If $f(q)$ were equal to $f(p)$ the left side would be 0, a contradiction. Therefore $f(p) \neq f(q)$ whenever $p \neq q$, which is to say f is one-to-one. ■

Two remarks that a full-marks script may state in one line each. First, only the symmetric part of Df ever appears, since $v^{\mathsf{T}} Df\, v = v^{\mathsf{T}} \left(\frac{1}{2}(Df + (Df)^{\mathsf{T}})\right) v$; this is why the hypothesis was written with $\frac{1}{2}(f_{12} + f_{21})$ rather than with f_{12} and f_{21} separately. Second, the positivity of f_{12} and f_{21} was never used, and the positivity of f_{11} and f_{22} is nearly free: the hypothesis forces $f_{11}f_{22} > \frac{1}{4}(f_{12} + f_{21})^2 \geq 0$, so f_{11} and f_{22} are nonzero with a common sign, which by continuity and connectedness of $\mathbb{R}^2$ is constant; if that sign were negative you would apply the argument to $-f$, which is injective if and only if f is.

Layer 1: WHAT

Block 1. Name the target: take arbitrary $p \neq q$ and aim to prove $f(p) \neq f(q)$.

Block 2. Read the hypothesis as positive definiteness of the symmetrised Jacobian $S = \frac{1}{2}(Df + (Df)^{\mathsf{T}})$.

Block 3. Prove the pointwise Lemma: $v^{\mathsf{T}} S v > 0$ for $v \neq 0$, by multiplying by f_{11} and completing the square.

Block 4. Build the scalar function $g(t) = v \cdot f(p + tv)$ on the segment from p to q, with $v = q - p$.

Block 5. Differentiate: $g'(t) = v^{\mathsf{T}} Df(\gamma(t)) v = Q_{\gamma(t)}(v) > 0$.

Block 6. Conclude $g(1) > g(0)$, that is $(q-p) \cdot (f(q) - f(p)) > 0$, so the images differ.

The nominal route stops at Block 2 with the words "so the Jacobian determinant is positive and f is locally invertible", then attempts to patch local invertibility into global invertibility by a connectedness or covering space argument that either fails or quietly assumes what it is proving. The bifurcation point is the sentence after you compute $\det Df > 0$. At that line you either reach for the inverse function theorem, which is a local statement and cannot produce a global conclusion, or you reach for the segment from p to q, which is a global object and can. The physical tell that the second choice is the right one: the inverse function theorem does not use the difference between $\frac{1}{4}(f_{12} + f_{21})^2$ and $f_{12}f_{21}$, and an unused hypothesis means a wrong route.

Layer 2: HOW

Block 1. Cue. The word "one-to-one". **Why natural.** Injectivity is by definition a statement about a *pair* of points. Writing p and q on the page immediately, before touching the hypothesis, turns an abstract property into two concrete objects you can join, and the only canonical thing you can do with two points of $\mathbb{R}^2$ is join them by a segment. This is not a guess; it is the only construction

available. **Link to the next block.** Now you need a hypothesis that says something about the segment, so look at what the hypothesis controls: derivatives, that is, infinitesimal behaviour along directions.

Block 2. Cue. The expression $\frac{1}{4}(f_{12}+f_{21})^2$ with an average inside a square. **Why natural.** A quadratic form $Av_1^2+Bv_1v_2+Cv_2^2$ is positive definite exactly when $A>0$ and $4AC-B^2>0$, and $4AC-B^2>0$ is $AC-\frac{1}{4}B^2>0$. The problem has literally printed the definiteness criterion for the form with $A=f_{11}$, $B=f_{12}+f_{21}$, $C=f_{22}$. The reason the cross term appears as a sum rather than as a product is that a quadratic form only sees the symmetric part of a matrix, since $v^{\mathsf{T}}Mv$ is a scalar and equals its own transpose $v^{\mathsf{T}}M^{\mathsf{T}}v$. So the moment you see $f_{12}+f_{21}$ you should be looking for the expression $v^{\mathsf{T}}Df\,v$ somewhere in your future. **Link to the next block.** The hypothesis is about $v^{\mathsf{T}}Df\,v$, so the solution must produce that expression; the only way a Jacobian gets squeezed between two copies of the same vector is a directional derivative in the direction v, dotted again with v.

Block 3. Cue. A quadratic in two variables that must be shown positive. **Why natural.** Completing the square is the only method that proves positivity of a quadratic form with an explicit certificate rather than an appeal. Multiply by A rather than dividing by it, because that keeps everything polynomial and makes the equality case transparent: the identity $A\,Q=(Av_1+\frac{1}{2}Bv_2)^2+\Delta v_2^2$ can be checked by eye. The equality analysis is where the strictness comes from, so do not skip it: you need $Q>0$, not $Q\geq 0$. **Link to the next block.** With pointwise positivity in hand, you can afford to let the point move along a path, since the bound holds at every point.

Block 4. Cue. You have two points, a hypothesis about derivatives, and a need for a global conclusion. **Why natural.** The mean value theorem does not exist for vector valued functions: there is no c with $f(q)-f(p)=Df(c)(q-p)$ in general, because the two components would need the same c. The repair is universal and worth installing permanently: pair with a fixed vector to make a scalar function of one real variable, then use one-variable calculus. Which fixed vector? Pair with $v=q-p$ itself, because that is the only vector in the problem and because it makes g' equal to the quadratic form $v^{\mathsf{T}}Df\,v$ that the hypothesis controls. Pairing with any other vector w would give $w^{\mathsf{T}}Df\,v$, a bilinear expression with no sign information. **Link to the next block.** Now differentiate, carefully.

Block 5. Cue. A composition of a C^1 map with a straight line. **Why natural.** Continuity of the partial derivatives is stated in the problem for a reason: existence of partial derivatives alone does not imply differentiability, and the chain rule needs differentiability, not just partials. So the phrase "with continuous partial derivatives" in the statement is not padding, it is the licence for this step, and a full-marks script says so in half a sentence. **Link to the next block.** Positivity of g' on $[0,1]$ gives strict monotonicity of g by the one-variable mean value theorem.

Block 6. Cue. $g(1)>g(0)$. **Why natural.** Unwind the definition: $g(1)-g(0)=v\cdot(f(q)-f(p))=(q-p)\cdot(f(q)-f(p))$. Equality of the images would make this zero. So injectivity drops out, and notice you have proved something stronger than asked, namely strict monotonicity of f as an operator. Stating the stronger conclusion costs nothing and shows the grader you know what you proved. **Link to the next block.** Done.

Layer 3: WHY

The mathematical truth is a single sentence: *a strictly monotone map is injective*, where strictly monotone means $\langle f(q)-f(p),\,q-p\rangle>0$ for all $p\neq q$. Injectivity follows because the inner

product of a nonzero conclusion with anything cannot vanish; if $f(q) = f(p)$ then the inner product is 0, contradiction. All the analysis in this problem exists to convert a pointwise hypothesis about Df into that global inequality, and the conversion is the fundamental theorem of calculus along the segment:

$$(q-p)\cdot(f(q)-f(p)) = \int_0^1 (q-p)^{\mathsf{T}}\, Df(p+t(q-p))\,(q-p)\,dt.$$

Read that identity as the correct multivariable replacement for "$f(b)-f(a) = f'(c)(b-a)$". The mean value theorem in its equality form dies in several variables; its integral form survives, and everything you want to do with derivatives across a gap must go through the integral form or through a scalar reduction like the one used above.

Why is positivity of the symmetric part the right condition, rather than positivity of $\det Df$? Because $\det Df > 0$ is a statement about the map's local behaviour up to orientation, and orientation preserving local diffeomorphisms can wrap the plane around itself infinitely often, as the complex exponential does. Positive definiteness of S is a statement about *every direction at once*: it says that moving in any direction v increases the component of f in that same direction v. That is a rigidity you cannot wrap. Concretely, the complex exponential fails the test: for $F(x,y) = (e^x\cos y, e^x\sin y)$ the symmetric part of DF at $(0,\pi)$ has $F_{11} = e^x\cos y = -1 < 0$, so S is not positive definite there. Every counterexample to the naive route is killed by the correct hypothesis, which is exactly what you expect when the hypothesis is the right one.

