, or by noting it is the determinant of the circulant matrix with rows the cyclic shifts of (x,y,z), whose eigenvalues at the eigenvectors $(1,\omega^i,\omega^{2i})$, $i=0,1,2$, for ω a primitive cube root of unity, are $x+\omega^i y+\omega^{2i}z$; the determinant is the product of these three eigenvalues, and multiplying the two complex conjugate factors for $i=1,2$ gives the real quadratic above.)

Substituting $z=-1$,

$$x^3+3xy+y^3-1=(x+y-1)\left(x^2-xy+y^2+x+y+1\right).$$

Doubling the second factor and regrouping,

$$2\left(x^2-xy+y^2+x+y+1\right)=(x-y)^2+(x+1)^2+(y+1)^2,$$

a sum of three squares, so the second factor is nonnegative and vanishes only when $x-y=0$, $x+1=0$, and $y+1=0$ hold simultaneously, that is, only at $(x,y)=(-1,-1)$.

Hence the curve is exactly

$$\{(x,y):x+y=1\}\ \cup\ \{(-1,-1)\}.$$

These two pieces are disjoint, since $(-1)+(-1)=-2\neq 1$.

Three distinct points cannot all lie on the line $x+y=1$, since a triangle needs non collinear vertices. Since the only point off the line is the single point $(-1,-1)$, and the three vertices are distinct, at most one of them can equal $(-1,-1)$. Combining these two restrictions, exactly one vertex, say A, equals $(-1,-1)$, and the other two, B and C, lie on the line $x+y=1$.

Write M for the foot of the perpendicular from $A=(-1,-1)$ to the line $x+y=1$. For ABC to be equilateral it must in particular be isosceles with apex A, and the altitude from the apex of an isosceles triangle bisects the base, so M must be the midpoint of BC. This pins down M as a single fixed point on the line, independent of any choice, and the altitude length

$$h=\frac{|(-1)+(-1)-1|}{\sqrt{1^2+1^2}}=\frac{3}{\sqrt{2}}=\frac{3\sqrt{2}}{2}$$

is likewise fixed. In an equilateral triangle of side s, the height satisfies $h=\frac{\sqrt{3}}{2}s$ (drop the altitude, apply Pythagoras to a half triangle of base $s/2$ and hypotenuse s), so s is forced to be $s=\dfrac{2h}{\sqrt{3}}$; conversely with M and h fixed and s chosen this way, the two points on the line at distance $s/2$ from M are automatically at distance s from A by the same Pythagorean identity run in reverse, so the resulting triangle genuinely is equilateral. This leaves no freedom: B and C are the unique pair of points on the line at distance $s/2$ either side of M, so there is exactly one such triangle, as a set of three points.

Its area is

$$\text{Area}=\frac{\sqrt{3}}{4}s^2=\frac{\sqrt{3}}{4}\cdot\frac{4h^2}{3}=\frac{h^2}{\sqrt{3}}.$$

With $h^2=\dfrac{9}{2}$,

$$\text{Area}=\frac{9/2}{\sqrt{3}}=\frac{9}{2\sqrt{3}}=\boxed{\frac{3\sqrt{3}}{2}}.$$

Layer 1: WHAT

Block 1: read "only one triangle" as a claim about the curve's rigidity, not about triangles. Block 2: match the left side against $x^3+y^3+z^3-3xyz$ with $z=-1$ and factor. Block 3: show the quadratic

factor is a sum of three squares, locate its unique real zero. Block 4: the curve is a line union one external point, so exactly one vertex is forced to that point. Block 5: turn the geometry into one scalar, the distance from that point to the line, and finish with the height-to-area formula for an equilateral triangle.

Nominal route: treat the cubic as one irreducible curve and search for three points related by a 120° rotation directly. Ideal route: factor first. The bifurcation point is the instant you decide whether to parametrise the curve or to test it against the sum-of-cubes-minus-$3xyz$ identity; everything downstream of that decision is either a nonlinear system in disguise or three lines of algebra followed by pure geometry.

Layer 2: HOW

Block 1. **Cue.** "only one set of three points" attached to a cubic that looks otherwise generic. **Why natural.** Uniqueness of an inscribed equilateral triangle is not a property a smooth irreducible cubic can have, by the continuous symmetry argument, so the curve must be degenerate. **Link to the next block.** Degeneracy of a cubic in two variables is almost always exposed by a known symmetric factorisation, so look for one.

Block 2. **Cue.** two cube terms and a cross term with coefficient exactly 3. **Why natural.** This is precisely the shape of $x^3 + y^3 + z^3 - 3xyz$ with the third variable fixed at a constant; the constant term -1 on the curve fixes $z = -1$ since $z^3 = -1$ matches and $-3xyz = 3xy$ matches simultaneously. **Link to the next block.** Once matched, the standard factorisation of that identity applies immediately.

Block 3. **Cue.** a quadratic factor that is claimed, or suspected, to vanish at only one real point. **Why natural.** A quadratic form that is a sum of squares is visibly nonnegative, and its zero set is exactly where every square vanishes at once; this replaces an inspection claim with an equation you can solve directly. **Link to the next block.** Locating the single zero of the quadratic factor tells you exactly which point is not on the line, which is the missing piece needed to pin down the triangle's apex.

Block 4. **Cue.** the curve splits into a line and one isolated point. **Why natural.** Three collinear points cannot form a triangle, and only one copy of the isolated point is available since the vertices are distinct, so the case analysis collapses to exactly one configuration: one vertex at the point, two on the line. **Link to the next block.** With the apex fixed and the opposite side confined to a fixed line, the triangle has no geometric freedom left except its size, which the equilateral condition also fixes.

Block 5. **Cue.** a fixed apex and a fixed supporting line for the opposite side. **Why natural.** The altitude from the apex of an isosceles or equilateral triangle bisects the base, so the foot of the altitude is forced to be the perpendicular projection of the apex onto the line; the altitude length is then just a distance computation, and the equilateral relation $h = \frac{\sqrt{3}}{2}s$ converts that one number into the side length and hence the area. **Link to the next block.** This is the last step: plug the computed height into the area formula.

Layer 3: WHY

The route is ideal because it exploits a general truth about degree bounds: a genuine irreducible cubic curve, viewed as a real algebraic curve, does not admit a distinguished finite set of inscribed equilateral triangles unless it is forced to by a rigid, low-dimensional configuration, and the only

way a cubic in two variables becomes that rigid is by factoring into lower degree pieces. The moment you see a uniqueness claim about a geometric configuration ON a curve of degree three or higher, the discernment mechanism is to ask whether the curve is secretly reducible before attempting any direct geometric attack, because reducibility is what converts a continuum of possibilities into a finite, checkable set.

You train this discernment by keeping a short mental stock of two and three variable identities that commonly hide inside contest cubics: the sum of cubes minus $3xyz$ used here, the difference of cubes, and sum-of-squares completions of quadratic forms. Seeing a coefficient of exactly 3 next to a cross product, sitting alongside matching cube terms, should fire the identity match before any other method is attempted, precisely because testing it costs one line and either succeeds spectacularly or fails harmlessly.

Revolving concepts

Symmetric factorisation $x^3+y^3+z^3-3xyz=(x+y+z)(x^2+y^2+z^2-xy-yz-zx)$**.** Provable by direct expansion, or as the determinant of the circulant matrix with rows the cyclic shifts of (x,y,z), whose eigenvalues at the eigenvectors $(1,\omega^i,\omega^{2i})$ for $i=0,1,2$ and ω a primitive cube root of unity are $x+\omega^i y+\omega^{2i}z$; the two complex conjugate eigenvalue factors for $i=1,2$ multiply to the real quadratic factor. See Book 1, field: Polynomials, topic: symmetric functions and circulant matrices. No recursion is present in this problem, so there is nothing to generalise along that axis here; the identity itself is the reusable object.

Sum-of-squares (SOS) certificates. Any positive semidefinite quadratic form in finitely many real variables can be written, after completing the square, as an explicit sum of squares, and its zero set is exactly the common zero set of every square in that decomposition. See Book 1, field: Inequalities, topic: sum of squares.

Equilateral triangle rigidity given one apex and the supporting line of the opposite side. If a triangle's apex A is fixed and its opposite side is required to lie on a fixed line not through A, requiring the triangle to be equilateral determines the other two vertices uniquely as an unordered pair: the altitude foot is the perpendicular projection of A, the altitude length is the fixed distance from A to the line, and the side length follows from $h=\frac{\sqrt{3}}{2}s$. See Book 1, field: Geometry, topic: equilateral and isosceles triangle relations.

Circuit Bank

- **WHEN** a two or three variable cubic has cube terms together with a $3xy$ or $3xyz$ style cross term **DO** test it against $x^3+y^3+z^3-3xyz=(x+y+z)(x^2+y^2+z^2-xy-yz-zx)$, fixing one variable at a constant if needed **BECAUSE** this is the single most common source of unexpected reducibility in a symmetric-looking cubic, and reducibility turns a curve-theoretic question into a line-and-point question

- **WHEN** a quadratic form is claimed or suspected to be positive semidefinite with an isolated zero **DO** complete the square into an explicit sum of squares **BECAUSE** the zero set of a sum of squares is visibly the simultaneous vanishing locus of every square, replacing an unjustified inspection claim with a solvable system

- **WHEN** a geometric configuration fixes one vertex and confines the opposite side to a fixed line **DO** reduce immediately to the single scalar distance from the vertex to the line **BECAUSE** for a prescribed triangle shape, that one scalar determines the entire triangle up to reflection, collapsing a two dimensional search to one number

Backtesting

1. First useful cue: "only one set of three points" attached to a cubic that otherwise looks like a generic curve.
2. Method the expression suggested: test the sum of cubes minus $3xyz$ identity with the constant term supplying the fixed third variable.
3. Where you would hesitate, and the thought to reinforce: confirming the quadratic factor really has a unique real zero rather than a whole conic of them; reinforce by writing it explicitly as a sum of squares rather than asserting positivity by inspection.
4. The trap the question sets: treating the cubic as one smooth irreducible curve and hunting for the triangle by a 120° rotation, which is possible in principle but costs far more ink and invites algebraic error.
5. What makes you recognise it faster next time: the exact coefficient pattern, cubes plus a coefficient 3 cross term, is now a stored shape rather than something to rediscover from scratch.
6. The reusable decision rule: symmetric cubic with cube terms and a 3-times cross product term, test the sum-of-cubes-minus-$3xyz$ identity before anything else.

Mirror drills

1. Factor $x^3 + y^3 - 3xy + 1$ and describe its real zero locus. *Answer:* set $z = 1$, matching $x^3 + y^3 + z^3 - 3xyz$ since $-3xyz = -3xy$; it factors as $(x + y + 1)(x^2 + y^2 + 1 - xy - x - y)$, and the second factor is $\frac{1}{2}[(x - y)^2 + (x - 1)^2 + (y - 1)^2]$, zero only at $(1, 1)$; the curve is the line $x + y = -1$ together with the point $(1, 1)$.
2. An equilateral triangle has one vertex fixed at the origin, with its opposite side required to lie on the line $x = 4$. Find its area. *Answer:* $h = 4$, so area $= h^2/\sqrt{3} = 16/\sqrt{3} = \dfrac{16\sqrt{3}}{3}$.
3. Show $2x^2 + 2y^2 + 2z^2 - 2xy - 2yz - 2zx$ is a sum of three squares, and find every real triple where it vanishes. *Answer:* it equals $(x - y)^2 + (y - z)^2 + (z - x)^2$, vanishing exactly when $x = y = z$.

20.8 B2. pigeonhole on fractional parts of partial sums

Prove that, for every set $X = \{x_1, x_2, \ldots, x_n\}$ of n real numbers, there exists a non-empty subset S of X and an integer m such that

$$\left| m + \sum_{s \in S} s \right| \leq \frac{1}{n+1}.$$

Read it out loud

An "there exists a subset and an integer" statement with a bound of exactly $\frac{1}{n+1}$ sitting against n given numbers is a fingerprint, not a coincidence. Whenever you see a bound of the shape $1/(k+1)$ attached to k objects, the honest first thought is pigeonhole: count out $k+1$ auxiliary quantities and place them on a line or a circle, because $k+1$ items forced into a space of total size 1 guarantees two of them within $1/(k+1)$ of each other. The examiners are not hiding this, they are handing it to you in the denominator.

The fields embedded are elementary number theory adjacent reasoning about fractional parts, and combinatorics in the form of the pigeonhole principle, applied on the continuous circle $\mathbb{R}/\mathbb{Z}$ rather than on a finite set of discrete boxes. What is really being tested is whether you can see that "subset S" secretly wants to be "a contiguous block of the list $x_1, \ldots, x_n$ in a fixed order," because only contiguous blocks come with the free telescoping identity that turns a difference of two auxiliary quantities into exactly the block sum you need.

Within the first thirty seconds you should have written down the $n+1$ partial sums $s_0 = 0, s_1 = x_1, s_2 = x_1 + x_2, \ldots, s_n = x_1 + \cdots + x_n$, because the count $n+1$ matches the denominator exactly, and the inclusion of the empty sum $s_0 = 0$ should already look deliberate: it is there to anchor the pigeonhole argument at a known point.