The discernment mechanism, stated as a rule you can run in the arena: match the scope of the hypothesis to the scope of the conclusion. A pointwise hypothesis plus a pointwise conclusion is a computation. A pointwise hypothesis plus a global conclusion always requires an integration or a connectedness argument, and in practice that means constructing a path and studying a function of one real variable on it. Ask yourself: what is the one-variable function here? If you cannot name it, you are not yet solving the problem. In this problem it is $g(t) = v\cdot f(p+tv)$, and once you have written it the rest is bookkeeping.

There is a second discernment rule, cheaper and just as reliable: *account for every hypothesis*. The problem gave you a strictly stronger condition than $\det Df > 0$. If your route only uses $\det Df > 0$, your route cannot be the intended one, and on a Putnam the intended one is nearly always the only complete one. This is why you should check, at the moment you commit to a method, whether any given condition is going unused. Here the unused-hypothesis alarm fires exactly at the bifurcation point.

How to train it. Take five theorems of the form "local property implies global property" and, for each, find where the extra hypothesis enters: a continuous locally constant function on a connected space is constant (connectedness), a local diffeomorphism that is proper is a covering map (properness, this is Hadamard's global inverse theorem), a function with zero derivative on an interval is constant (the interval), a locally injective map need not be injective (no extra hypothesis, no theorem). Building that table once makes the trap in this problem visible on sight rather than after ten minutes.

Cultural note worth carrying: the question of when $\det Df$ being nonvanishing forces global injectivity is deep. Over the complex numbers with polynomial f, the statement that $\det Df$ a nonzero constant implies f is invertible is the Jacobian conjecture, open since 1939. So when you feel that "the Jacobian is positive, surely it is injective" ought to be provable, you are feeling the pull of an open problem. Trust the counterexample instead.

Revolving concepts

Quadratic forms and definiteness. For a symmetric S, the form $Q(v) = v^{\mathsf{T}}Sv$ is positive definite when $Q(v) > 0$ for all $v \neq 0$. Sylvester's criterion: positive definite exactly when every leading principal minor is positive, which in the two by two case is $S_{11} > 0$ and $\det S > 0$. Equivalently for

$Av_1^2 + Bv_1v_2 + Cv_2^2$: $A > 0$ and $B^2 - 4AC < 0$, the familiar discriminant condition. See Book 1, field: Linear algebra, topic: quadratic forms and Sylvester's criterion.

Symmetric and skew parts. Any square M splits as $\frac{1}{2}(M + M^\mathsf{T}) + \frac{1}{2}(M - M^\mathsf{T})$, and $v^\mathsf{T} M v = v^\mathsf{T} \left(\frac{M+M^\mathsf{T}}{2}\right) v$ because the skew part contributes $v^\mathsf{T} K v = -v^\mathsf{T} K v = 0$. This is the single fact that explains the shape of the problem's hypothesis. See Book 1, field: Matrices and determinants, topic: symmetric and skew symmetric decomposition.

Continuous partials imply differentiability. If all partial derivatives of $F : \mathbb{R}^n \to \mathbb{R}$ exist in a neighbourhood of p and are continuous at p, then F is differentiable at p. The converse of the naive statement is false: $F(x, y) = xy/(x^2 + y^2)$ extended by 0 has both partials at the origin but is not even continuous there. The problem's phrase "with continuous partial derivatives" is what licenses the chain rule. See Book 1, field: Real analysis, topic: total differentiability versus partial derivatives.

Mean value theorem, vector valued failure and its repairs. For $F : \mathbb{R} \to \mathbb{R}^m$ with $m \geq 2$ there is in general no c with $F(b) - F(a) = F'(c)(b - a)$; take $F(t) = (\cos t, \sin t)$ on $[0, 2\pi]$. The repairs are (i) the integral form $F(b) - F(a) = \int_a^b F'$, (ii) the inequality $\|F(b) - F(a)\| \leq (b - a) \sup \|F'\|$, and (iii) pairing with a fixed vector to return to the scalar case, which is what this solution does. See Book 1, field: Real analysis, topic: mean value theorems in several variables.

Monotone operators. A map $f : \mathbb{R}^n \to \mathbb{R}^n$ is monotone if $\langle f(q) - f(p), q - p \rangle \geq 0$ for all p, q, and strictly monotone if the inequality is strict for $p \neq q$. Strictly monotone implies injective. If f is C^1, then f is monotone if and only if the symmetric part of Df is positive semidefinite everywhere, and positive definiteness everywhere gives strict monotonicity by the integral identity above. The gradient of a convex function is monotone, and this is the special case where Df is symmetric. See Book 1, field: Real analysis, topic: monotone operators and convexity.

Global inverse theorems. The inverse function theorem is local. Hadamard's global inverse theorem says a local diffeomorphism $\mathbb{R}^n \to \mathbb{R}^n$ that is proper (preimages of compact sets are compact) is a global diffeomorphism. The condition in this problem gives properness as well, since $\langle f(q) - f(p), q - p \rangle > 0$ with a definiteness bound forces $\|f(q)\| \to \infty$, so in fact f here is a bijection onto $\mathbb{R}^2$; the problem only asks for the injective half. See Book 1, field: Real analysis, topic: local versus global inverse theorems.

Generalisation to n dimensions. The identical proof shows: if $f : \mathbb{R}^n \to \mathbb{R}^n$ is C^1 and $Df(x) + Df(x)^\mathsf{T}$ is positive definite for every x, then f is injective. There is no recursion or induction anywhere in this problem; the generalisation is in the dimension, not in an index.

Circuit Bank

- **WHEN** a hypothesis containing $\partial f_1/\partial x_2 + \partial f_2/\partial x_1$ as a symmetric sum **DO** write the symmetrised Jacobian $\frac{1}{2}(Df + (Df)^\mathsf{T})$ and test it for positive definiteness **BECAUSE** a quadratic form $v^\mathsf{T} M v$ sees only the symmetric part of M, so a hypothesis that symmetrises the off diagonal entries is announcing that a quadratic form in a single direction v is coming
- **WHEN** you must prove a smooth map on all of $\mathbb{R}^n$ is globally injective **DO** take arbitrary $p \neq q$, set $v = q - p$, and study $g(t) = v \cdot f(p + tv)$ on $[0, 1]$ **BECAUSE** injectivity is a statement about pairs, the segment is the only canonical object joining a pair, and pairing with v converts the vector problem into a one-variable problem where the mean value theorem is legal
- **WHEN** the inverse function theorem seems to finish an injectivity problem **DO** stop, and test your argument against $(x, y) \mapsto (e^x \cos y, e^x \sin y)$ **BECAUSE** that map has positive Jacobian determinant everywhere and is periodic, so any argument deriving global injectivity from a nonvanishing Jacobian alone is wrong
- **WHEN** a quadratic $Av_1^2 + Bv_1v_2 + Cv_2^2$ must be shown strictly positive with $A > 0$ **DO**

multiply by A and write $AQ = (Av_1 + \frac{1}{2}Bv_2)^2 + (AC - \frac{1}{4}B^2)v_2^2$ **BECAUSE** multiplying rather than dividing keeps the identity polynomial and makes the equality case visible, which is what turns a nonnegativity statement into a strict positivity statement

- **WHEN** you have chosen a method and one stated hypothesis is still unused **DO** treat that as an alarm and change method **BECAUSE** Putnam hypotheses are minimal by construction, so an unused hypothesis nearly always means your route proves something weaker than what was asked

Backtesting

1. First useful cue: the printed expression $f_{11}f_{22} - \frac{1}{4}(f_{12} + f_{21})^2$, which is the determinant of the symmetrised Jacobian and the discriminant condition for a positive definite binary quadratic form.
2. Method the expression suggested: produce $v^{\mathsf{T}} Df\, v$ somewhere, which means a directional derivative in direction v paired again with v, which means the function $g(t) = v \cdot f(p + tv)$ on the segment joining the two points.
3. Where you would hesitate, and the thought to reinforce: after computing $\det Df > 0$ it feels like the inverse function theorem should close the problem. Reinforce: *local hypotheses give local conclusions; to go global you must integrate along a path or use compactness*. Keep the complex exponential counterexample in memory as the permanent refutation.
4. The trap the question sets: the positivity of all four partials is a decoy that pushes you toward coordinatewise monotonicity, which handles only the directions in the first and third quadrants; and the Jacobian determinant is a decoy that pushes you toward the inverse function theorem. Neither uses the actual hypothesis.
5. What makes you recognise it faster next time: memorise the phrase "positive definite symmetric part equals strictly monotone equals injective". This problem is that theorem in dimension two with the definition spelled out.
6. The reusable decision rule: to prove a global property of a differentiable map, build a one-variable function along a segment whose derivative is exactly the quantity the hypothesis controls.

Mirror drills

1. Prove that if $f : \mathbb{R}^n \to \mathbb{R}^n$ is C^1 and $Df(x) + Df(x)^{\mathsf{T}}$ is positive definite at every x, then f is injective. *Answer:* identical proof; $g(t) = v \cdot f(p + tv)$ has $g'(t) = v^{\mathsf{T}} Df\, v = \frac{1}{2}v^{\mathsf{T}}(Df + Df^{\mathsf{T}})v > 0$ for $v \neq 0$.
2. Exhibit a C^∞ map $\mathbb{R}^2 \to \mathbb{R}^2$ with $\det Df > 0$ everywhere that is not injective, and say which hypothesis of B5 it violates. *Answer:* $(x, y) \mapsto (e^x \cos y, e^x \sin y)$, with $\det Df = e^{2x} > 0$ and period 2π in y; it violates positivity of $f_{11} = e^x \cos y$, hence the definiteness of the symmetric part.
3. Let $\varphi : \mathbb{R}^n \to \mathbb{R}$ be C^2 with positive definite Hessian everywhere. Prove $\nabla\varphi$ is injective, and deduce that a strictly convex function has at most one stationary point. *Answer:* apply drill 1 to $f = \nabla\varphi$, whose Jacobian is the (symmetric) Hessian; injectivity of $\nabla\varphi$ means $\nabla\varphi(x) = 0$ has at most one solution.

8.12 B6. Exponential weights bound restricted composition counts

Let S be the set of sequences of length 2018 whose terms are in the set $\{1,2,3,4,5,6,10\}$ and sum to 3860. Prove that the cardinality of S is at most

$$2^{3860} \cdot \left(\frac{2018}{2048}\right)^{2018}.$$

Read it out loud

Count the sequences of a fixed length, from a fixed finite alphabet of positive integers, with a fixed total. Then bound that count. Say the bound aloud in its factored form: something to the power of the *sum*, times something to the power of the *length*. That is

$$2^{3860}\left(\frac{2018}{2048}\right)^{2018} = (2^{\,\text{sum}}) \cdot \left(\lambda^{\,\text{length}}\right), \qquad \lambda = \frac{2018}{2048}.$$

A bound whose two exponents are the two parameters of the problem is not a bound somebody derived by estimating binomial coefficients. It is a bound that came out of a product, because products are the only things that turn into powers, and it has one factor per term of the sequence plus one factor per unit of sum.

Now attack the constant. The bound contains $2048 = 2^{11}$, which appears nowhere in the problem, so it was manufactured. Reduce: $\frac{2018}{2048} = \frac{1009}{1024} = \frac{1009}{2^{10}}$. And $2^{10} = 1024$ is exactly what you get when you put the largest alphabet element, 10, into an exponent of 2. So compute the one quantity that the alphabet and the number 2 can produce together:

$$\sum_{j\in\{1,2,3,4,5,6,10\}} 2^{-j} = \left(\frac{1}{2}+\frac{1}{4}+\frac{1}{8}+\frac{1}{16}+\frac{1}{32}+\frac{1}{64}\right)+\frac{1}{1024} = \frac{63}{64}+\frac{1}{1024} = \frac{1008+1}{1024} = \frac{1009}{1024}.$$

That is λ, on the nose. The problem is now over, and you have not yet written a single line of proof. Everything after this is bookkeeping: you must find the argument in which the number $\sum_j 2^{-j}$ gets raised to the power 2018 and compared against 2^{-3860} times a count.

The fields wired in: combinatorics (compositions with restricted parts), generating functions (the product $\left(x+x^2+\cdots+x^6+x^{10}\right)^{2018}$, whose coefficient of x^{3860} is the answer), and probability in the guise of the exponential moment method, also called the Chernoff bound. What is really being tested is whether you know that a coefficient of a power series with nonnegative coefficients is bounded by the value of the series at any positive argument, divided by the corresponding power. That single sentence is the problem.

Within thirty seconds, write down: $\lambda = 2018/2048 = 1009/1024 = \sum_{j\in A} 2^{-j}$, and the plan "weight each sequence by $2^{-(\text{its sum})}$ and sum over all sequences".

Approaches, ranked worst to best

1. **Exact count.** *Cue:* it is a finite count, so compute it. *Circuit:* stars and bars, or expand the generating function. You cannot expand $\left(x+\cdots+x^6+x^{10}\right)^{2018}$ by hand, and even the crude relaxation to all positive integer parts gives, by stars and bars, $\binom{3859}{2017} \approx 10^{1158}$. The target is about 10^{1149}. So the relaxation overshoots by a factor of about 10^9 and the route is dead, not merely painful. Ranked last. It does earn one thing: computing the trivial bound tells you the margin is thin, and thin margins mean the intended argument is tight and structural rather than wasteful.

2. **Multinomial and Stirling.** *Cue:* classify by how many of each letter you use. *Circuit:* maximise a multinomial coefficient subject to two linear constraints. Writing k_j for the number of terms

equal to j, the count is $\sum \binom{2018}{k_1,\ldots,k_7}$ over all (k_j) with $\sum k_j = 2018$ and $\sum jk_j = 3860$. You would then bound each multinomial by its entropy exponential, maximise by Lagrange multipliers, and count the number of terms in the sum. This works in principle, and it is the honest large deviations calculation. It ranks second to last because Stirling error terms, the number of summands and the constrained maximisation together cost pages, and every one of those pages is a chance to lose a point.

3. **Double induction on length and sum.** *Cue:* a recursion on the last term is available. *Circuit:* strengthen the statement to all (k, n) and induct. Define $a(k, n)$ as the number of sequences of length k from the alphabet summing to n. Splitting on the last term gives $a(k, n) = \sum_{j \in A} a(k-1, n-j)$, and the strengthened claim $a(k, n) \leq 2^n \lambda^k$ then propagates:

$$\sum_{j \in A} 2^{n-j} \lambda^{k-1} = 2^n \lambda^{k-1} \sum_{j \in A} 2^{-j} = 2^n \lambda^{k-1} \cdot \lambda = 2^n \lambda^k.$$

This is a complete and correct solution, and it is the one printed in the official file. It ranks third because you have to invent the strengthened statement (the original statement at a single (k, n) is not inductable), organise a two variable induction, and check the degenerate cases where $n \leq k$ or n is out of range. All of that work disappears in the next two routes, and the reason it disappears is that the induction is nothing but the distributive law applied one factor at a time.

4. **Probabilistic Chernoff.** *Cue:* a count of length 2018 sequences with a fixed sum is a probability. *Circuit:* apply Markov's inequality to $e^{\lambda X}$. Let $X_1, \ldots, X_{2018}$ be independent and uniform on the alphabet. Then $|S| = 7^{2018} \Pr\left[\sum X_i = 3860\right]$, and $\Pr[\sum X_i = 3860] \leq 2^{3860} \mathbb{E}\left[2^{-\sum X_i}\right] = 2^{3860} \left(\frac{1}{7} \sum_j 2^{-j}\right)^{2018}$ by Markov applied to the positive random variable $2^{-\sum X_i}$. Correct, and identical in content to the best route, but it dresses a finite sum as an expectation and pays a 7^{2018} that immediately cancels. Ranked fourth: same idea, extra costume.

5. **Weight and compare.** *Cue:* the bound factors as 2^{sum} times λ^{length}, and $\lambda = \sum_j 2^{-j}$. *Circuit:* attach a positive weight to every object, sum over a superset, and keep only the terms you care about. Best. Give the sequence s the weight $2^{-\sigma(s)}$ where $\sigma(s)$ is its sum. Sum over *all* sequences of length 2018 from the alphabet: by the distributive law the total is $\left(\sum_j 2^{-j}\right)^{2018} = \lambda^{2018}$. Every sequence in S contributes exactly 2^{-3860}, and all weights are positive, so $|S|\, 2^{-3860} \leq \lambda^{2018}$. Six lines, no induction, no error terms, no probability. It also exposes the free parameter: the number 2 was never sacred, and replacing it by $1/x$ gives a whole family of bounds, of which the problem's is the tightest.

The ideal solution

Write $A = \{1, 2, 3, 4, 5, 6, 10\}$, let $T = A^{2018}$ be the set of *all* sequences of length 2018 with terms in A, and for $s = (s_1, \ldots, s_{2018}) \in T$ write $\sigma(s) = s_1 + \cdots + s_{2018}$. Thus $S = \{s \in T : \sigma(s) = 3860\}$.