Approaches, ranked worst to best

1. **ad hoc existence.** *Cue:* "there exists". *Circuit:* try small numerical examples and guess a rounding argument, or hope for a slick continuity claim without any pigeonhole structure. (this gives you no constructive handle on which S and m to use, does not generalise past a single worked example, and is very likely to stall on a clean general proof)

2. **brute subset pigeonhole.** *Cue:* "subset S". *Circuit:* enumerate all 2^n subset sums, take their fractional parts, and pigeonhole among those. (this is not wrong in spirit, but the 2^n subset sums have no natural order and no automatic telescoping structure between any two of them, so recovering a specific S and a clean bound of exactly $1/(n+1)$ from an unstructured family of 2^n points is far more ink than the bound requires)

3. **prefix sum pigeonhole on the circle.** *Cue:* denominator $n+1$ against n numbers. *Circuit:* build the $n+1$ partial sums including the empty one, take fractional parts, sort them around $[0,1)$, and pigeonhole the $n+1$ gaps between consecutive values, which sum to exactly 1. (this is ideal because partial sums come with a built in telescoping identity, so the gap you find translates immediately into a genuine contiguous block S and an explicit integer m)

The ideal solution

For $i = 0, 1, \ldots, n$ define the partial sums $s_i = x_1 + x_2 + \cdots + x_i$, so $s_0 = 0$ is the empty sum. Write $\{t\} = t - \lfloor t \rfloor \in [0,1)$ for the fractional part of a real number t. Sort the $n+1$ values $\{s_0\}, \{s_1\}, \ldots, \{s_n\}$ into ascending order as $0 \leq t_0 \leq t_1 \leq \cdots \leq t_n < 1$; since $\{s_0\} = \{0\} = 0$ is among the values being sorted and no fractional part is negative, in fact $t_0 = 0$ exactly.

Consider the $n+1$ nonnegative real numbers

$$g_1 = t_1 - t_0, \quad g_2 = t_2 - t_1, \quad \ldots, \quad g_n = t_n - t_{n-1}, \quad g_{n+1} = 1 - t_n.$$

These telescope:

$$g_1 + g_2 + \cdots + g_{n+1} = (t_n - t_0) + (1 - t_n) = 1 - t_0 = 1,$$

using $t_0 = 0$. Since $n+1$ nonnegative reals sum to exactly 1, their average is $\frac{1}{n+1}$, so at least one of them satisfies $g_k \le \frac{1}{n+1}$; fix such an index $k \in \{1, \ldots, n+1\}$.

Case A: $1 \le k \le n$**.** Here $g_k = t_k - t_{k-1}$ is an internal gap. Since the $n+1$ sorted values $t_0, \ldots, t_n$ arise from a permutation of the $n+1$ indices $0, \ldots, n$, the positions $k-1$ and k correspond to two distinct indices $p \ne q$ in $\{0, \ldots, n\}$, with $t_{k-1} = \{s_p\}$ and $t_k = \{s_q\}$. Let $i = \min(p, q)$ and $j = \max(p, q)$, so $0 \le i < j \le n$. Put

$$S = \{x_{i+1}, x_{i+2}, \ldots, x_j\} \quad \text{(nonempty, since } i < j\text{)}, \qquad m = \lfloor s_i \rfloor - \lfloor s_j \rfloor.$$

Then

$$m + \sum_{s \in S} s = m + (s_j - s_i) = \big(s_j - \lfloor s_j \rfloor\big) - \big(s_i - \lfloor s_i \rfloor\big) = \{s_j\} - \{s_i\},$$

which equals $\pm(t_k - t_{k-1})$ depending on whether $j = q$ or $j = p$. Either way,

$$\left| m + \sum_{s \in S} s \right| = g_k \le \frac{1}{n+1}.$$

Case B: $k = n+1$**.** Here the minimal gap is the wraparound gap $g_{n+1} = 1 - t_n \le \frac{1}{n+1}$. Since $n \ge 1$, $\frac{1}{n+1} < 1$, so $t_n = 1 - g_{n+1} > 0$, meaning s_n is not an integer and $\lceil s_n \rceil = \lfloor s_n \rfloor + 1$. Take $S = \{x_1, \ldots, x_n\} = X$ (nonempty) and $m = -\lceil s_n \rceil$. Then

$$m + s_n = s_n - \lceil s_n \rceil = \big(s_n - \lfloor s_n \rfloor\big) - 1 = t_n - 1,$$

so $|m + s_n| = 1 - t_n = g_{n+1} \le \frac{1}{n+1}$.

In either case a nonempty $S \subseteq X$ and an integer m have been produced with $|m + \sum_{s \in S} s| \le \frac{1}{n+1}$. ■

Layer 1: WHAT

Block 1: build the $n+1$ partial sums, deliberately including the empty sum $s_0 = 0$. Block 2: pass to fractional parts, sort them on $[0, 1)$, and note $t_0 = 0$ makes the $n+1$ gaps between consecutive sorted values, including the wraparound gap, telescope to exactly 1. Block 3: average the $n+1$ nonnegative gaps to get one gap of length at most $\frac{1}{n+1}$. Block 4: if that gap is internal, translate it into a contiguous block S of the original list and an integer m built from the two relevant floors. Block 5: if that gap is the wraparound one, take S to be the whole list and m the negative ceiling of the full sum.

Nominal route: enumerate all 2^n subset sums and pigeonhole among those, or attempt an unstructured existence argument. Ideal route: restrict to the $n+1$ ordered partial sums. The bifurcation point is the choice of WHICH auxiliary family to pigeonhole: an unstructured family of 2^n subset sums with no natural differences to exploit, against a structured family of $n+1$ partial sums whose pairwise differences are automatically contiguous block sums.

Layer 2: HOW

Block 1. Cue. a bound of $\frac{1}{n+1}$ next to a set of n numbers. **Why natural.** the denominator $n+1$ is the exact count of auxiliary objects a pigeonhole argument on n items typically needs, and including the empty sum is what anchors the sorted list at a known value. **Link to the next block.** once you have $n+1$ real numbers, the natural next move is to place them on some bounded space and measure gaps.

Block 2. **Cue.** the auxiliary numbers are fractional parts, which live in $[0,1)$, a space of total length 1. **Why natural.** sorting them and taking consecutive differences, plus the wraparound difference back to 1, is the only way to make $n+1$ numbers in $[0,1)$ account for the entire length 1 without leftover. **Link to the next block.** this telescoping identity is exactly what lets you invoke averaging.

Block 3. **Cue.** $n+1$ nonnegative numbers summing to a fixed total. **Why natural.** the minimum of any collection of nonnegative reals cannot exceed their average, so at least one gap is at most $\frac{1}{n+1}$. **Link to the next block.** the found gap corresponds to a pair of the original partial sums, and the two cases (internal gap or wraparound gap) must be handled separately because only internal gaps come with two genuine indices already present in the list.

Block 4. **Cue.** an internal gap between two sorted fractional parts. **Why natural.** the identity $\{s_j\} - \{s_i\} = (s_j - s_i) - (\lfloor s_j \rfloor - \lfloor s_i \rfloor)$ converts a difference of fractional parts directly into a contiguous block sum plus an integer correction. **Link to the next block.** choosing $m = \lfloor s_i \rfloor - \lfloor s_j \rfloor$ makes that correction explicit and finishes the case.

Block 5. **Cue.** the wraparound gap, where no second partial sum index is available past s_n. **Why natural.** the identity here is between s_n and the nearest integer above it, since $g_{n+1} \le \frac{1}{n+1} < 1$ guarantees s_n is not itself an integer, so the ceiling is well defined. **Link to the next block.** this closes the only remaining case, completing the proof.

Layer 3: WHY

The underlying truth is a form of Dirichlet's pigeonhole principle on the circle group $\mathbb{R}/\mathbb{Z}$: any $n+1$ points placed on a circle of circumference 1 leave $n+1$ arcs between them that sum to exactly the circumference, so some arc is at most $\frac{1}{n+1}$ long. This is the same mechanism behind Dirichlet's classical approximation theorem, where the $n+1$ points are the fractional parts of $0, \alpha, 2\alpha, \ldots, n\alpha$ for a single real α. Here the points are instead the fractional parts of the partial sums of a whole list of numbers, and the reason partial sums, rather than arbitrary subset sums, are the right auxiliary family is that the DIFFERENCE of any two partial sums is automatically a contiguous block sum, which is exactly the kind of subset sum the problem allows.

The discernment mechanism to train is this: whenever a bound of the shape $\frac{1}{n+1}$ (or more generally $\frac{1}{k+1}$) sits next to a set of n (or k) objects, count out $k+1$ auxiliary quantities to pigeonhole, and ask "$k+1$ of WHAT." The "+1" is almost never accidental; it is the fingerprint of needing one extra, often trivial or empty, term to close a telescoping identity exactly at the boundary. Drilling this pattern across problems, rather than rediscovering it from scratch each time, is what makes this recognition instantaneous in the arena.

Revolving concepts

Dirichlet's approximation theorem. For any real α and positive integer N, there exist integers p, q with $1 \le q \le N$ and $|q\alpha - p| < \frac{1}{N}$, obtained by pigeonholing the $N+1$ fractional parts $\{0\}, \{\alpha\}, \ldots, \{N\alpha\}$ either into N bins of width $\frac{1}{N}$ or, as here, by sorting and taking the smallest gap. See Book 1, field: Number theory, topic: Dirichlet approximation.

Prefix sum trick for contiguous block existence. For a sequence $x_1, \ldots, x_n$, define $s_0 = 0$, $s_i = s_{i-1} + x_i$; any contiguous block sum $x_{i+1} + \cdots + x_j$ equals $s_j - s_i$, so a question about the existence of a contiguous block with a numeric property reduces to a question about a pair of partial sums, usually attacked via pigeonhole on residues in the discrete case or fractional parts in the continuous case. *Recursion and its generalisation:* the defining recursion is $s_i = s_{i-1} + x_i$, $s_0 = 0$; its general solution method is telescoping, $s_j - s_i = x_{i+1} + \cdots + x_j$, and this generalises to any associative combination, sums, exclusive-ors, products, wherever a problem asks for the

existence of a contiguous block satisfying a property, by pigeonholing the $n+1$ partial values under whichever equivalence (equal residue, close fractional part) the property demands. See Book 1, field: Sequences and recurrences, topic: prefix sum pigeonhole.

Averaging as a weak pigeonhole. If nonnegative reals $g_1, \ldots, g_k$ sum to a fixed total T, then $\min_i g_i \le T/k$; this is the continuous cousin of the discrete pigeonhole statement that $k+1$ items into k boxes force a repeat, and it is the exact tool that extracts "some gap is small" from "the gaps sum to 1." See Book 1, field: Inequalities, topic: averaging and extremal principle.

Fractional part and floor or ceiling identities. $\{t\} = t - \lfloor t \rfloor \in [0,1)$; for non integer t, $\lceil t \rceil = \lfloor t \rfloor + 1$; and $\{a\} - \{b\} = (a-b) - (\lfloor a \rfloor - \lfloor b \rfloor)$, the identity that converts a difference of fractional parts into an integer adjusted difference of the original reals. See Book 1, field: Real analysis, topic: floor and fractional part manipulation.

Circuit Bank

- **WHEN** a claimed bound has denominator $n+1$ attached to a set of n objects **DO** build $n+1$ auxiliary quantities, such as partial sums including a trivial empty one, and pigeonhole them **BECAUSE** the "+1" is almost always the exact count of auxiliary objects the pigeonhole argument needs, and the trivial term is what closes the telescoping identity at the boundary
- **WHEN** you need "some subset has property P" where P is really a numeric proximity claim **DO** restrict to contiguous blocks via prefix sums rather than all 2^n subsets **BECAUSE** differences of prefix sums are exactly contiguous block sums, giving a structured, telescoping family instead of an unstructured one
- **WHEN** you have k nonnegative reals known to sum to a fixed total **DO** immediately conclude the minimum one is at most the total divided by k **BECAUSE** this averaging step is the cheapest possible pigeonhole and is very often the entire existence content of the problem
- **WHEN** sorting real numbers into a cyclic order via fractional parts on $[0,1)$ **DO** deliberately include the value 0 itself among the numbers being sorted **BECAUSE** it anchors the smallest sorted value at 0 and makes the wraparound gap close the telescoping sum to exactly the full circumference rather than to an unknown leftover

Backtesting

1. First useful cue: a denominator of $n+1$ sitting next to a set of n numbers.
2. Method the expression suggested: pigeonhole the $n+1$ partial sums, including the empty one, by fractional part around the unit circle.
3. Where you would hesitate, and the thought to reinforce: justifying that the wraparound case still yields a genuine nonempty S and a well defined integer m; reinforce by checking $g_{n+1} \le \frac{1}{n+1} < 1$ forces s_n to be non integer, so the ceiling step is legitimate.
4. The trap the question sets: enumerating all 2^n subset sums instead of the $n+1$ structured partial sums, which loses the automatic contiguous block structure and makes recovering a specific S and m far harder than necessary.
5. What makes you recognise it faster next time: the phrase "there exists a nonempty subset and an integer" next to a $\frac{1}{n+1}$ bound is now a stored trigger for prefix sum pigeonhole on a circle.
6. The reusable decision rule: n numbers, bound $\frac{1}{n+1}$, build $n+1$ prefix sums, pigeonhole fractional parts on the circle, read the contiguous block off the smallest gap.