Attach to each $s \in T$ the weight

$$w(s) = 2^{-\sigma(s)} = \prod_{i=1}^{2018} 2^{-s_i} > 0.$$

Step 1: the total weight of T. Expanding a product of sums by the distributive law, the 7^{2018} terms of

$$\prod_{i=1}^{2018} \left(\sum_{j \in A} 2^{-j} \right)$$

are exactly the products $\prod_{i=1}^{2018} 2^{-s_i}$, one for each choice of $(s_1, \ldots, s_{2018}) \in T$. Hence

$$\sum_{s \in T} w(s) = \left(\sum_{j \in A} 2^{-j} \right)^{2018}.$$

Step 2: evaluate the constant.

$$\sum_{j \in A} 2^{-j} = \frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16} + \frac{1}{32} + \frac{1}{64} + \frac{1}{1024} = \left(1 - \frac{1}{64}\right) + \frac{1}{1024} = \frac{1008}{1024} + \frac{1}{1024} = \frac{1009}{1024} = \frac{2018}{2048}.$$

Step 3: keep only the sequences you want. Every weight is positive and $S \subseteq T$, so

$$\sum_{s \in S} w(s) \;\le\; \sum_{s \in T} w(s) = \left(\frac{2018}{2048} \right)^{2018}.$$

Every $s \in S$ has $\sigma(s) = 3860$ and therefore $w(s) = 2^{-3860}$ exactly, so the left side equals $|S| \cdot 2^{-3860}$. Hence

$$|S| \cdot 2^{-3860} \le \left(\frac{2018}{2048} \right)^{2018},$$

and multiplying by $2^{3860} > 0$ gives

$$\boxed{|S| \;\le\; 2^{3860} \left(\frac{2018}{2048} \right)^{2018}.}$$

■

(The inequality in Step 3 is in fact strict, since $T \setminus S$ is nonempty: the constant sequence of ones lies in T and has sum $2018 \neq 3860$. The problem only asks for "at most", so nothing more is needed.)

Remark 8.12.1. The number 2 is a free parameter in disguise. For any real $x > 0$, set $P(x) = x + x^2 + x^3 + x^4 + x^5 + x^6 + x^{10}$. The same three steps with the weight $x^{\sigma(s)}$ give

$$|S|\, x^{3860} \le \sum_{s \in T} x^{\sigma(s)} = P(x)^{2018}, \qquad \text{so} \qquad |S| \le \frac{P(x)^{2018}}{x^{3860}} \quad \text{for every } x > 0.$$

The problem hands you the case $x = \frac{1}{2}$. Which x is best? Minimising log of the right side, that is $2018 \log P(x) - 3860 \log x$, gives the stationarity condition

$$\frac{xP'(x)}{P(x)} = \frac{3860}{2018}.$$

At $x = \frac{1}{2}$ we have $xP'(x) = \sum_{j \in A} j\, 2^{-j} = \frac{1930}{1024}$ and $P(x) = \frac{1009}{1024}$, so the left side is $\frac{1930}{1009}$, and the right side is $\frac{3860}{2018} = \frac{1930}{1009}$. They agree exactly. So $x = \frac{1}{2}$ is precisely the optimal choice, and the number 3860, which plays no other role in the problem, was chosen to make it so.

Layer 1: WHAT

Block 1. Read the bound as a product: $(2^{\text{sum}}) \cdot \left(\lambda^{\text{length}}\right)$, one factor per unit of sum and one per term.

Block 2. Reduce 2018/2048 to 1009/1024 and recognise it as $\sum_{j \in A} 2^{-j}$.

Block 3. Define the weight $w(s) = 2^{-\sigma(s)}$ on the set T of all sequences from the alphabet.

Block 4. Compute $\sum_{s \in T} w(s) = \left(\sum_j 2^{-j} \right)^{2018}$ by the distributive law.

Block 5. Throw away every sequence not in S; the weights are positive so the sum only drops.

Block 6. On S the weight is the constant 2^{-3860}, so the surviving sum is $|S|2^{-3860}$. Rearrange.

The nominal route tries to count S, or to bound each multinomial coefficient in a classification of S, and drowns. The bifurcation point is the instant you look at 2018/2048 and decide whether it is a ratio to be estimated or a value to be recognised. Recognition costs one line of arithmetic and finishes the problem; estimation costs the rest of the three hours. A related and equally sharp way to put it: the nominal route counts the objects, the ideal route *weighs* them, and weighing is easier because weight is multiplicative across coordinates while counting with a constraint is not.

Layer 2: HOW

Block 1. **Cue.** A bound of the form $\alpha^n \beta^k$ where n is the sum and k is the length. **Why natural.** Exponentials in a parameter come from products with one factor per unit of that parameter. A length 2018 sequence has 2018 coordinates, so β^{2018} says "one factor per coordinate", which is the signature of independence across coordinates: the sum over all sequences of a product of per-coordinate quantities factors into a product of sums. And 2^{3860}, with 3860 the constrained total, says "one factor per unit of sum", which is the signature of a weight of the form $x^{\sigma(s)}$. Both exponents therefore point at the same object before you have done any work. **Link to the next block.** If the answer is a product of per-coordinate sums, you need to know what one coordinate contributes, so evaluate β and try to see it as a sum over the alphabet.

Block 2. **Cue.** The constant $2048 = 2^{11}$, which is not in the problem, sitting under 2018. **Why natural.** Manufactured constants are messages. Cancel the factor 2 to get 1009/1024, and note $1024 = 2^{10}$ with 10 the largest alphabet element; that pairing is what tells you to try $\sum_j 2^{-j}$ rather than, say, $\sum_j 2^j$ or a geometric sum with a different ratio. The arithmetic then confirms it exactly, and exact confirmation of a guessed identity is proof that you have found the intended structure, not a coincidence. **Link to the next block.** You now know the per-coordinate contribution is $\sum_j 2^{-j}$, so the weight on a whole sequence must be $\prod_i 2^{-s_i} = 2^{-\sigma(s)}$.

Block 3. **Cue.** You want to bound $|S|$, and you know a quantity attached to sequences that factorises. **Why natural.** Counting a constrained set is hard because the constraint couples the coordinates. Weighting is easy because a weight of the form $x^{\sigma(s)}$ decouples: it is a product of one factor per coordinate. So replace the hard question "how many s have $\sigma(s) = 3860$" by the easy question "what is the total weight of everything", and let the weight itself detect the constraint. This is the same manoeuvre as introducing a generating function, stripped of the formal power series language. **Link to the next block.** Now compute the easy total.

Block 4. **Cue.** A sum over a Cartesian product of a product of per-coordinate terms. **Why natural.** Distributivity, nothing more: expanding $\prod_{i=1}^{k} \left(\sum_{j \in A} c_j \right)$ produces exactly one term for each choice function $i \mapsto s_i$. Say this explicitly in the write up; it is the only step in the proof with any content, and a grader wants to see that you know why the product of sums equals the sum over sequences. **Link to the next block.** You now have the total over the superset T, and you want a statement about the subset S.

Block 5. **Cue.** A subset of a set on which a positive function is summed. **Why natural.** If $w > 0$ then $\sum_S w \leq \sum_T w$ for $S \subseteq T$. This is the entire inequality of the problem, and it is the discrete form of Markov's inequality: one nonnegative term of a sum is at most the whole sum. The positivity of the weight is what makes discarding terms safe, so check it once and say so. **Link to the next block.** On S the weight is constant, so the left side collapses to a multiple of $|S|$.

Block 6. Cue. Constant weight on the constrained set. **Why natural.** The constraint $\sigma(s) = 3860$ was chosen by the problem, and it is precisely what makes w constant on S: the weight was designed to be a function of the sum alone. That is the moment the design pays off. Rearranging is trivial. **Link to the next block.** Finished, and the free parameter question remains for the remark.

Layer 3: WHY

The truth beneath this problem is one inequality, and it has three names depending on who is speaking. A combinatorialist says: if a power series has nonnegative coefficients, then for $x > 0$ each coefficient satisfies $a_n x^n \le \sum_m a_m x^m$, so $a_n \le x^{-n} F(x)$. A probabilist says: for a nonnegative random variable Y and $t > 0$, $\Pr[Y \ge t] \le \mathbb{E}[Y]/t$, which is Markov's inequality, and applying it to $Y = x^{\sum X_i}$ produces the Chernoff bound. A student who has not met either says: one term of a sum of positive numbers is at most the sum. All three are the same sentence, and the third is enough to write a full marks solution. Install the sentence, not the vocabulary.

The second truth is that the bound has a free parameter, and free parameters must be optimised. The family $|S| \le x^{-n} P(x)^k$ holds for every $x > 0$; the best member is at $xP'(x)/P(x) = n/k$, which says: choose the weight so that the *weighted average value of a single term* equals the average value n/k that the constraint demands. That is exponential tilting. You are reweighting the uniform measure on the alphabet until its mean lands exactly on the target mean, and at that tilt the bound is as tight as this method can be. The general statement is Cramér's theorem in large deviations: $\frac{1}{k} \log \Pr\left[\frac{1}{k}\sum X_i \approx c\right] \to -I(c)$, where the rate function I is the Legendre transform of the logarithm of the moment generating function. The tilt condition above is exactly the equation defining the Legendre transform's stationary point. Knowing this tells you in advance that the method is not merely valid but essentially sharp, which is confirmed by the numbers: the true value of $|S|$ is about 8.05×10^{1146}, and the bound is about 10^{1149}, a factor of roughly 150 across a quantity with more than a thousand digits.

The examiners nudged in exactly two places, and both are numbers. First, 2048, which is not natural to the problem and exists only so that 2018/2048 reduces to $\sum_j 2^{-j}$. Second, 3860, which is otherwise irrelevant and exists only so that $x = 1/2$ is the exact optimum of the family of bounds. When two of the constants in a problem have no combinatorial meaning, they are keys, and the discernment habit to train is: *before estimating anything, try to recognise every constant in the target expression as an exact value of some natural quantity built from the data*. Reverse engineering the answer is not cheating; on a bounding problem it is the primary method, because the shape of the bound tells you which inequality was used to produce it.

How to train the recognition. Take twenty published bounds of the form C^n or $\alpha^n \beta^k$ and, for each, work out what quantity the base is: an alphabet sum, a moment generating function at a specific point, an entropy exponential $2^{H(p)n}$, or a spectral radius. After twenty you will see 1009/1024 and think "that is $\sum 2^{-j}$ over the alphabet" as fast as you see 0.5 and think one half.

Knowledge gaps, stated honestly

This problem has an unusual profile and you should be clear about it. The theory needed to *write* the solution is essentially nil: the distributive law, a geometric sum, and the observation that a subsum of positive terms is at most the whole sum. Nothing there is beyond A-level. The theory needed to *find* the solution is entirely beyond A-level, and it is the following, in order of priority.

(1) Ordinary generating functions as bookkeeping. The single fact that $\left(\sum_{j \in A} x^j\right)^k = \sum_n a(k,n) x^n$, where $a(k,n)$ counts length k sequences from A summing to n. Without this, the weight $2^{-\sigma(s)}$ looks arbitrary; with it, the weight is just evaluation at $x = 1/2$.

(2) Markov's inequality and the exponential moment (Chernoff) method: bound a tail or a coefficient by evaluating a positive series at a point of your choosing. This is the single most

reusable estimation technique in competition combinatorics and probability, and it is not taught anywhere in the A-level or Further Maths syllabus.

(3) Exponential tilting and Legendre duality, that is, the fact that the free parameter should be chosen so that the tilted mean equals the target mean, and that this choice makes the bound sharp to first order in the exponent. This is Cramér's theorem territory.

(4) Optional but worth knowing exists: Cauchy's coefficient formula and the saddle point method, which convert the same inequality into an asymptotic equality and would produce the constant 8.05×10^{1146} rather than an upper bound.

If you have not installed (1) and (2), you will not find this problem in the arena no matter how long you sit with it, and no amount of cleverness substitutes. That is what a knowledge gap means, and this is one.

Revolving concepts

Compositions with restricted parts. A composition of n into k parts from a set A is exactly an element of A^k summing to n; the count is $a(k,n) = [x^n]\left(\sum_{j\in A} x^j\right)^k$. Unrestricted positive parts give $\binom{n-1}{k-1}$ by stars and bars, which here is $\binom{3859}{2017}$ and is the crude comparison bound. See Book 1, field: Combinatorics, topic: compositions and stars and bars.

Generating functions and the recursion, generalised. The recursion behind the official solution is $a(k,n) = \sum_{j\in A} a(k-1, n-j)$, obtained by deleting the last term. This is a linear recursion in k with a shift in n, and its general solution method is exactly the generating function: multiply by x^n, sum over n, and get $G_k(x) = P(x)G_{k-1}(x)$ with $G_0 = 1$, hence $G_k(x) = P(x)^k$. Every recursion of the form "the count at stage k is a fixed nonnegative combination of shifted counts at stage $k-1$" solves this way, and the accompanying bound is the general fact

$$a(k,n) \le x^{-n}P(x)^k \quad \text{for every } x > 0, \qquad \text{optimised at } \frac{xP'(x)}{P(x)} = \frac{n}{k}.$$

Carry that display; it is the reusable object, and this problem is its instance with $P(x) = x + \cdots + x^6 + x^{10}$, $k = 2018$, $n = 3860$, $x = 1/2$. See Book 1, field: Generating functions, topic: products, coefficient extraction and coefficient bounds.

Markov's inequality and Chernoff bounds. For $Y \ge 0$ and $t > 0$, $\Pr[Y \ge t] \le \mathbb{E}[Y]/t$. Applied to $Y = e^{\theta\sum X_i}$ with independent X_i, it gives $\Pr\left[\sum X_i \ge a\right] \le e^{-\theta a}\left(\mathbb{E}e^{\theta X}\right)^k$ for every $\theta > 0$, and independence is what turns the expectation of the product into the product of expectations. See Book 1, field: Probability, topic: concentration inequalities.

Exponential tilting and the Legendre transform. Given a distribution p on A, the tilted distribution $p_\theta(j) \propto p(j)e^{\theta j}$ has mean $\frac{d}{d\theta}\log \mathbb{E}[e^{\theta X}]$. Choosing θ so that this mean equals the target n/k minimises the Chernoff bound, and the minimum value is $e^{-kI(n/k)}$ with I the Legendre transform of $\log \mathbb{E}[e^{\theta X}]$. See Book 1, field: Probability, topic: large deviations and Cramer's theorem.

Weighted counting as a general habit. Whenever a constraint couples coordinates, look for a weight that is multiplicative across coordinates and that is constant on the constrained set. Then the total weight is computable by factorisation, and the constrained count falls out by comparison. The same habit proves $\binom{2n}{n} \le 4^n$, bounds the number of self avoiding walks, and underlies the probabilistic method. See Book 1, field: Combinatorics, topic: weighted counting and the first moment method.

Circuit Bank

- **WHEN** a bound of the shape $\alpha^{\text{sum}}\beta^{\text{length}}$ **DO** look for a per-coordinate weight, because only products give exponents in a parameter **BECAUSE** the sum over a Cartesian product of a multiplicative weight factorises into a product of identical per-coordinate sums, which is where β^k comes from

- **WHEN** an unexplained constant in the target, such as 2048 or 1009/1024 **DO** try to realise it exactly as a natural quantity built from the data, here $\sum_{j\in A} 2^{-j}$ **BECAUSE** competition bounds are reverse engineered from the intended proof, so the constants in the answer identify the inequality that produced them
- **WHEN** you must bound the number of solutions of a linear constraint over a finite alphabet **DO** weight each object by x^{sum}, sum over everything, and discard the terms you do not need **BECAUSE** all weights are positive, so a subsum is at most the whole sum; this is Markov's inequality in its discrete form and needs no probability language
- **WHEN** a valid bound still contains a free positive parameter **DO** optimise it, and check whether the problem's numbers make the optimum a round value **BECAUSE** the family $a(k,n) \le x^{-n}P(x)^k$ is tightest at $xP'(x)/P(x) = n/k$, and a problem that hands you $x = 1/2$ has usually chosen n to sit exactly at that stationary point
- **WHEN** a counting problem where a constraint couples the coordinates **DO** stop counting and start weighing **BECAUSE** counting with a coupled constraint does not factorise, but a multiplicative weight does, and the constraint can be recovered afterwards because the weight is constant on the constrained set

Backtesting

1. First useful cue: the factored shape of the bound, 2^{3860} against the sum and $(2018/2048)^{2018}$ against the length, followed immediately by the reduction $2018/2048 = 1009/1024 = \sum_{j\in A} 2^{-j}$.
2. Method the expression suggested: weighted counting. Attach $2^{-\sigma(s)}$ to every sequence, factorise the total over all sequences, then discard everything outside S.
3. Where you would hesitate, and the thought to reinforce: the instinct to estimate $|S|$ directly, or to set up the multinomial classification. Reinforce the thought: *a bound with exponents equal to the problem's parameters was produced by a product, so find the product*. Also reinforce that discarding positive terms is a legal and powerful move, not a lossy accident.
4. The trap the question sets: the number 3860 invites you to think it matters combinatorially. It does not; it appears in the proof only as the exponent of the constant weight on S. Its real role is to make $x = 1/2$ the optimal tilt, which you can only see after the fact.
5. What makes you recognise it faster next time: build the reflex that any target of the form $x^{-n}P(x)^k$ is a coefficient bound. Whenever a bound has two exponents and the problem has two parameters, write the generating function down within the first minute.
6. The reusable decision rule: to bound the number of objects satisfying an additive constraint, weight every object by x^{sum} for a positive x of your choosing, sum over all objects by factorisation, and compare; then optimise x if the problem has not chosen it for you.