Mirror drills

1. Show that among any 5 integers, some nonempty subset has sum divisible by 5. *Answer:* pigeonhole the 6 partial sums $s_0, \dots, s_5$ modulo 5; two share a residue, and their difference is a contiguous run divisible by 5.
2. For any 4 reals, exhibit the guarantee from the ideal solution explicitly. *Answer:* it is the case $n = 4$ of the theorem just proved, giving a nonempty subset S and integer m with $|m + \sum_{s \in S} s| \le \frac{1}{5}$.
3. Prove Dirichlet's approximation theorem: for irrational α and positive integer N, some $q \in \{1, \dots, N\}$ has $\|q\alpha\| \le \frac{1}{N+1}$, where $\|\cdot\|$ denotes distance to the nearest integer. *Answer:* apply the ideal solution with $x_i = \alpha$ for every i and $n = N$, so the partial sums are $s_i = i\alpha$, and the produced $S = \{x_1, \dots, x_q\}$ for some q gives $|m + q\alpha| \le \frac{1}{N+1}$.

20.9 B3. counting linear partitions of a planar point set

Let S be a finite set of points in the plane. A linear partition of S is an unordered pair $\{A, B\}$ of subsets of S such that $A \cup B = S$, $A \cap B = \emptyset$, and A and B lie on opposite sides of some straight line disjoint from S (A or B may be empty). Let L_S be the number of linear partitions of S. For each positive integer n, find the maximum of L_S over all sets S of n points.

Read it out loud

"Find the maximum of L_S over all sets S of n points" is an extremal combinatorics question wearing a geometry costume. Extremal questions of this exact shape, maximise a count over all configurations of size n, split cleanly into two independent jobs: an upper bound valid for every configuration, and a matching construction that actually attains it. You should read the problem already planning to write two separate arguments, not one.

The fields embedded are combinatorial geometry, in particular the behaviour of a separating line as it varies continuously, and induction. What is really being tested is whether you can set up a controlled removal, take away one point and ask how much the count can possibly grow back when it is reinstated, since a direct global count over an arbitrary configuration of n points has no natural handle to grab.

The first cue worth writing down within thirty seconds is the phrase "A or B may be empty," which tells you the trivial partition, everything on one side, always exists, so $L_S \geq 1$ for every S; and the phrase "opposite sides of some straight line" tells you every other partition is indexed by a direction or position of a line, a continuously varying object, which is exactly the kind of structure a rotating sweep argument is built for.

Approaches, ranked worst to best

1. **direct arrangement count.** *Cue:* the target $\binom{n}{2} + 1$ resembles the classical regions-cut-by-lines formula. *Circuit:* draw all $\binom{n}{2}$ lines through pairs of points and count the regions they cut the plane into. (the target number is suggestively similar, but L_S counts partitions by an ARBITRARY separating line, not regions cut specifically by those $\binom{n}{2}$ lines through pairs of points; turning one count into the other needs a bijection this approach does not supply for free, and chasing it directly is a harder dual-arrangement computation than the problem requires)

2. **single-point rotation only.** *Cue:* a line can be rotated about one fixed point. *Circuit:* fix one point P, rotate a line through it by 180°, and count how the partition of the rest changes. (this correctly captures part of the mechanism and will be reused, but on its own it only counts partitions realised via lines through that one fixed point, undercounting the true maximum; it needs to be wired into an induction as a lemma, not used as the whole argument)

3. **removal induction with a rotating-line lemma, plus a convex position construction.** *Cue:* "maximum over all sets of n points" splits into a bound and a construction. *Circuit:* remove one point P, relate linear partitions of S to those of $S \setminus \{P\}$ via a restriction map, bound how many outputs of that map have two preimages using the single-point rotation from the previous approach, close with Pascal's identity, then separately exhibit a convex n-gon attaining equality via a bijection with pairs of edges. (this is ideal because the bound and the construction are proved by two independently clean arguments, each using the tool suited to it)

The ideal solution

The claim is $\max_S L_S = \binom{n}{2} + 1$.

Upper bound, by induction on n. For $n = 1$, a single point has exactly one linear partition, the trivial one, since any line disjoint from S leaves the point on one side; $L_S = 1 = \binom{1}{2} + 1$.

Suppose the bound $L_{S'} \le \binom{n-1}{2} + 1$ holds for every set S' of $n-1$ points, where $n \ge 2$, and let S be a set of n points. Fix any $P \in S$ and put $S' = S \setminus \{P\}$. Every line disjoint from S is also disjoint from S', so it induces a linear partition of S' as well as of S; this defines a restriction map f from linear partitions of S to linear partitions of S', by deleting P from whichever side it fell on.

Fix a partition $\pi' = \{A', B'\}$ of S' and let $\mathcal{F}(\pi')$ be the (nonempty) family of all lines disjoint from S' that induce π', keeping A' on a fixed side and B' on the other. As a line varies continuously within $\mathcal{F}(\pi')$, by translating or rotating while staying disjoint from S' and preserving which side A' and B' are on, the signed distance from P to the line varies continuously.

If every line in $\mathcal{F}(\pi')$ places P on the same side, then every S-partition restricting to π' places P on that same side too, so $f^{-1}(\pi')$ has at most one element. If instead two lines of $\mathcal{F}(\pi')$ place P on opposite sides, the signed distance from P to the line changes sign somewhere along a continuous path within $\mathcal{F}(\pi')$ joining them, so by the intermediate value theorem some line in this family passes exactly through P; call such a π' special. Only for special π' can $f^{-1}(\pi')$ have two elements, the two extensions obtained by attaching P to either side, so in every case $|f^{-1}(\pi')| \le 2$.

Now bound the number of special partitions. Parametrise lines through P by direction $\theta \in [0, \pi)$, a line and its reverse direction being the same line. For each of the $n-1$ points $Q \in S'$, there is exactly one direction, namely that of the segment PQ, at which the line through P passes through Q; at every other direction the line through P is disjoint from S' and induces some partition of S', and this partition can only change as θ crosses one of these $n-1$ critical directions. Hence at most $n-1$ distinct partitions of S' are induced by lines through P, so there are at most $n-1$ special partitions.

Combining these bounds,

$$L_S = \sum_{\pi' \in \mathrm{image}(f)} |f^{-1}(\pi')| \le L_{S'} + (\text{number of special } \pi' \text{ in the image}) \le \binom{n-1}{2} + 1 + (n-1),$$

since every non special π' contributes exactly its own count of 1 toward $L_{S'}$, and every special one contributes at most one unit more than that. By Pascal's identity, $\binom{n-1}{2} + (n-1) = \binom{n}{2}$, so $L_S \le \binom{n}{2} + 1$. This closes the induction, so $L_S \le \binom{n}{2} + 1$ for every set S of n points.

A construction attaining equality. For $n \ge 3$, let S be the vertices $v_1, \dots, v_n$ of a convex n-gon in cyclic order, with edges $e_1 = v_1v_2, \dots, e_n = v_nv_1$. Any line disjoint from S either misses the convex hull entirely, giving the trivial partition, or crosses the boundary at two points interior to two distinct edges e_i, e_j (it cannot pass through a vertex, since it is disjoint from S), splitting the vertices into the two arcs of the polygon boundary strictly between e_i and e_j on each side. Conversely, for any pair of distinct edges e_i, e_j, a line can be drawn crossing exactly those two edges, close to a segment joining interior points of each, inducing the partition into the two arcs they bound; distinct pairs of edges give distinct arc splits, since the pair of edges crossed is recoverable from the split as the two edges each arc exits through. So the nontrivial linear partitions of S are in exact bijection with the $\binom{n}{2}$ unordered pairs of distinct edges, giving $L_S = \binom{n}{2} + 1$, the extra 1 for the trivial partition. For $n = 1, 2$ this value is checked directly: $L_S = 1 = \binom{1}{2} + 1$ for a single point, and $L_S = 2 = \binom{2}{2} + 1$ for two points, one trivial partition and one separating them.

Since the upper bound is attained, $\max_S L_S = \boxed{\binom{n}{2} + 1}$.

Layer 1: WHAT

Block 1: base case $n = 1$. Block 2: build the restriction map f from linear partitions of S to linear partitions of $S \setminus \{P\}$. Block 3: show every fibre of f has size at most 2, and size 2 is only possible for

partitions achieved by some line through P, using continuity and the intermediate value theorem. Block 4: bound the number of such special partitions by $n-1$, by rotating a line through P and counting critical directions. Block 5: combine via Pascal's identity to close the induction on the upper bound. Block 6: separately construct a convex n-gon and biject its nontrivial partitions with pairs of edges to show the bound is attained.

Nominal route: attempt to count L_S directly via the arrangement of all $\binom{n}{2}$ pairwise-point lines and the standard regions-cut-by-lines formula. Ideal route: compare S to the $(n-1)$-point problem through a restriction map with a provably small correction term, then separately verify tightness. The bifurcation point is the decision of whether to attack the n-point configuration directly, which has no natural recursive handle since a general point set is not in special position, or to compare it to the $(n-1)$-point configuration and control exactly how much one extra point can add.

Layer 2: HOW

Block 1. **Cue.** "maximum of L_S over all sets S of n points." **Why natural.** an extremal count over configurations rarely has a clean closed form from a direct global count; it almost always wants an inductive comparison to the $(n-1)$ case. **Link to the next block.** the natural way to compare to the $(n-1)$ case is to remove one point and ask how partitions restrict.

Block 2. **Cue.** removing a point P from S. **Why natural.** every separating line for S is automatically a separating line for the smaller set $S \setminus \{P\}$, so restriction is a well defined map with no extra work. **Link to the next block.** the whole upper bound now rests on understanding how many partitions of S can restrict to the same partition of $S \setminus \{P\}$.

Block 3. **Cue.** a partition of S' might be achieved by several different separating lines. **Why natural.** the family of lines realising a fixed partition of S' is a connected set, since any two such lines can be joined by a continuous deformation staying within that family, so the signed distance from P to the line varies continuously along it; a continuous quantity that takes both signs must vanish somewhere, by the intermediate value theorem, which is exactly a line through P. **Link to the next block.** this shows the only partitions with more than one preimage are those achieved by some line through P, converting an open ended geometric worry into a bounded count.

Block 4. **Cue.** lines through the single fixed point P. **Why natural.** rotating a line through P by a full 180° only changes which side each other point of S' falls on at one critical direction per point, since a point's side flips exactly when the line's direction matches the direction from P to that point. **Link to the next block.** counting critical directions, rather than counting partitions directly, bounds the number of special partitions by $n-1$, the number of other points.

Block 5. **Cue.** an inductive bound of the shape $\binom{n-1}{2}+1+(n-1)$. **Why natural.** Pascal's identity $\binom{n-1}{2}+(n-1)=\binom{n}{2}$ collapses this immediately to $\binom{n}{2}+1$, confirming the induction is exactly tight rather than merely an upper estimate. **Link to the next block.** having proved the universal bound, a separate matching construction is needed to know the bound is not wasteful.

Block 6. **Cue.** convex position, and the phrase "A or B may be empty" recalling the trivial partition. **Why natural.** placing the points in convex position makes every pair of boundary edges correspond to a genuinely distinct achievable separation, with no coincidences from interior points, so counting edge pairs directly counts nontrivial partitions. **Link to the next block.** this closes the problem, since the bound and the construction now agree exactly.

Layer 3: WHY

The underlying truth is that a linear partition is indexed, many-to-one, by the direction and position of a separating line, and the space of lines disjoint from a fixed finite point set, modulo "induces the same partition," is a disjoint union of open connected cells. Connectivity within a cell is precisely what licenses the intermediate value theorem step: if a fixed point P sits on different sides for two lines in the same cell, some line in that cell must pass through P. Whenever an extremal count is asked for objects induced by a continuously varying separator, a line, a hyperplane, a threshold, the discernment mechanism is to look first for a removal induction with a bounded correction term, because a direct global count over a continuum of separators rarely closes without first discretising the problem this way.

You train this by explicitly writing the restriction map for a candidate induction and asking "what is the largest number of preimages any single output can have," since that number is exactly the correction term the induction needs; and by keeping "convex or general position is usually the extremiser" as a standing first guess whenever the construction half of an extremal geometry problem is needed, since it is confirmed correct far more often than not for this style of problem.

Revolving concepts

Extremal induction via a restriction map with bounded fibre size. Remove one generator from an n-object configuration, relate the count to the $(n-1)$-object case through a restriction map, bound the fibre size of that map, here at most 2, and bound how many outputs actually achieve the larger fibre size, here at most $n-1$ via a geometric argument, then add the correction term, often closing via a combinatorial identity such as Pascal's rule. See Book 1, field: Combinatorics, topic: incremental extremal counting.

Sweeping or rotating line through a fixed point. Rotating a line about a fixed point through a finite point set changes the induced combinatorial partition only at finitely many critical directions, one per other point, giving an immediate upper bound on the number of distinct partitions realised. See Book 1, field: Discrete structures and graphs, topic: line arrangements and sweep arguments.