Mirror drills

1. Prove $\binom{2n}{n} \le 4^n$ in one line by weighted counting. *Answer:* $\binom{2n}{n}$ is one term of $\sum_k \binom{2n}{k} = (1+1)^{2n} = 4^n$, and all terms are positive. Same circuit with $x = 1$.
2. Let $b(k,n)$ be the number of sequences of length k with terms in $\{1,2\}$ summing to n. Prove $b(k,n) \le x^{-n}(x+x^2)^k$ for all $x > 0$, and find the optimal x when $n = 3k/2$. *Answer:* the same weighting argument; the tilt condition $\frac{x(1+2x)}{1+x} = \frac{n}{k} = \frac{3}{2}$ gives $2x^2 + x = \frac{3}{2} + \frac{3}{2}x$, that is $4x^2 - x - 3 = 0$, so $x = 1$, which is correct because $n/k = 3/2$ is the mean of the uniform distribution on $\{1,2\}$.

3. State and prove the Chernoff bound: for independent X_i and $\theta > 0$, $\Pr\left[\sum_{i=1}^{k} X_i \geq a\right] \leq e^{-\theta a}\left(\mathbb{E}e^{\theta X}\right)^k$. *Answer:* the event is $e^{\theta \sum X_i} \geq e^{\theta a}$; apply Markov to the positive random variable $e^{\theta \sum X_i}$ and factor the expectation using independence.

Chapter 9

Putnam 2017

9.1 A1. the smallest set generated by squares and a shift

Let S be the smallest set of positive integers such that

(a) 2 is in S,

(b) n is in S whenever n^2 is in S, and

(c) $(n+5)^2$ is in S whenever n is in S.

Which positive integers are not in S?

(The set S is smallest in the sense that S is contained in any other set satisfying (a), (b) and (c).)

Read it out loud

The phrase that should catch your eye is "the smallest set such that". You are not given S as a formula or a recurrence: you are given a seed, 2, and two rules, and S is the least set that swallows the seed and stays closed under those rules. That word, smallest, is the whole command term: S is the intersection of every closed set containing the seed, which turns "which integers are missing" into two separate, finite tasks rather than one open search.

Look at what the rules do. Rule (c) shifts n up by 5 then squares, producing much larger numbers. Rule (b) takes a known perfect square and extracts its root, producing smaller numbers. One rule climbs, one descends, and both are built to meet on perfect squares, so expect to compose them.

The constant 5 is not decoration. Because (c) always adds a multiple of the same constant before squaring, and squaring is exactly the operation for which divisibility by a prime transfers cleanly ($p \mid m \iff p \mid m^2$), the residue of the seed mod 5 is the first thing to write down. The other loose end is the fixed point of squaring, $1^2 = 1$, which deserves a separate glance whenever a rule and its near inverse coexist.

Approaches, ranked worst to best

1. **raw forward generation.** *Cue:* the request to name missing integers invites listing. *Circuit:* repeated application of (b) and (c) to whatever is currently known. (this only ever proves a number IS in S by exhibiting a chain; it can never certify a number is NOT in S, since minimality is a global property, not a property of what you have generated so far.)

2. **induction on "$n \notin S$" without first naming a closed candidate.** *Cue:* the request for a clean description. *Circuit:* strong induction on the size of n. (workable in principle, but only after reinventing the residue invariant inside the inductive step, so it hides the same insight the pincer states openly.)

3. **guess a closed superset, then generate to match it.** *Cue:* the word "smallest" attached to closure conditions. *Circuit:* the two inequality pincer for smallest closed sets: guess T, prove T closed ($S \subseteq T$), then chase the seed through the rules until every part of T is reached ($T \subseteq S$). (correct and short: each half is mechanical once the residue invariant names T.)

The ideal solution

Claim. The positive integers not in S are exactly 1 and the multiples of 5.

Let T be the set of positive integers other than 1 and the multiples of 5.

Half 1: $S \subseteq T$. It suffices that T satisfies (a), (b), (c), since S is contained in every set that does. Condition (a): $2 \in T$. Use throughout that 5 is prime, so $5 \mid m \iff 5 \mid m^2$ for any positive integer m, and that $m^2 = 1 \iff m = 1$.

(b) If $n^2 \in T$ then $n^2 \neq 1$ and $5 \nmid n^2$, so $n \neq 1$ and $5 \nmid n$, giving $n \in T$.

(c) If $n \in T$ then $n \neq 1, 5 \nmid n$, so $n \geq 2$, hence $n+5 \geq 7$ and $(n+5)^2 \geq 49 \neq 1$. Also $5 \mid (n+5) \iff 5 \mid n$, false, so $5 \nmid (n+5)^2$. Hence $(n+5)^2 \in T$.

So T is closed under (a), (b), (c), giving $S \subseteq T$.

Half 2: $T \subseteq S$. First derive a free shift: if $n \in S$ then $(n+5)^2 \in S$ by (c), and applying (b) to the integer $n+5$ gives $n+5 \in S$. So

$$n \in S \implies n+5 \in S, \quad \text{hence} \quad n \in S \implies n+5k \in S \text{ for every } k \geq 0. \tag{d}$$

Chase the seed using (c), (d), (b) in turn:

$$2 \xrightarrow{(c)} 49 \xrightarrow{(c)} 54^2 \xrightarrow{(d),+220} 56^2 \xrightarrow{(b)} 56 \xrightarrow{(d),+65} 121 \xrightarrow{(b)} 11 \xrightarrow{(d),+5} 16 \xrightarrow{(b)} 4 \xrightarrow{(d),+5} 9 \xrightarrow{(b)} 3,$$

and, continuing from 16,

$$16 \xrightarrow{(d),+20} 36 \xrightarrow{(b)} 6.$$

(Each (d) jump adds a multiple of 5: $220 = 5 \cdot 44$, $65 = 5 \cdot 13$, $20 = 5 \cdot 4$.) This exhibits $2, 3, 4, 6 \in S$, one representative of each nonzero residue class mod 5 ($2, 3, 4, 1$ respectively), and each is the least member of its class inside T (the class of 1 starts at 1, excluded, then continues at 6). By (d), every larger member of each class also lies in S, so $T \subseteq S$.

Combining both halves, $S = T$:

the positive integers not in S are 1 and every positive multiple of 5.

Layer 1: WHAT

Block 1: read "smallest set satisfying closure conditions" as the two inequality pincer. Block 2: extract the invariant, divisibility by the prime 5, and flag the fixed point $n = 1$. Block 3: build T from the invariant, verify closure, giving $S \subseteq T$. Block 4: compose (c) then (b) into the free shift rule (d). Block 5: chase the seed to land on $3, 4, 6$ (with 2), one per nonzero residue class. Block 6: read off that these are minimal class representatives, invoke (d) for the rest, combine into $S = T$.

The nominal route never leaves Block 1: it enumerates from 2, notices the pattern, and stops at a guess. The bifurcation point is the moment right after that guess, where the ideal route asks how to rule out every other exclusion and is forced into Blocks 2 and 3, while the zombie route never asks and so never builds T.

Layer 2: HOW

Block 1. **Cue.** S is defined by "smallest" plus closure rules, not a formula. **Why natural.** A least closed set is the intersection of all closed supersets, which is only useful once you exhibit one such superset and one generated subset. **Link to the next block.** Choosing the pincer raises the question of which invariant makes a superset easy to verify.

Block 2. **Cue.** Rule (c) shifts by the fixed constant 5 before squaring. **Why natural.** A shift by a multiple of 5 preserves residue mod 5, and 5 prime gives $5 \mid m \iff 5 \mid m^2$, so both rules preserve "not a multiple of 5" in the same direction. **Link to the next block.** The fixed point $n = 1$ is the only remaining loose end, so it joins the invariant to define T.

Block 3. **Cue.** T (everything except 1 and multiples of 5) is now concrete. **Why natural.** Verifying (a), (b), (c) for T is one line each, because the invariant was chosen to be preserved by both rules. **Link to the next block.** Closure only gives $S \subseteq T$; the harder, generative half remains.

Block 4. **Cue.** (b) and (c) are near inverses, one squares, one extracts a root. **Why natural.** Composing them collapses to plain addition: $(n+5)^2$ is already the perfect square (b) needs, so no further squaring is required. **Link to the next block.** Membership now propagates by $+5$ for free, shrinking the task to one representative per residue class.

Block 5. **Cue.** Four residue classes each need one representative, reachable by computation alone. **Why natural.** Every arrow is forced: (c) is used to manufacture a new square, (d) to close the gap between two squares (or two representatives) by a multiple of 5, (b) the instant a square appears. **Link to the next block.** The numbers landed on, $2, 3, 4, 6$, are exactly the least members of their classes in T.

Block 6. **Cue.** The four representatives cover residues $1, 2, 3, 4$ and residue 0 is excluded entirely, matching T. **Why natural.** Rule (d) turns one membership fact into an entire upward class, so four facts expand into all of T. **Link to the next block.** Both inclusions now hold, giving $S = T$ and the boxed answer.

Layer 3: WHY

The route is ideal because the problem is a closure operator on the positive integers, and every closure operator generated by a seed and finite rules sits between the same two bounds: any closed superset bounds it above, any explicit derivation bounds it below. Forward search only ever touches the lower bound, since minimality is a property of every closed superset at once, not of one growing set. The discernment mechanism is syntactic: see "the smallest set such that" attached to closure rules and commit to a two sided inclusion before anything else.

The invariant, divisibility by 5, is forced by matching the shift constant in (c) to a property both rules preserve, and primality is exactly what makes $p \mid m \iff p \mid m^2$ hold with no extra hypothesis. Had the shift been composite, say 4, that same style of invariant would fail ($4 \mid m^2$ does not force $4 \mid m$, take $m = 2$), and you would need the prime factor 2 instead. Train this by factorising the shift constant and testing its prime factors as candidate invariants, never the shift constant itself.

Revolving concepts

Smallest set satisfying closure conditions. The intersection of every set containing the generators and closed under the rules, equivalently everything reachable from the generators by finitely many rule applications. The double inclusion technique here generalises directly to generated subgroups, generated ideals, and the smallest sigma algebra containing a collection of sets. See Book 1, field: Logic and set theory, topic: closure systems.

Prime divisibility of powers. For a prime p, $p \mid m \iff p \mid m^k$ for any $k \geq 1$, from unique factorisation. This is why primality of the shift constant, not merely its value, is load bearing. See Book 1, field: Number theory, topic: prime factorisation.

Fixed points of squaring. Among integers, $n^2 = n$ only at $n = 0, 1$. Whenever a rule and its near inverse coexist, the fixed points of the rule are the first place sporadic exceptions hide. See Book 1, field: Number theory, topic: fixed points.

Additive closure and residue classes. A subset of the positive integers closed under adding a fixed c is, within each residue class mod c it meets, an up set: everything from some threshold onward. See Book 1, field: Sequences and recurrences, topic: numerical semigroups. Generalised recursion: whenever closure gives $n \in S \Rightarrow n + c \in S$ and representatives $r_1, \ldots$ are realised for the nonzero residues mod c actually present, S equals the union of $\{n \equiv r_i \pmod{c} : n \geq r_i\}$; the infinite description collapses to a finite list of realised classes and their least elements, the pattern to hunt for in any shift plus closure problem.

Circuit Bank

- **WHEN** a set is defined as smallest satisfying closure conditions **DO** split into two inclusions, a guessed closed superset from the rules' arithmetic, then explicit generation from the seed **BECAUSE** minimality gives the upper inclusion for free once any closed candidate is verified, while the lower inclusion needs an explicit derivation closure alone cannot supply
- **WHEN** a closure rule shifts by a fixed constant k before a power or root **DO** test divisibility by each prime factor of k, not by k itself **BECAUSE** $p \mid m \iff p \mid m^j$ holds cleanly only for primes, so composite constants need their prime factors as the invariant
- **WHEN** two closure rules resemble an operation and its near inverse **DO** compose them directly and simplify **BECAUSE** such compositions often collapse a complicated rule into a much simpler net operation that does the remaining work

Backtesting

1. First useful cue: "the smallest set of positive integers such that", attached to closure rules.
2. Method the expression suggested: the shift constant 5 is prime, so test divisibility by 5 immediately.
3. Where you would hesitate: after guessing the exclusions from a few generated examples, unsure how to rule out every other one; reinforce that minimality only bites once a closed candidate is named and verified.
4. The trap the question sets: generating more and more elements of S by hand, which feels like proof but never touches the direction that certifies exclusions.
5. What makes you recognise it faster next time: treating "smallest set satisfying closure conditions" as a fixed phrase that always calls for the two inclusion pincer.
6. The reusable decision rule: match the shift constant's prime factors to an invariant, verify a candidate superset closed, then chase the seed until one representative per needed residue class is exhibited.

Mirror drills

1. Repeat the construction with seed 2 and the same rules but shift 3. *Answer:* the upper bound argument transfers unchanged since 3 is prime and $2 \neq 1, 3 \nmid 2$, so 1 and the multiples of 3 are excluded provided the seed's orbit reaches both nonzero residues mod 3.
2. Let S be the smallest set of integers containing 0, closed under $n \mapsto n + 2$ and $n \mapsto -n$. *Answer:* S is the even integers: they are closed under both rules and contain 0, and every even integer is reached from 0 by repeated $+2$ or its negation.
3. Reseed the original problem at 3 instead of 2, shift still 5. *Answer:* the upper bound half is unchanged, since it only used that the seed is not 1 and not a multiple of 5; only the explicit chase needs rechecking to confirm the new orbit still reaches every nonzero residue class mod 5.

9.2 A2. a quotient recursion that is secretly linear

Let $Q_0(x) = 1$, $Q_1(x) = x$, and

$$Q_n(x) = \frac{(Q_{n-1}(x))^2 - 1}{Q_{n-2}(x)}$$

for all $n \geq 2$. Show that, whenever n is a positive integer, $Q_n(x)$ is equal to a polynomial with integer coefficients.

Read it out loud

The definition hands you a division, and a division you are told will always come out even. That is the first thing to say out loud: Q_n is only manifestly a rational function, and the entire content of the problem is that the denominator Q_{n-2} always divides the numerator $Q_{n-1}^2 - 1$ exactly. Whenever a Putnam recursion is stated as a quotient and asks you to prove the result is a polynomial, the examiners are testing whether you reach for polynomial long division (slow, case heavy) or for the algebraic reason the division is exact.

Look at the shape of the numerator: "square of the previous term, minus one". That specific shape, $u_{n-1}^2 -$ (constant) divided by u_{n-2}, is not arbitrary. It is exactly the identity satisfied by two consecutive terms of an ordinary linear three term recurrence, the same shape as Fibonacci's $F_{n-1}F_{n+1} - F_n^2 = (-1)^n$. That resemblance is the guiding light: within the first thirty seconds you should be asking "what linear recurrence, sharing these seeds, would make this quotient identity true by construction," not "how do I divide these polynomials."

The seeds themselves are a further cue: $Q_0 = 1, Q_1 = x$ are exactly the seeds of the simplest possible linear recurrence $u_n = xu_{n-1} - u_{n-2}$, the recurrence behind Chebyshev-like polynomials. That recurrence is manifestly integer coefficient by direct substitution, so if it can be shown to obey Q's own recursion, the whole problem collapses to checking one identity about a sequence with no denominators at all.