Maximum regions cut by n lines. n lines in general position, no two parallel, no three concurrent, divide the plane into $\binom{n}{2}+n+1$ regions. *Recursion and its generalisation:* adding the k-th line to $k-1$ previously placed lines crosses them in $k-1$ distinct points, splitting the new line into k pieces and so adding k new regions, giving the recursion $R(k) = R(k-1)+k$ with $R(0)=1$, solved by summation to $R(n) = 1+\sum_{k=1}^{n} k = \binom{n}{2}+n+1$; the same additive recursion, plus summation, pattern applies whenever a new generic object crosses all previous ones in distinct points. This closely related shape is why counts like $\binom{n}{2}+1$ recur across discrete geometry extremal problems. See Book 1, field: Discrete structures and graphs, topic: arrangements of lines.

Convex position as the extremiser for linear-separation counting. For problems asking for the maximum number of distinct ways a straight line can separate a finite point set, convex, general position, configurations typically attain the extremal count, since every pair of boundary edges or points then yields a genuinely distinct achievable separation, free of coincidences from interior points. See Book 1, field: Geometry, topic: convex position extremal configurations.

Circuit Bank

- **WHEN** an extremal problem counts combinatorial objects induced by a continuously varying separator, a line, a hyperplane, a threshold **DO** remove one generator and build the restriction map to the $(n-1)$ problem, bounding how many outputs have two or more preimages **BECAUSE** this converts an unbounded looking global count into an induction with an explicitly boundable correction term
- **WHEN** you need to bound how many distinct combinatorial states are visible from lines or

rays through one fixed point **DO** rotate through the full range of directions and count only the critical directions where the state can change **BECAUSE** a sweeping parameter changes the combinatorics only at finitely many critical values, one per other object, and counting those values is always easier than counting states directly

- **WHEN** an inductive bound produces an expression of the shape $\binom{n-1}{2} + (n-1)$ **DO** simplify immediately via Pascal's identity to $\binom{n}{2}$ **BECAUSE** recognising this pattern instantly confirms the induction is tight and closes the algebra in one line
- **WHEN** you need to prove an upper bound is attained, not merely valid **DO** reach for the convex or general position construction first **BECAUSE** convex configurations are almost always the extremiser for "number of distinct linear separations" style problems, and the bijection with pairs of boundary features is usually immediate

Backtesting

1. First useful cue: "find the maximum of L_S over all sets S of n points," an extremal-over-configurations phrasing.
2. Method the expression suggested: a removal induction with a rotating-line lemma to bound the correction term.
3. Where you would hesitate, and the thought to reinforce: justifying that a partition can have at most 2 preimages under restriction, and that only special, through-P, partitions achieve 2; reinforce with the explicit intermediate value theorem argument on the signed distance from P to a continuously varying line.
4. The trap the question sets: counting L_S directly via the arrangement of all $\binom{n}{2}$ point-pairwise lines using the standard regions formula, which resembles the target closely but is not counting the same object without an extra justification step.
5. What makes you recognise it faster next time: the shape "$\binom{n}{2} + 1$" is now stored as "one trivial case plus one case per pair of boundary features," so it should immediately suggest an edge-pair or point-pair bijection for the construction half, and a remove-one-point induction for the bound half.
6. The reusable decision rule: extremal count of line-induced separations, split into a removal induction with a rotating-line correction bound, and a convex position construction with an edge-pair bijection.

Mirror drills

1. n lines in general position, no two parallel, no three concurrent, divide the plane into how many regions? *Answer:* $\binom{n}{2} + n + 1$, by the same style of induction, the k-th line adds k new regions.
2. How many nontrivial linear partitions of a convex n-gon isolate exactly one vertex? *Answer:* n, one for each vertex, corresponding to the n pairs of adjacent edges.
3. If S has n points, no three collinear, and $L_S = \binom{n}{2} + 1$, must S be in convex position? *Hint:* yes; if a point lay strictly inside the hull of the others, some pair of edges could no longer be simultaneously crossed by a line without ambiguity about that interior point's side, collapsing two of the $\binom{n}{2}$ candidate partitions into one, so equality forces convex position.

20.10 B4. Counting cube vertices inside a subspace

Let Z denote the set of points in $\mathbb{R}^n$ whose coordinates are 0 or 1. (Thus Z has 2^n elements, which are the vertices of a unit hypercube in $\mathbb{R}^n$.) Given a vector subspace V of $\mathbb{R}^n$, let $Z(V)$ denote the number of members of Z that lie in V. Let k be given, $0 \leq k \leq n$. Find the maximum, over all vector subspaces $V \subseteq \mathbb{R}^n$ of dimension k, of the number of points in $V \cap Z$.

Read it out loud

This is a counting question wearing a linear algebra coat. A finite set, the 2^n vertices of the unit cube, and a continuous object, a k dimensional subspace: how much of the finite set can the continuous object swallow? The fields wired in are linear algebra (dimension, rank, spanning sets) and finite combinatorics (counting points over a two letter alphabet). There is no metric geometry here. Any line you write involving a length or an angle is wasted ink.

Now read the parameters, because they are the loudest guiding light on this paper. You are given n and k with $0 \leq k \leq n$. Does the answer depend on both? Test $k = n$: the count is 2^n. Test $k = 0$: the count is 1. Test $k = 1$ in $\mathbb{R}^2$: the line $y = x$ takes $(0,0)$ and $(1,1)$, and no line through the origin takes three cube vertices, since the origin plus two more would already force dimension 2. So the data reads $1, 2, 4, \ldots$, that is 2^k, with no trace of n. That absence is the examiners telling you where the bound comes from. A bound that cannot see n cannot depend on how the cube sits inside $\mathbb{R}^n$, so it must come from dimension alone, and your proof should never mention n.

Within thirty seconds write two things. The construction: $V_0 = \{x : x_1 = \cdots = x_{n-k} = 0\}$ is k dimensional and meets Z in the 2^k vertices supported on the last k coordinates. And the remaining task: every k dimensional subspace holds at most 2^k cube vertices. On a "find the maximum" the construction is worth almost nothing and the bound is worth almost everything. Then say the sentence that contains the entire solution: a cube vertex is a point each of whose coordinates takes one of two values, and dimension k says only k coordinates are really free. Two values, k free coordinates, 2^k points. Your only job is to turn "only k coordinates are really free" into a theorem, and that theorem already exists: row rank equals column rank.

Approaches, ranked worst to best

1. **Tabulate small cases and assert the pattern.** *Cue:* two free parameters and the words "find the maximum". *Circuit:* compute, guess, hope. You reach 2^k in two minutes and prove nothing. A construction with no upper bound is 1 out of 10. Reconnaissance only.

2. **Chase dependences among the cube vertices.** *Cue:* "dimension k" reads as "any $k+1$ of them are dependent". *Circuit:* Steinitz exchange, maximal independent subsets. Pick independent cube vertices $v_1, \ldots, v_k$ spanning V and try to force every other cube vertex in V to be one of 2^k combinations. It stalls immediately, and you should be able to say why: the coefficients are not restricted. In $\mathbb{R}^3$, $(1,1,1) = (1,1,0) + (0,0,1)$ but also $(1,0,1) + (0,1,1) - (0,0,1)$. This route never uses the alphabet, and the alphabet is where the problem lives.

3. **Slice the cube by a coordinate hyperplane and induct.** *Cue:* $Z = \{0,1\} \times \{0,1\}^{n-1}$ is a product. *Circuit:* split into $x_n = 0$ and $x_n = 1$, induct on $n + k$. Generically each slice drops the dimension by one and contributes 2^{k-1}. Correct, and it proves the stronger affine statement, but it costs three pieces of bookkeeping: you must strengthen the claim to affine planes before the induction closes, since the slice $x_n = 1$ is affine; you must handle the degenerate branch where V lies inside one slice; and you must induct on $n + k$ rather than on either alone.

4. **Reduce modulo 2 and count inside $\mathbb{F}_2^n$.** *Cue:* the coordinates are 0 or 1, exactly the elements of $\mathbb{F}_2$. *Circuit:* integer dependences survive reduction, and an odd minor lifts. Reduction is injective on Z. If the image held $k+1$ vectors independent over $\mathbb{F}_2$, the integer matrix they lift

to would have an odd, hence nonzero, maximal minor, so those $k+1$ cube vertices would be independent over $\mathbb{R}$ and $\dim V > k$. So the image lies in an $\mathbb{F}_2$ subspace of dimension at most k, which has $2^{\dim}$ elements. Short and structurally honest: it explains why the answer is a power of two. It ranks below the next route only because it spends machinery you can avoid.

5. **Take the rank, then choose k coordinates that determine the point.** *Cue:* "dimension k" sitting next to "each coordinate takes two values". *Circuit:* row rank equals column rank, then count coordinatewise. Stack the points of $V \cap Z$ as rows. The row space lies in V, so the rank is at most k, so some k columns span all the columns, so any two rows agreeing on those k coordinates agree everywhere. Each of those coordinates takes two values, so there are at most 2^k rows. Four sentences, no induction, no finite fields, and no mention of n.

The ideal solution

The maximum is $\boxed{2^k}$.
Construction. Let $V_0 = \{x \in \mathbb{R}^n : x_1 = \cdots = x_{n-k} = 0\}$, the span of the last k standard basis vectors, so $\dim V_0 = k$. A point of Z lies in V_0 exactly when its first $n-k$ coordinates vanish and its last k are arbitrary elements of $\{0,1\}$, so $|V_0 \cap Z| = 2^k$.
Bound. Everything rests on one fact about matrices.

Lemma 20.10.1. *Let M be a real matrix of rank r. Then there is a set J of r column indices such that any two rows of M agreeing in every coordinate belonging to J are equal.*

Proof. The rank is the dimension of the column space, so choose J with $|J| = r$ such that the columns C_j, $j \in J$, form a basis of the column space. Every column satisfies $C_i = \sum_{j\in J} \lambda_{ij} C_j$ for real scalars λ_{ij}. If rows s and t agree on J, that is $(C_j)_s = (C_j)_t$ for all $j \in J$, then for every i,

$$(C_i)_s = \sum_{j\in J} \lambda_{ij}(C_j)_s = \sum_{j\in J} \lambda_{ij}(C_j)_t = (C_i)_t,$$

so the two rows agree in every coordinate and are equal. □

Let $\dim V = k$. Since Z is finite, so is $V \cap Z$; let M be the matrix whose rows are its distinct elements in any order. Every row lies in V, so the row space of M is a subspace of V and

$$r := \operatorname{rank} M = \dim(\text{row space of } M) \le \dim V = k.$$

Take J from the lemma. Then the restriction map

$$\pi_J : V \cap Z \to \{0,1\}^J, \qquad x \mapsto (x_j)_{j\in J}$$

is injective: two points with the same image are two rows agreeing on J, hence the same row. The codomain has exactly 2^r elements, since each coordinate of a point of Z is 0 or 1. Therefore $|V \cap Z| \le 2^r \le 2^k$.

The two halves meet, so the maximum is exactly 2^k. Edge cases behave: for $k = 0$ we get $V = \{0\}$, M has the single row 0, $r = 0$, $J = \emptyset$, and the bound reads 1; for $k = n$ it reads 2^n. The matrix always has at least one row, since $0 \in V \cap Z$ for every subspace, so no empty case arises.

Remark 20.10.2. The same proof bounds $|A \cap Z|$ for an *affine* k plane A. If the intersection is empty there is nothing to prove; otherwise fix $p \in A \cap Z$ and let M have rows $q - p$ for $q \in A \cap Z$. These lie in the k dimensional direction space of A, so $\operatorname{rank} M \le k$, and injectivity of $(q-p) \mapsto (q-p)|_J$ with p fixed gives injectivity of $q \mapsto q|_J \in \{0,1\}^J$.

Remark 20.10.3. Coordinate subspaces are not the only maximisers. Partition part of $\{1,\dots,n\}$ into nonempty blocks $B_1,\dots,B_k$ and let V be the span of their indicator vectors; then $\sum c_i \mathbf{1}_{B_i} \in Z$ exactly when every $c_i \in \{0,1\}$, so $|V \cap Z| = 2^k$. In $\mathbb{R}^3$ the span of $(1,1,0)$ and $(0,0,1)$ holds four cube vertices, while the span of $(1,1,0)$ and $(0,1,1)$ holds only three, namely $(0,0,0), (1,1,0), (0,1,1)$.

Layer 1: WHAT

Block 1. Read the parameters: the answer is 2^k with no n in it, so look for a proof that never uses n.

Block 2. Write the coordinate subspace, count 2^k, and declare the construction finished.

Block 3. Name what makes a cube vertex special: every coordinate takes one of two values. So the count will be a power of 2 whose exponent counts coordinates.

Block 4. Convert "dimension k" into "at most k coordinates matter" by stacking the points into a matrix and using row rank equals column rank.

Block 5. Choose k spanning columns, prove the restriction is injective, count 2^k.

Nominal against ideal. The nominal route keeps the points of $V \cap Z$ as vectors and tries to control them through a basis of V, bounding the count by bounding the coefficients. The coefficients are not bounded, so the route does not merely run slowly, it controls the wrong data.

The bifurcation point is Block 4 and it is one word long: transpose. Up to Block 3 the two routes agree. At Block 4 the nominal route studies rows and their coefficients; the ideal route studies columns and their spans. Rows are points, columns are coordinates, and the alphabet restriction is a statement about coordinates. Decide to look at columns and the problem is over.

Layer 2: HOW

Block 1. **Cue.** Two parameters, n and k, and a request for a maximum. **Why natural.** Test the extremes before computing anything: $k = 0$ gives 1, $k = n$ gives 2^n. The pattern 2^k contains no n, and a bound blind to n cannot depend on the embedding of the cube. That rules out in advance every route that begins by exploiting the geometry of $\mathbb{R}^n$. **Link to the next block.** Knowing the answer, split the work the way every maximum question splits: construction, then bound.

Block 2. **Cue.** "Vector subspace of dimension k" with a cube attached. **Why natural.** The cheapest k dimensional subspace is a coordinate subspace, and a coordinate subspace meets the cube in a k dimensional face. That is the definition of a face, so it needs no thought. **Link to the next block.** One line spent, so all remaining attention can go to finding the shortest possible bound.

Block 3. **Cue.** "whose coordinates are 0 or 1". **Why natural.** This clause is not decoration; it says the alphabet has size 2. When a count comes out as a power of 2, the exponent counts independent binary choices. So the shape of the answer already tells you the proof will exhibit k binary choices determining the point. You are no longer hunting a proof, you are hunting the k choices. **Link to the next block.** The only structure producing the number k is $\dim V$, so the choices must come from dimension. What converts dimension into a count of coordinates?

Block 4. **Cue.** The word "dimension" next to the word "coordinates". **Why natural.** Rank is the one theorem that translates between them, being at once the dimension of the row span and of the column span. List the points as rows: the row rank is at most $\dim V = k$ by definition of span, so the column rank is at most k, so at most k coordinate functions on your point set are independent. Note what this move required: treating all of $V \cap Z$ at once as a single matrix. The count is a property of the whole set, so the whole set must be the object. **Link to the next block.** A spanning set of columns yields an injective restriction map, and injectivity plus a two letter alphabet is a count.

Block 5. **Cue.** A set injecting into $\{0,1\}^J$ with $|J| \leq k$. **Why natural.** Injectivity turns a hard count into a trivial one: the domain is no larger than the codomain, and the codomain is a set of binary strings of length at most k. The only algebra in the whole solution is the two line proof that agreeing on the basis columns forces agreeing on all columns. **Link to the next block.** The bounds meet at 2^k, so nothing remains.

Layer 3: WHY

The truth underneath is rank duality, stated in the form the problem needs: if $S \subseteq A^n$ with A a finite alphabet of size q, and the span of S in $\mathbb{R}^n$ has dimension at most k, then $|S| \leq q^k$. The proof is the one above with 2 replaced by q. Read the statement carefully: the ambient dimension has vanished and so has the geometry, and what is left is an exchange rate between dimension and information. One dimension buys one coordinate, one coordinate buys $\log_2 q$ bits, so k dimensions buy q^k points. This problem is a statement about how much information a low dimensional linear space can carry when its points are written in a finite alphabet.

The discernment mechanism you must train is knowing when to transpose. A matrix has two readings, and you should always ask which reading the hypothesis lives in and which the conclusion lives in. Here the hypothesis is about rows, since it says the points lie in a k dimensional space; the constraint on entries is about columns, since it caps the values a coordinate can take. Hypothesis in rows, constraint in columns: transpose. Whenever a problem pairs a rank condition on a family of vectors with an entrywise condition on those vectors, rank duality is the bridge, and the reading in which the constraint is simplest is the one to work in. The examiners nudged three times: they told you parenthetically that Z has 2^n elements, which plants "power of two" before you start; they wrote $0 \leq k \leq n$ with no relation between the two, signalling uniformity in n; and they added an editorial note removing an ambiguity in the phrasing, which is their way of saying the ambiguity was never the difficulty. The same rank duality also explains why the modulo 2 route lands on the same number: both routes compute a rank, one over $\mathbb{R}$ and one over $\mathbb{F}_2$, and the minor lifting argument says exactly that reduction cannot increase rank.

Revolving concepts

Rank. For a real $m \times n$ matrix, the row rank equals the column rank, and this common value also equals the largest size of a nonvanishing minor. Orbiting facts: invariance under elementary operations, $\operatorname{rank} M \leq \min(m, n)$, and rank plus nullity equals n. The minor characterisation is what powers the finite field route. See Book 1, field: Linear algebra, topic: rank.

Span and dimension. If every row of M lies in a subspace V then the row space is contained in V, so $\operatorname{rank} M \leq \dim V$. This is the only property of V the ideal solution uses. See Book 1, field: Linear algebra, topic: subspaces and dimension.

The hypercube. Vertices of $\{0,1\}^n$ correspond to subsets of $\{1, \ldots, n\}$ by indicator vectors, so every cube statement has a set system translation. Fixing some coordinates and freeing the rest gives a face; a k dimensional face has 2^k vertices. See Book 1, field: Discrete structures and graphs, topic: hypercube.

The field $\mathbb{F}_2$. The two element field with $1 + 1 = 0$. A d dimensional subspace of $\mathbb{F}_2^n$ has exactly 2^d elements, since a basis gives d independent binary choices. Lifting lemma: an integer matrix with an odd maximal minor has that minor nonzero over $\mathbb{R}$, so reduction modulo 2 cannot increase rank. See Book 1, field: Abstract algebra, topic: finite fields.

Affine planes. A k dimensional affine plane is $p + W$ with $\dim W = k$. Subtracting one point of a set from all of them converts affine to linear without changing cardinality, and is the standard first move when a problem says "plane" rather than "subspace". See Book 1, field: Linear algebra, topic: affine subspaces.

The recursion, generalised. The slicing route is a recursion and deserves to be written as one. Let $f(n,k)$ be the largest number of points of $\{0,1\}^n$ on an affine k plane. Slicing by $x_n = 0$ and $x_n = 1$ gives

$$f(n,k) \leq \max\{\, 2f(n-1,k-1),\ f(n-1,k) \,\}, \qquad f(n,0) = 1,$$

the first branch generic and the second the degenerate case where the plane lies inside a slice; induction on $n + k$ gives $f(n,k) \leq 2^k$. Install the general shape, not the instance: a quantity defined on $\{0,1\}^n$ is bounded by splitting the cube into its two facets, applying the hypothesis to each, and

adding. The additive sibling $g(n,d) \le g(n-1,d) + g(n-1,d-1)$, $g(n,0) = 1$, solves to $\sum_{i=0}^{d} \binom{n}{i}$ and is the Sauer and Shelah lemma. The present problem is its linear algebraic sibling: "dimension at most k" plays the role of "shatters nothing of size $k+1$". See Book 1, field: Combinatorics, topic: VC dimension and shattering.

Circuit Bank

- **WHEN** you see vectors with entries from a finite alphabet of size q lying in a space of dimension k **DO** stack them as rows, take the rank, choose k spanning columns, and bound the count by q^k **BECAUSE** row rank equals column rank turns "dimension k" into "k coordinates determine the point", and a finite alphabet then caps the number of points
- **WHEN** a hypothesis is about the rows of a natural matrix and the constraint is about its entries columnwise **DO** transpose, that is, study the column space instead **BECAUSE** rank duality is the only bridge between the two readings, and you should work in the reading where the constraint is simplest
- **WHEN** the answer to a "find the maximum" omits one of the given parameters **DO** look for a proof that never mentions that parameter **BECAUSE** the absence tells you which structure carries the bound, so any argument using the absent parameter is doing unnecessary work
- **WHEN** the objects are 0 or 1 vectors **DO** consider reducing modulo 2 into $\mathbb{F}_2^n$ **BECAUSE** 0 and 1 are exactly the elements of $\mathbb{F}_2$, subspaces there have size $2^{\dim}$, and an odd maximal minor lifts, so reduction cannot increase rank
- **WHEN** an induction over a cube stalls because a slice is affine rather than linear **DO** strengthen the statement to affine planes and induct on the sum of the parameters **BECAUSE** a stronger hypothesis is usually the only way to close a slicing recursion, and $n+k$ decreases in both branches

Backtesting

1. First useful cue: the answer 2^k contains no n, visible after two seconds of testing $k = 0$ and $k = n$, which forces a dimension only proof.
2. Method the expression suggested: "coordinates are 0 or 1" beside "dimension k" is an instruction to stack the points into a matrix and use row rank equals column rank.
3. Where you would hesitate, and the thought to reinforce: forming a matrix out of the entire intersection feels like discarding structure. Reinforce the opposite thought, that the count is a property of the whole set, so the whole set must be the algebraic object.
4. The trap the question sets: controlling the coefficients of cube vertices in terms of a chosen basis of cube vertices. The coefficients are unrestricted, so the trap costs you the paper.
5. What makes you recognise it faster next time: a rank hypothesis paired with an entrywise constraint. That pairing means transpose, every time.
6. The reusable decision rule: a subset of A^n spanning a space of dimension k has at most $|A|^k$ elements, and the proof is column selection.

Mirror drills

1. Let $S \subseteq \{0,1,2\}^n$ lie in a k dimensional subspace of $\mathbb{R}^n$. Show $|S| \le 3^k$. *Answer:* identical argument; stack S as rows, rank at most k, choose k spanning columns, and the injection lands in $\{0,1,2\}^k$.

2. What is the maximum number of points of $\{0,1\}^n$ on an affine k plane? *Answer:* 2^k again. Subtract one point of the intersection from all of them and apply the rank argument to the differences.

3. In $\mathbb{R}^3$ exhibit a plane through the origin holding exactly three cube vertices and one holding four, and name the feature that separates them. *Answer:* the span of $(1,1,0)$ and $(0,1,1)$ holds three; the span of $(1,1,0)$ and $(0,0,1)$ holds four. The second is spanned by indicators of *disjoint* coordinate blocks, so every subfamily sum is again a 0 or 1 vector.

20.11 B5. Maximising a weighted quadratic integral functional

For each continuous function $f : [0,1] \to \mathbb{R}$, let $I(f) = \int_0^1 x^2 f(x)\,dx$ and $J(x) = \int_0^1 x\,(f(x))^2\,dx$. Find the maximum value of $I(f) - J(f)$ over all such functions f.

Read it out loud

Say the structure aloud before you touch a pen. You are asked to maximise, over an infinite dimensional space of functions, a quantity that is linear in f minus quadratic in f, with both terms carrying a weight that vanishes at the same endpoint. That is the entire description. The fields wired in are real analysis (integration and continuity), inequalities, and the calculus of variations, which appears here only so that you can recognise it and decline it. Note the harmless slip in the statement: J is defined with the letter x on the left and used as $J(f)$; it is a function of f, and nothing in the problem depends on the typo.

The first structural move is forced. Two integrals over the same interval with the same variable should be one integral, so write

$$I(f) - J(f) = \int_0^1 \left(x^2 f(x) - x f(x)^2\right) dx.$$

Now look at the integrand with x frozen. It is a quadratic in the single real number $f(x)$, with leading coefficient $-x$, and on $[0,1]$ that leading coefficient is at most zero. A quadratic with nonpositive leading coefficient has a maximum, not a minimum, and you find it by completing the square. That is the whole solution, and it should be on the page within thirty seconds.

Before proving anything, run the reconnaissance that tells you the answer. The two weights are x^2 against f and x against f^2, which are balanced when f scales like x, so try $f(x) = cx$. Then $I = c/4$ and $J = c^2/4$, so $I - J = (c - c^2)/4$, maximised at $c = 1/2$ with value $1/16$. You now know the target and, more usefully, you know the centre of the square you are about to complete. The remaining question is not what the answer is but why no other function beats it.

The one thing worth flagging in advance, because it is where the examiners did their design work, is the point $x = 0$. There the quadratic degenerates: the coefficient of $f(x)^2$ vanishes, so at that single point $f(0)$ is unconstrained by the objective. Watch whether that costs you anything. It will not, and the reason it does not is the real content of Layer 3.

Approaches, ranked worst to best

1. **Discretise into a Riemann sum and maximise a finite quadratic form.** *Cue:* "quadratic in f" plus "maximum". *Circuit:* diagonalise a quadratic form, then pass to the limit. You replace f by its values on a grid, maximise a diagonal quadratic form in those values, and let the mesh go to zero. It gives the right number and it is a nightmare to justify: you must show the maxima of the discretisations converge to the supremum of the functional and that the limit is attained by a continuous function. Every one of those steps is harder than the problem.

2. **Euler and Lagrange, the first variation.** *Cue:* "maximum over all such functions" is the phrase that names the calculus of variations. *Circuit:* perturb $f \to f + \varepsilon g$, differentiate at $\varepsilon = 0$, set the derivative to zero. You get $\int_0^1 g(x)\left(x^2 - 2xf(x)\right) dx = 0$ for every continuous g, and the fundamental lemma of the calculus of variations forces $x^2 - 2xf(x) = 0$, so $f(x) = x/2$ on $(0,1]$ and $f(0) = 0$ by continuity. It is correct, but it is overbuilt in two ways: a stationary point is not a maximum until you add the second variation $-\int_0^1 x g(x)^2 dx \le 0$, and you have spent the fundamental lemma on a problem with no derivative of f in it at all. Machinery you did not need.

3. **Guess the one parameter family $f = cx$ and optimise c.** *Cue:* the weights x^2 and x balance exactly when f scales like x. *Circuit:* reduce an infinite dimensional problem to a one dimensional one. Twenty seconds to the number $1/16$, and it proves only that the maximum is at least $1/16$. Indispensable as reconnaissance, worthless as a write up. Never confuse the two.

4. **Cauchy and Schwarz with the weight x.** *Cue:* J contains xf^2, so $\sqrt{x}f$ is the natural object, and $x^2 f = x^{3/2} \cdot \sqrt{x} f$. *Circuit:* split a product so that one factor squares to a given integral. You get

$$I(f) = \int_0^1 x^{3/2} \cdot \sqrt{x} f(x)\, dx \le \Big(\int_0^1 x^3 dx \Big)^{1/2} J(f)^{1/2} = \tfrac{1}{2}\sqrt{J(f)},$$

so with $t = \sqrt{J(f)} \ge 0$ we have $I - J \le t/2 - t^2 \le 1/16$. Complete, short, and honest. It ranks below the next route only because it needs two equality analyses stitched together: equality in Cauchy and Schwarz forces f proportional to x, and $t = 1/4$ then pins the constant to $1/2$.

5. **Complete the square pointwise, inside the integral.** *Cue:* the integrand is a quadratic in $f(x)$ with nonpositive leading coefficient, at each fixed x. *Circuit:* maximise under the integral sign when no derivative of the unknown appears. Six lines, one identity, one sign observation, one exhibited maximiser. This is the ideal solution.

The ideal solution

The maximum is $\boxed{\frac{1}{16}}$, attained only by $f(x) = x/2$.

For every real number y and every x, expanding the right hand side verifies the identity

$$x^2 y - x y^2 = \frac{x^3}{4} - x\Big(y - \frac{x}{2}\Big)^2.$$

Apply it with $y = f(x)$ for each $x \in [0,1]$. Since $x \ge 0$ on $[0,1]$, the subtracted term $x\big(f(x) - x/2\big)^2$ is nonnegative, so

$$x^2 f(x) - x f(x)^2 \le \frac{x^3}{4} \qquad \text{for every } x \in [0,1].$$

Both sides are continuous on $[0,1]$, so integrating preserves the inequality:

$$I(f) - J(f) = \int_0^1 \big(x^2 f(x) - x f(x)^2\big) dx \le \int_0^1 \frac{x^3}{4}\, dx = \frac{1}{16}.$$

The bound is attained. The function $f(x) = x/2$ is continuous on $[0,1]$ and makes the subtracted term identically zero, so for it $I(f) - J(f) = 1/16$. Hence the supremum is achieved and the maximum value is $1/16$.

Remark 20.11.1 (Uniqueness of the maximiser). Suppose $I(f) - J(f) = 1/16$. Subtracting the displayed inequality from the equality gives

$$\int_0^1 x\Big(f(x) - \frac{x}{2}\Big)^2 dx = 0.$$

The integrand is continuous and nonnegative on $[0,1]$, and a continuous nonnegative function with zero integral is identically zero. Hence $x\big(f(x) - x/2\big)^2 = 0$ for all x, so $f(x) = x/2$ for every $x \in (0,1]$, and $f(0) = 0$ follows from continuity at 0. So $f(x) = x/2$ is the unique maximiser, even though the objective never constrains the single value $f(0)$ directly.

Layer 1: WHAT

Block 1. Merge the two integrals into one integral of $x^2 f - x f^2$.

Block 2. Freeze x and read the integrand as a quadratic in the real number $f(x)$, with leading coefficient $-x \leq 0$.

Block 3. Complete the square: the pointwise maximum is $x^3/4$, attained at $f(x) = x/2$.

Block 4. Observe that the pointwise maximiser, the function $x \mapsto x/2$, is itself continuous, hence admissible. Therefore the pointwise optimum and the global optimum coincide and no variational machinery is needed.

Block 5. Integrate the pointwise bound to get $1/16$, exhibit the maximiser, and prove uniqueness from the vanishing of a continuous nonnegative integral.

Nominal against ideal. The nominal route reads "maximum over all continuous functions" and reaches for the calculus of variations, because that is the machine whose label matches the phrase. It then spends four lines on a perturbation argument, one lemma on the fundamental lemma, and one more line on the second variation, to reach a conclusion the ideal route reaches by expanding a bracket.

The bifurcation point is Block 4, and it is a single test: does the integrand contain f'? Here it does not. An integral of $\Phi(x, f(x))$ with no derivative of f has no coupling between different values of x, so the values $f(x)$ can be chosen independently, one x at a time. Maximising inside the integral is then legitimate, provided the resulting pointwise maximiser is an admissible function. If f' had appeared, the values would be coupled and the calculus of variations would be the correct tool. That single test is the reusable content of this problem.

Layer 2: HOW

Block 1. **Cue.** Two integrals, same interval, same variable, subtracted. **Why natural.** Linearity of the integral says a difference of integrals is the integral of the difference, and you always want one integrand rather than two because you can only inspect structure in an expression you can see whole. Nothing is lost and everything becomes visible. **Link to the next block.** With one integrand in front of you, the next question is what kind of object it is.

Block 2. **Cue.** $x^2 f(x) - x f(x)^2$: degree two in $f(x)$, degree at most two in x. **Why natural.** Read it as a polynomial in $f(x)$ with coefficients depending on x, because $f(x)$ is the unknown and x is the parameter. Once you do, it is $-xy^2 + x^2 y$ with $y = f(x)$, and the sign of the leading coefficient decides everything. On $[0,1]$ that coefficient is $-x \leq 0$, so the quadratic is concave and has a maximum. **Link to the next block.** A concave quadratic is maximised by completing the square, which is the one manipulation A level installs and which never stops paying.

Block 3. **Cue.** A concave quadratic in y with a parameter. **Why natural.** Completing the square converts "maximise" into "read off", and it does so with an identity rather than an inequality, which means no hypotheses and no error terms. The vertex sits at $y = x/2$ and the maximum value is $x^3/4$; both come out of the same line of algebra. **Link to the next block.** You now have a pointwise bound. The question is whether the pointwise bound is achievable simultaneously at every x by one admissible function.

Block 4. **Cue.** The pointwise argmax is $x \mapsto x/2$, and the admissible class is the continuous functions. **Why natural.** This is the step that decides which method the problem is. The pointwise maximisers form a function, and that function is continuous, so it lies in the class over which you are maximising. Hence the supremum of the integral equals the integral of the pointwise supremum. This is legitimate precisely because the integrand involves $f(x)$ and not $f'(x)$: with no derivative present, different values of x do not constrain each other, and the constraint of continuity is satisfied

for free by the argmax. **Link to the next block.** Nothing prevents the bound from being attained, so integrate it and evaluate.

Block 5. Cue. $\int_0^1 x^3/4\,dx$ and the phrase "find the maximum". **Why natural.** The word maximum, as opposed to supremum, obliges you to exhibit a function attaining the value. Producing $f(x) = x/2$ costs one sentence and converts a bound into an answer. The uniqueness statement costs one more sentence and uses the standard fact that a continuous nonnegative function with zero integral vanishes identically, which is worth including because it also disposes of the awkward point $x = 0$. **Link to the next block.** The value $1/16$ is both an upper bound and an attained value, so it is the maximum.

Layer 3: WHY

There are two truths beneath this route, and both are worth more than the problem.

The first is the pointwise principle. For a functional $F(f) = \int_a^b \Phi(x, f(x))\,dx$ in which no derivative of f appears, the values of f at different points are not coupled by anything except the admissibility class. Therefore

$$\sup_f F(f) \le \int_a^b \sup_y \Phi(x, y)\,dx,$$

always, with equality whenever the map $x \mapsto \operatorname{argmax}_y \Phi(x, y)$ is single valued and admissible. The calculus of variations exists to handle the opposite case, where f' appears and the values are coupled along the interval, so that you cannot move one value without moving its neighbours. Learn to run the test first: look for f' in the integrand. Absent means pointwise; present means Euler and Lagrange.

The second is the quadratic structure, which is best seen in the language of inner products. On $[0, 1]$ define the weighted inner product $\langle u, v\rangle = \int_0^1 x\,u(x)v(x)\,dx$, with norm $\|u\|^2 = \int_0^1 xu(x)^2dx$, and let $g(x) = x$. Then $J(f) = \|f\|^2$ and $I(f) = \int_0^1 x \cdot f(x) \cdot x\,dx = \langle f, g\rangle$, so the problem reads: maximise $\langle f, g\rangle - \|f\|^2$. In any inner product space,

$$\langle f, g\rangle - \|f\|^2 = \frac{\|g\|^2}{4} - \left\|f - \frac{g}{2}\right\|^2 \le \frac{\|g\|^2}{4},$$

with equality exactly at $f = g/2$. That is one identity covering every problem of this shape, and here it gives $\|g\|^2 = \int_0^1 x^3dx = 1/4$ and the answer $1/16$ immediately. The pointwise completion of the square and this Hilbert space identity are the same computation seen at two zoom levels, which is why the ideal route feels like a triviality once you have seen it: it is a triviality, in the right coordinates.

Now the design of the question, which is where the examiners hid the real difficulty. Write the general integrand as $\Phi(x, y) = b(x)y - a(x)y^2$ with $a \ge 0$. The pointwise maximum is $b(x)^2/(4a(x))$ at $y = b(x)/(2a(x))$, so the answer is $\int_0^1 \frac{b(x)^2}{4a(x)}\,dx$ whenever that makes sense. Here $a(x) = x$ vanishes at the endpoint, but $b(x) = x^2$ vanishes faster, so $b^2/(4a) = x^3/4$ is continuous and integrable and the pointwise maximiser $x/2$ is continuous. Break that balance and the problem changes character entirely: for $\int_0^1 \big(f(x) - xf(x)^2\big)dx$ we have $b^2/(4a) = 1/(4x)$, which is not integrable, and indeed taking the continuous functions $f_M(x) = \min\{1/(2x), M\}$ gives values at least $\frac{1}{4}\log(2M)$, so the supremum is infinite and there is no maximum. So the choice of the weights x^2 and x was not decoration; it was the condition that makes the answer finite and attained. Reading a question's design is how you learn what the setter was protecting against.

Revolving concepts

Completing the square. For $a \neq 0$, $ay^2 + by + c = a(y + b/2a)^2 + c - b^2/4a$, so a concave quadratic ($a < 0$) has maximum $c - b^2/4a$ at $y = -b/2a$. Here it is applied with x as a silent parameter, which is the only new habit required. See Book 1, field: Polynomials, topic: quadratics and the vertex.

Weighted inner products and the L^2 norm. For a weight $w \geq 0$ on $[a, b]$, $\langle u, v\rangle_w = \int wuv$ is an inner product on continuous functions when $w > 0$ on the interior, with the Cauchy and Schwarz inequality $|\langle u, v\rangle_w| \leq \|u\|_w \|v\|_w$ and equality exactly for proportional u, v. The identity $\langle f, g\rangle - \|f\|^2 = \|g\|^2/4 - \|f - g/2\|^2$ solves every "linear minus quadratic" maximisation in one line. See Book 1, field: Real analysis, topic: inner product spaces.

The calculus of variations. For $F(f) = \int \Phi(x, f, f')dx$ the stationarity condition is the Euler and Lagrange equation $\frac{d}{dx}(\partial\Phi/\partial f') = \partial\Phi/\partial f$. When Φ does not involve f' this degenerates to $\partial\Phi/\partial f = 0$, which is exactly the pointwise maximisation. The fundamental lemma of the calculus of variations, that a continuous h with $\int hg = 0$ for all continuous g is identically zero, is what converts the first variation into a pointwise equation. See Book 1, field: Calculus and integrals, topic: variational problems.

A continuous nonnegative function with zero integral vanishes. If $h \geq 0$ is continuous on $[a, b]$ and $\int_a^b h = 0$ then $h \equiv 0$; otherwise $h(x_0) = \varepsilon > 0$ gives an interval of positive length on which $h > \varepsilon/2$, forcing a positive integral. This is the standard tool for turning an equality case into pointwise information. See Book 1, field: Real analysis, topic: positivity and integrals.

Monotonicity of the integral. If $u \leq v$ pointwise on $[a, b]$ and both are integrable then $\int u \leq \int v$. It is the only step in the ideal solution that moves from local to global, and it is worth naming as such: the entire proof is one pointwise inequality plus one application of monotonicity.

No recursion here, and that is informative. This problem contains no sequence, no induction, no telescoping and no self similar structure to generalise. That absence is a signal: a functional with no recursive structure and no derivative of the unknown is a one shot pointwise problem, and any method you reach for that builds an iteration or an approximating sequence is fighting the problem rather than reading it.

Circuit Bank

- **WHEN** an integral functional contains f but no f' **DO** maximise the integrand pointwise with x frozen, then check the pointwise maximiser is an admissible function **BECAUSE** with no derivative present nothing couples different values of x, so the supremum of the integral is the integral of the supremum whenever the argmax is admissible

- **WHEN** the objective is linear in the unknown minus quadratic in it with a nonnegative weight **DO** write it as $\|g/2\|^2 - \|f - g/2\|^2$ in the weighted inner product **BECAUSE** in any inner product space $\langle f, g\rangle - \|f\|^2$ is maximised at $f = g/2$ with value $\|g\|^2/4$, which hands you both the answer and the unique maximiser

- **WHEN** a weight in the objective vanishes at an endpoint **DO** check that the pointwise maximum $b^2/(4a)$ is still integrable there **BECAUSE** that integrability is exactly the line between a finite attained maximum and an infinite supremum, and it is where the setter did the design work

- **WHEN** the question says maximum rather than supremum **DO** exhibit the maximiser and verify it lies in the stated class **BECAUSE** a bound alone answers a different question, and the attainment sentence costs one line

Backtesting

1. First useful cue: two integrals over the same interval, subtracted, giving one integrand that is quadratic in $f(x)$ with leading coefficient $-x \leq 0$.
2. Method the expression suggested: complete the square in $f(x)$ with x as a parameter, then integrate the resulting pointwise bound.
3. Where you would hesitate, and the thought to reinforce: at the claim that maximising inside the integral is allowed. Reinforce the test rather than the anxiety: no f' in the integrand means no coupling between different x, so pointwise optimisation is exact provided the argmax is admissible, and here it is the continuous function $x/2$.
4. The trap the question sets: the phrase "over all such functions", which baits you into the calculus of variations, and the degenerate point $x = 0$, where the coefficient of $f(x)^2$ vanishes and an unwary equality argument leaves $f(0)$ undetermined. Continuity closes that gap.
5. What makes you recognise it faster next time: an integrand that is a polynomial in $f(x)$ alone. That is a pointwise problem wearing variational clothes.
6. The reusable decision rule: for $\int \big(b(x)f - a(x)f^2\big)dx$ with $a \geq 0$, the maximum is $\int b^2/(4a)$ at $f = b/(2a)$, valid whenever that function is admissible and the integral converges.

Mirror drills

1. Find the maximum of $\int_0^1 \big(xf(x) - f(x)^2\big)dx$ over continuous f. *Answer:* $b^2/(4a) = x^2/4$, so the maximum is $\int_0^1 x^2/4\,dx = 1/12$, attained at $f(x) = x/2$.
2. Find the maximum of $\int_0^1 \big(x^3 f(x) - xf(x)^2\big)dx$ over continuous f. *Answer:* $b^2/(4a) = x^5/4$, so the maximum is $1/24$, attained at $f(x) = x^2/2$.
3. Show that $\int_0^1 \big(f(x) - xf(x)^2\big)dx$ has no maximum over continuous f. *Answer:* here $b^2/(4a) = 1/(4x)$ is not integrable at 0; take $f_M(x) = \min\{1/(2x), M\}$, which is continuous, and the integral is at least $\int_{1/(2M)}^1 \frac{dx}{4x} = \frac{1}{4}\log(2M) \to \infty$.

20.12 B6. Asymptotics of a self slowing recursion

Let k be an integer greater than 1. Suppose $a_0 > 0$, and define

$$a_{n+1} = a_n + \frac{1}{\sqrt[k]{a_n}}$$

for $n > 0$. Evaluate

$$\lim_{n\to\infty} \frac{a_n^{k+1}}{n^k}.$$

Read it out loud

This is a differential equation that has been discretised and handed to you as a sequence. The increment $a_{n+1} - a_n$ depends only on the current value, so the process is autonomous, and the increment $a_n^{-1/k}$ decreases as a_n grows, so the sequence is increasing and slowing. Every question about such a sequence is a question about the balance between those two facts. The fields wired in are real analysis (limits of sequences, Cesaro means) and the asymptotics of recursions, with a separable first order ODE as the guiding light.

Read the target next, because the examiners have already told you the answer's shape. They ask for $\lim a_n^{k+1}/n^k$, which is a finite nonzero limit only if a_n grows like $n^{k/(k+1)}$. So the growth exponent is a gift and you never have to discover it. More than that: rewriting $a_n^{k+1}/n^k = \left(a_n^{(k+1)/k}/n\right)^k$ shows that the quantity actually being controlled is $a_n^{(k+1)/k}$ divided by n. The exponent $(k+1)/k$ is being pointed at, and it is the exponent of the substitution.

Now do the twenty second reconnaissance that makes everything else routine. Replace the recursion by the differential equation $y' = y^{-1/k}$, which is what "increment equals a function of the current value" means in continuous time. Separate: $y^{1/k}\,dy = dx$, so $\frac{k}{k+1}y^{(k+1)/k} = x + C$, so $y^{(k+1)/k} \sim \frac{k+1}{k}x$ and $y^{k+1}/x^k \to \left(\frac{k+1}{k}\right)^k$. You now have the answer, and you also have the substitution: the ODE separated into the variable $y^{(k+1)/k}$, so that is the variable in which the recursion will behave. This is the central point of the whole problem and it is not a guess; the substitution is read off the separation.

Two small blemishes in the statement deserve a sentence and no more. The recursion is written "for $n > 0$", which leaves a_1 undefined; it is plainly intended for all $n \geq 0$. And the hypothesis that k is an integer greater than 1 is never used: everything below works for any real $k > 0$.

Approaches, ranked worst to best

1. **Compute numerically for small k and guess.** *Cue:* a limit with a free parameter k. *Circuit:* tabulate and pattern match. For $k = 2$ you get 2.25, and recognising that as $(3/2)^2$ requires you to already suspect the form. Zero marks on a B6, and it does not even suggest a method.

2. **Bootstrap two sided bounds on a_n directly.** *Cue:* the sequence is increasing with shrinking increments. *Circuit:* prove $c_1 n^{k/(k+1)} \leq a_n \leq c_2 n^{k/(k+1)}$, then improve the constants. This works, and it is essentially the official second solution: convexity gives a lower bound for $a_n^{(k+1)/k}$, that lower bound feeds back into the increment to give an upper bound, and the two constants meet. But you must run the bootstrap at least twice and carry explicit constants through every inequality, and you must recognise that the loop converges. Correct, expensive, and error prone under time pressure.

3. **Guess the answer and control the error sequence.** *Cue:* the limit is a clean constant, so posit $a_n \approx Ln^{k/(k+1)}$. *Circuit:* set $b_n = a_n - Ln^{k/(k+1)}$ and show b_n stays bounded. This is the official third solution. It proves more than you were asked, namely a second order statement, and it

costs three separate Taylor estimates plus an $O(n^{-2})$ summation. On a paper where B6 is the last thing you reach, this is the wrong trade.

4. **Substitute $b_n = a_n^{(k+1)/k}$ and bound the increment by Taylor with remainder.** *Cue:* the exponent visible in the target. *Circuit:* make the increments asymptotically constant, then estimate the error. The official first solution. Correct and short, but it invokes Taylor's theorem with an explicit remainder bound in order to prove a statement that is only a limit. You are paying for an error term you will never use.

5. **Substitute $b_n = a_n^{(k+1)/k}$, factor the recursion into $b_{n+1} = b_n(1 + 1/b_n)^{(k+1)/k}$, read the increment limit as a derivative, then apply Cesaro.** *Cue:* the ODE $y' = y^{-1/k}$ separates exactly into the variable $y^{(k+1)/k}$. *Circuit:* change to the variable in which the recursion becomes "add a constant", then convert increments into growth. No remainder terms, no bootstrap, no constants to chase. One substitution, one difference quotient, one standard lemma. This is the ideal solution.

The ideal solution

Write $m = \dfrac{k+1}{k} > 1$. The answer is $\boxed{\left(\dfrac{k+1}{k}\right)^k}$.

Step 1: the sequence increases to infinity. Since $a_0 > 0$ and $a_{n+1} = a_n + a_n^{-1/k}$, induction gives $a_n > 0$ for all n, so the increments $a_n^{-1/k}$ are positive and (a_n) is strictly increasing. Suppose it were bounded, say $a_n \to L$ with $0 < a_0 \le L < \infty$. A convergent sequence has $a_{n+1} - a_n \to 0$, but $a_{n+1} - a_n = a_n^{-1/k} \to L^{-1/k} > 0$, a contradiction. Hence (a_n) is increasing and unbounded, so $a_n \to \infty$.

Step 2: the substitution makes the increments constant. Put $b_n = a_n^m$. Since $a_n^{-1/k} = a_n \cdot a_n^{-(k+1)/k} = a_n \cdot a_n^{-m}$, the recursion factors as

$$a_{n+1} = a_n\big(1 + a_n^{-m}\big),$$

and raising to the power m gives

$$b_{n+1} = a_n^m\big(1 + a_n^{-m}\big)^m = b_n\Big(1 + \frac{1}{b_n}\Big)^m.$$

Therefore, writing $t_n = 1/b_n$,

$$b_{n+1} - b_n = b_n\Big[\Big(1 + \frac{1}{b_n}\Big)^m - 1\Big] = \frac{(1+t_n)^m - 1}{t_n}.$$

By Step 1, $b_n = a_n^m \to \infty$, so $t_n \to 0^+$. The function $t \mapsto (1+t)^m$ is differentiable at $t = 0$ with derivative m, and the displayed quotient is exactly its difference quotient at 0. Hence

$$\lim_{n\to\infty}(b_{n+1} - b_n) = m = \frac{k+1}{k}.$$

No remainder estimate is needed, because a derivative is precisely the limit of this quotient.

Step 3: from increments to growth.

Lemma 20.12.1 (Cesaro mean)**.** *If $x_i \to c$ then $\frac{1}{n}\sum_{i=1}^n x_i \to c$.*

Proof. Let $\varepsilon > 0$. Choose N with $|x_i - c| < \varepsilon/2$ for all $i > N$, and put $C = \sum_{i=1}^N |x_i - c|$, a fixed number. For $n > N$,

$$\Big|\frac{1}{n}\sum_{i=1}^n x_i - c\Big| \le \frac{1}{n}\sum_{i=1}^n |x_i - c| \le \frac{C}{n} + \frac{n-N}{n}\cdot\frac{\varepsilon}{2} < \frac{C}{n} + \frac{\varepsilon}{2},$$

which is less than ε as soon as $n > 2C/\varepsilon$. □

Apply the lemma to $x_i = b_i - b_{i-1}$, which converges to m by Step 2. The sum telescopes, so

$$\frac{b_n - b_0}{n} = \frac{1}{n}\sum_{i=1}^{n}(b_i - b_{i-1}) \longrightarrow m,$$

and since $b_0/n \to 0$ we get $b_n/n \to m$.

Step 4: conclude. Because $mk = k+1$,

$$\frac{a_n^{k+1}}{n^k} = \frac{\left(a_n^m\right)^k}{n^k} = \left(\frac{b_n}{n}\right)^k \longrightarrow m^k = \left(\frac{k+1}{k}\right)^k,$$

using continuity of $t \mapsto t^k$. This is the required limit.

Remark 20.12.2. Nothing above used that k is an integer, or that $k > 1$; the argument holds for every real $k > 0$, and for $k = 1$ it gives $\lim a_n^2/n = 2$ for the recursion $a_{n+1} = a_n + 1/a_n$. The answer written as $\left(1 + 1/k\right)^k$ increases with k and tends to e, and the growth exponent $k/(k+1)$ tends to 1, both reflecting the fact that a larger k makes the increment $a_n^{-1/k}$ decay more slowly and the sequence closer to linear.

Layer 1: WHAT

Block 1. Read the recursion as the discretisation of $y' = y^{-1/k}$, separate it, and obtain both the answer $\left(\frac{k+1}{k}\right)^k$ and the substitution exponent $(k+1)/k$.

Block 2. Prove $a_n \to \infty$, which costs three lines and is the only hypothesis every later step needs.

Block 3. Set $b_n = a_n^{(k+1)/k}$ and factor a_n out of the recursion, so that the recursion for b is autonomous and self contained: $b_{n+1} = b_n(1 + 1/b_n)^m$.

Block 4. Recognise $b_{n+1} - b_n = \left((1+t)^m - 1\right)/t$ with $t = 1/b_n \to 0$ as a difference quotient, so the increment limit is a derivative, not an estimate.

Block 5. Convert "the increments tend to m" into "b_n/n tends to m" by telescoping and the Cesaro mean lemma.

Block 6. Raise to the power k and read off the answer.

Nominal against ideal. The nominal route keeps the sequence in the variable it was handed, guesses $a_n \approx Cn^{k/(k+1)}$, and tries to prove that by induction with explicit inequalities. It can be made to work, but every line carries constants, every constant has to be improved by a second pass, and any slip in a direction of an inequality is invisible until the constants fail to meet.

The bifurcation point is Block 3, and it is the decision to change variable rather than to estimate. The zombie route estimates a_n; the ideal route changes coordinates so that there is nothing left to estimate. Name the principle in the form you will reuse: for $a_{n+1} = a_n + f(a_n)$, the right variable is $F(a) = \int \frac{da}{f(a)}$, because in that variable the recursion becomes "add approximately 1", and "add exactly 1" is the only recursion whose asymptotics are free.

Layer 2: HOW

Block 1. Cue. $a_{n+1} - a_n$ is a function of a_n alone, and the question asks for a limit of a_n^{k+1}/n^k. **Why natural.** An autonomous increment is a discrete derivative, so the continuous shadow $y' = y^{-1/k}$ is not an analogy but the leading order behaviour, and it is separable, which is the easiest class of ODE there is. The separation integrates $y^{1/k}$, producing $y^{(k+1)/k}$, which is exactly the exponent hidden in the requested ratio. Two independent signals point at the same power, so the substitution is forced rather than inspired. **Link to the next block.** You know the answer and the substitution; what remains is to make the argument discrete and rigorous.

Block 2. **Cue.** A positive increasing sequence with no a priori bound. **Why natural.** Every later step is an asymptotic statement, and asymptotics are meaningless unless $a_n \to \infty$. The cheapest proof is the standard one: an increasing sequence either diverges or converges, and if it converged its increments would tend to zero, whereas here they tend to a positive number. Notice this argument uses only that $t \mapsto t^{-1/k}$ is continuous and positive at L, so it is reusable verbatim for any positive increment function. **Link to the next block.** With $a_n \to \infty$ in hand, any expression tending to zero in a_n may be treated as a small parameter.

Block 3. **Cue.** The exponent $(k+1)/k$, delivered by the separation and by the target. **Why natural.** Do not raise the recursion to the power m blindly; first factor a_n out of the right hand side, because $a_n^{-1/k} = a_n \cdot a_n^{-m}$ turns the additive recursion into a multiplicative one, $a_{n+1} = a_n(1 + a_n^{-m})$. Multiplicative recursions survive being raised to a power, additive ones do not. After raising, $a_n^{-m} = 1/b_n$, so the new recursion mentions b_n and nothing else. That closure is the point: the recursion for b is autonomous, and its increment involves only $1/b_n$. **Link to the next block.** The increment is now an explicit function of one small quantity, so take its limit.

Block 4. **Cue.** The shape $\big((1+t)^m - 1\big)/t$ with $t \to 0$. **Why natural.** This is the difference quotient of $t \mapsto (1+t)^m$ at $t = 0$, so its limit is the derivative m by definition. Recognising it as such removes the need for Taylor's theorem with remainder entirely; a remainder bound would be needed only if you wanted a rate, and you do not. Train the reflex: whenever a limit has the form $(\varphi(t) - \varphi(0))/t$ with $t \to 0$, stop estimating and differentiate. **Link to the next block.** Increments converge, so the sequence itself grows linearly, provided you have a theorem that says so.

Block 5. **Cue.** A sequence whose consecutive differences converge. **Why natural.** A sequence is the telescoping sum of its increments, so b_n/n is the average of the first n increments up to the vanishing term b_0/n. Averages preserve limits, which is the Cesaro mean lemma, and it is worth proving in three lines rather than citing, both because a grader may want it and because the proof is the same ε split you use everywhere. This is the special case $b_n = n$ of the Stolz and Cesaro theorem. **Link to the next block.** You have $b_n/n \to m$, and the requested expression is a fixed power of b_n/n.

Block 6. **Cue.** $a_n^{k+1} = \big(a_n^m\big)^k$ because $mk = k+1$. **Why natural.** The problem asked for a_n^{k+1}/n^k rather than $a_n^{(k+1)/k}/n$ purely to disguise the substitution; undoing the disguise is one line, and continuity of $t \mapsto t^k$ transports the limit. **Link to the next block.** Done, with the answer in the form $\big(1 + 1/k\big)^k$.

Layer 3: WHY

The mathematical truth here is that the ODE heuristic stops being a heuristic the moment you name the change of variable, and it is worth stating the general theorem because it swallows the entire problem class.

Proposition 20.12.3. *Let $f : (0,\infty) \to (0,\infty)$ be decreasing, let $a_0 > 0$, and let $a_{n+1} = a_n + f(a_n)$. Suppose $a_n \to \infty$ and $f(a + f(a))/f(a) \to 1$ as $a \to \infty$. Define $F(a) = \int_{a_0}^{a} \frac{dt}{f(t)}$. Then $F(a_n)/n \to 1$.*

Proof. $F(a_{n+1}) - F(a_n) = \int_{a_n}^{a_n + f(a_n)} \frac{dt}{f(t)}$. On that interval of length $f(a_n)$, monotonicity of f gives $f(a_n + f(a_n)) \le f(t) \le f(a_n)$, so

$$1 = \frac{f(a_n)}{f(a_n)} \le F(a_{n+1}) - F(a_n) \le \frac{f(a_n)}{f(a_n + f(a_n))}.$$

The right hand side tends to 1 by hypothesis, so the increments of $F(a_n)$ tend to 1, and the Cesaro mean lemma gives $F(a_n)/n \to 1$. □

Apply this with $f(a) = a^{-1/k}$: then $F(a) = \frac{k}{k+1}\left(a^{(k+1)/k} - a_0^{(k+1)/k}\right)$ and $f(a + f(a))/f(a) = (1 + a^{-(k+1)/k})^{-1/k} \to 1$, so $\frac{k}{k+1}a_n^{(k+1)/k}/n \to 1$, which is Step 3 again. The proposition is worth more than the problem: it tells you that for $a_{n+1} = a_n + e^{-a_n}$ you get $e^{a_n} \sim n$, hence $a_n \sim \log n$, and for $a_{n+1} = a_n + a_n^{-p}$ you get $a_n^{p+1} \sim (p+1)n$, with no new work in either case.

The discernment mechanism, the thing that decides between estimating and substituting, has three signals and you should be able to name all three. First, the increment is a function of the current value alone, which is what makes an ODE comparison legitimate rather than decorative. Second, the increment function is monotone, which is exactly the hypothesis the integral squeeze in the proposition needs; if f oscillated, the squeeze would fail and you would be back to estimating. Third, the question supplied the normalisation a_n^{k+1}/n^k, which tells you which power of a_n is the natural variable, so you are being handed the change of coordinates. When all three are present, never estimate. Change variable and let the recursion become trivial.

There is a second, smaller truth worth extracting: the difference between needing a rate and needing a limit. The official first solution invokes Taylor's theorem with remainder to bound $\left|a_{n+1}^m - a_n^m - m\right|$ by a multiple of a_n^{-m}. That bound is true and it is more than the problem asks, since you only need the difference to converge, and convergence of $\left((1+t)^m - 1\right)/t$ is the definition of a derivative. Every time you reach for a quantitative estimate, ask whether the qualitative statement suffices; if it does, the qualitative route is shorter and has fewer places to make an arithmetic slip. That instinct is worth several marks a paper.

Knowledge gaps this problem exposes

Say plainly what must be installed before this problem is even approachable, because pretending otherwise wastes your training time. You need the Cesaro mean lemma and preferably the Stolz and Cesaro theorem it generalises to; neither is in the A level or Further Maths syllabus, and without one of them you cannot get from "increments converge" to "the sequence is asymptotically linear". You need the derivative as a limit of difference quotients used in reverse, that is, recognising an unfamiliar quotient as a derivative you already know. You need separable first order ODEs, which you have, but used as an asymptotic oracle for a discrete process, which you do not. And you need comfort with the idea that a change of variable can be chosen so that a recursion becomes trivial, rather than being chosen to simplify an expression. That last one is a habit, not a theorem, and it is the one that takes longest to install.

Revolving concepts

Monotone sequences. An increasing sequence either converges or tends to infinity, and a convergent sequence has increments tending to zero. Together these give the standard divergence test used in Step 1. See Book 1, field: Sequences and recurrences, topic: monotone convergence.

The derivative as a limit of difference quotients. $\varphi'(0) = \lim_{t\to 0}\left(\varphi(t) - \varphi(0)\right)/t$. Used forwards this defines the derivative; used backwards it evaluates limits such as $\left((1+t)^m - 1\right)/t \to m$ with no expansion required. See Book 1, field: Calculus and integrals, topic: differentiation from first principles.

Cesaro means and the Stolz and Cesaro theorem. If $x_i \to c$ then the averages converge to c. The general theorem: if (B_n) is positive, strictly increasing and unbounded and $(A_{n+1} - A_n)/(B_{n+1} - B_n) \to L$, then $A_n/B_n \to L$; the case $B_n = n$ is the mean lemma. This is the discrete analogue of l'Hopital's rule, and that analogy is the right way to remember when to reach for it. See Book 1, field: Real analysis, topic: Cesaro summation.

Separable first order ODEs. $y' = g(y)$ separates as $\int dy/g(y) = x + C$. The antiderivative $F(y) = \int dy/g(y)$ is the coordinate in which the flow has unit speed, which is exactly why it is the right substitution for the discrete problem too. See Book 1, field: Calculus and integrals, topic: separable equations.

The general recursion, generalised. The recursion $a_{n+1} = a_n + f(a_n)$ with f positive and decreasing is the whole family this problem lives in, and the proposition above is its general solution: with $F(a) = \int^a dt/f(t)$ you get $F(a_n) \sim n$, that is, $a_n \sim F^{-1}(n)$. Instances to keep on hand: $f(a) = a^{-p}$ gives $a_n \sim \big((p+1)n\big)^{1/(p+1)}$; $f(a) = e^{-a}$ gives $a_n \sim \log n$; $f(a) = 1/(a \log a)$ gives $\frac{1}{2}a_n^2 \log a_n \sim n$. The same idea in reverse handles decreasing sequences such as $a_{n+1} = a_n - a_n^2$, where $F(a) = -1/a$ gives $1/a_n \sim n$, hence $a_n \sim 1/n$; that variant appears on the Putnam and on olympiads at least as often as the increasing one, so install both directions. See Book 1, field: Sequences and recurrences, topic: asymptotics of first order recursions.

Circuit Bank

- **WHEN** a recursion has the form $a_{n+1} = a_n + f(a_n)$ with f monotone **DO** write the ODE $y' = f(y)$, separate it, and use $F(a) = \int da/f(a)$ as the new variable **BECAUSE** in that variable the recursion becomes "add approximately 1", and adding a constant is the only recursion whose asymptotics come for free
- **WHEN** the consecutive differences of a sequence converge **DO** conclude the sequence divided by n converges to the same limit **BECAUSE** the sequence is the telescoping sum of its increments and Cesaro averaging preserves limits, which is the case $B_n = n$ of Stolz and Cesaro
- **WHEN** the question hands you a normalisation such as a_n^{k+1}/n^k **DO** read the growth exponent and the substitution straight off it before doing any work **BECAUSE** a finite nonzero limit forces the growth rate, so the examiner has already told you which power of a_n is the natural variable
- **WHEN** a limit has the shape $(\varphi(t) - \varphi(0))/t$ with $t \to 0$ **DO** call it a derivative rather than expanding **BECAUSE** recognising a difference quotient removes every remainder estimate, and you only need a rate if the problem asks for one
- **WHEN** an additive recursion must be raised to a power **DO** factor the leading term out first to make it multiplicative **BECAUSE** powers pass through products but not through sums, so $a_{n+1} = a_n(1 + a_n^{-m})$ survives being raised to the power m while $a_n + a_n^{-1/k}$ does not

Backtesting

1. First useful cue: the increment depends only on a_n, so the sequence is a discretised separable ODE, and the requested ratio names the exponent $(k+1)/k$.
2. Method the expression suggested: substitute $b_n = a_n^{(k+1)/k}$, the variable into which $y' = y^{-1/k}$ separates, and show its increments converge.
3. Where you would hesitate, and the thought to reinforce: at raising the recursion to a fractional power, which feels illegitimate on a sum. Reinforce the fix rather than the fear: factor a_n out first so the recursion is multiplicative, and then the power passes through cleanly.
4. The trap the question sets: the exponents. Writing the target as a_n^{k+1}/n^k rather than as a power of $a_n^{(k+1)/k}/n$ hides the substitution, and mishandling $mk = k+1$ at the last step throws away the whole solution.
5. What makes you recognise it faster next time: any recursion of the form "current value plus a decreasing function of the current value". That shape means change variable by $\int da/f(a)$, always.
6. The reusable decision rule: for $a_{n+1} = a_n + f(a_n)$ with f positive, decreasing, and satisfying $f(a + f(a))/f(a) \to 1$, you have $F(a_n) \sim n$ where $F(a) = \int^a dt/f(t)$.

Mirror drills

1. Let $a_0 > 0$ and $a_{n+1} = a_n + 1/a_n$. Evaluate $\lim a_n^2/n$. *Answer:* $F(a) = a^2/2$, so $a_n^2/(2n) \to 1$ and the limit is 2, which is the case $k = 1$ of the problem.

2. Let $a_{n+1} = a_n + e^{-a_n}$ with a_0 real. Find the asymptotic behaviour of a_n. *Answer:* increments are positive and $a_n \to \infty$ by the same divergence test, so with $F(a) = e^a$ you get $e^{a_n}/n \to 1$, that is $a_n - \log n \to 0$.

3. Let $x_0 \in (0, 1)$ and $x_{n+1} = x_n - x_n^2$. Find $\lim n x_n$. *Answer:* x_n decreases to 0, and $1/x_{n+1} - 1/x_n = 1/(1 - x_n) \to 1$, so by the Cesaro mean lemma $1/(n x_n) \to 1$ and the limit is 1. Same circuit, decreasing direction.