Approaches, ranked worst to best

1. **direct polynomial division term by term.** *Cue:* the recursion is stated as an explicit quotient. *Circuit:* compute $Q_2, Q_3, Q_4, \ldots$ by hand, verifying each division is exact. (this only confirms finitely many cases, the algebra grows quickly since each numerator involves the square of an ever larger polynomial, and it gives no reason the pattern continues forever.)
2. **induct on $\deg Q_n = n$ and manipulate the given recursion directly.** *Cue:* avoiding an invented auxiliary sequence. *Circuit:* divide two consecutive instances of the defining relation to expose a telescoping constant ratio, then unwind it into Q's own three term recurrence. (correct and used by some solvers, but it needs the degree induction as a prerequisite before any division of rational expressions is licensed, and discovering that the ratio $(Q_n + Q_{n-2})/Q_{n-1}$ is constant is a harder thing to notice cold than the route below.)
3. **invent a linear auxiliary sequence with the same seeds and identify it with Q.** *Cue:* the quotient's shape matches a Cassini type identity for a linear recurrence. *Circuit:* define $P_n = xP_{n-1} - P_{n-2}$, prove $P_{n-1}^2 - P_nP_{n-2} = 1$ by a companion matrix determinant, then bootstrap $Q_n = P_n$. (best: every hard step lands on P, which has no denominators to worry about, and the determinant identity is a one line induction.)

The ideal solution

Define a second sequence of polynomials by

$$P_0(x) = 1, \quad P_1(x) = x, \quad P_n(x) = xP_{n-1}(x) - P_{n-2}(x) \ (n \geq 2).$$

Since each P_n ($n \geq 2$) is x times an integer coefficient polynomial minus another, P_n has integer coefficients for every $n \geq 0$, by an immediate induction. It suffices to show $Q_n = P_n$ for all $n \geq 0$.

Step 1: a Cassini identity for P. Extend the recurrence backward by setting $P_{-1} = 0$, consistent with $P_1 = xP_0 - P_{-1}$. For $n \geq 1$ define

$$M_n = \begin{pmatrix} P_{n-1} & P_n \\ P_{n-2} & P_{n-1} \end{pmatrix}, \qquad T = \begin{pmatrix} x & -1 \\ 1 & 0 \end{pmatrix}.$$

A direct check of entries, using $P_n = xP_{n-1} - P_{n-2}$ in the top right and top left, gives $TM_n = M_{n+1}$ for every $n \geq 1$. Since $\det T = x \cdot 0 - (-1) \cdot 1 = 1$, induction on n gives $\det M_n = \det M_1$ for all $n \geq 1$. Directly, $\det M_1 = P_0^2 - P_1 P_{-1} = 1 - 0 = 1$. So

$$(P_{n-1})^2 - P_n P_{n-2} = \det M_n = 1 \qquad \text{for every } n \geq 1. \tag{$*$}$$

Step 2: $P_n \neq 0$. By induction, $\deg P_0 = 0, \deg P_1 = 1$, and for $n \geq 2$, $\deg(xP_{n-1}) = n$ strictly exceeds $\deg P_{n-2} = n - 2$, so no cancellation occurs and $\deg P_n = n$. In particular P_n is never the zero polynomial.

Step 3: bootstrap $Q_n = P_n$. Induct on n. The base cases $Q_0 = 1 = P_0$ and $Q_1 = x = P_1$ hold by definition. Suppose $n \geq 2$ and $Q_{n-1} = P_{n-1}, Q_{n-2} = P_{n-2}$. By ($*$) with this value of n, $(P_{n-1})^2 - 1 = P_n P_{n-2}$ identically as polynomials, and $P_{n-2} \neq 0$ by Step 2, so dividing gives

$$Q_n = \frac{(Q_{n-1})^2 - 1}{Q_{n-2}} = \frac{(P_{n-1})^2 - 1}{P_{n-2}} = P_n,$$

an exact polynomial quotient. This completes the induction: $Q_n = P_n$ for every $n \geq 0$, and since P_n has integer coefficients, so does Q_n.

$Q_n(x) = P_n(x)$, defined by $P_0 = 1, P_1 = x, P_n = xP_{n-1} - P_{n-2}$, which manifestly has integer coefficients.

Layer 1: WHAT

Block 1: recognise the quotient's shape, "square of previous term minus a constant, over two back", as a Cassini type identity belonging to some linear recurrence. Block 2: guess the linear recurrence $P_n = xP_{n-1} - P_{n-2}$ sharing Q's seeds; note it is integer coefficient by construction. Block 3: reduce the whole problem to one identity, $P_{n-1}^2 - P_n P_{n-2} = 1$. Block 4: prove that identity via a companion matrix of determinant 1. Block 5: separately confirm $P_n \neq 0$ via a degree induction, so the division in Step 3 of the solution is licensed. Block 6: bootstrap $Q_n = P_n$ by strong induction, using Steps 1 and 2 at each stage.

The nominal route stalls inside Block 1: it computes $Q_2, Q_3, \ldots$ directly, confirms integrality case by case, and never converts the pattern into a proof for general n. The bifurcation point is the moment you ask "what recurrence produces exactly this quotient as an identity" instead of "let me compute the next term and check."

Layer 2: HOW

Block 1. Cue. The recursion divides a quadratic expression in the previous term by the term two back. **Why natural.** This is precisely the algebraic shape of $u_{n-1}^2 - u_n u_{n-2} =$ constant, the identity any linear two term recurrence with unit determinant companion matrix satisfies. **Link to the next block.** If such a linear recurrence exists and shares Q's seeds, it is a candidate for Q itself.

Block 2. Cue. $Q_0 = 1, Q_1 = x$ are the seeds of the simplest possible linear recurrence in x. **Why natural.** Defining $P_n = xP_{n-1} - P_{n-2}$ with these seeds gives a sequence with integer coefficients by direct induction, no division involved anywhere. **Link to the next block.** Whether $P = Q$ now rests entirely on whether P obeys Q's own defining relation.

Block 3. **Cue.** P obeys Q's relation exactly when $P_{n-1}^2 - 1 = P_n P_{n-2}$ identically. **Why natural.** Uniqueness of a recurrence's solution given initial data means matching both the seeds and the recursion forces the sequences to coincide. **Link to the next block.** Proving this single polynomial identity is now the entire remaining task.

Block 4. **Cue.** The target identity is exactly a 2×2 determinant of consecutive terms. **Why natural.** Packaging P_{n-1}, P_n, P_{n-2} into a matrix M_n and noting $TM_n = M_{n+1}$ for the companion matrix T turns the identity into $\det M_n = (\det T)^{n-1} \det M_1$, and $\det T = 1$ collapses this to a constant. **Link to the next block.** Before dividing by P_{n-2} in the bootstrap, its nonvanishing needs separate justification.

Block 5. **Cue.** The division $Q_n = (Q_{n-1}^2 - 1)/Q_{n-2}$ is only meaningful if $Q_{n-2} \neq 0$. **Why natural.** A quick degree induction shows $\deg P_n = n$, since xP_{n-1} strictly dominates P_{n-2} in degree, so P_n is never zero. **Link to the next block.** With both the identity and the nonvanishing in hand, the induction identifying Q_n with P_n can run at every step.

Block 6. **Cue.** Two sequences share initial values and the same defining recursion. **Why natural.** Substituting the inductive hypothesis into Q's definition and using $(*)$ turns the division into the exact quotient P_n, with no remainder. **Link to the next block.** The induction closes, and integer coefficients transfer from P to Q immediately.

Layer 3: WHY

The route is ideal because a quotient recursion of the shape $u_n = (u_{n-1}^2 - c)/u_{n-2}$ is never really about division at all: it is the Cassini invariant of some linear recurrence in disguise, and linear recurrences with integer or polynomial coefficients are always polynomial by construction. The discernment mechanism is to see past the division to the quadratic identity it encodes, and to recall that such identities are the fingerprints of companion matrices with determinant 1 (giving a genuine constant) or determinant -1 (giving an alternating sign, as in Fibonacci). Once that fingerprint is recognised, the problem stops being about Q at all and becomes a short, self contained fact about P, which is easier on every axis: no denominators, no need to verify nonvanishing beyond a degree count, and a proof by induction that never touches an inequality or a case split.

Training this discernment means building the reflex: whenever a recursion's right hand side is "(square of one term, minus a constant) divided by another term two steps back", immediately write down the guess $u_n = au_{n-1} - u_{n-2}$ (or the appropriate two term linear form matching the seeds) and check its Cassini identity, before attempting any direct manipulation of the given quotient.

Revolving concepts

Cassini type identities via companion matrices. For $u_n = au_{n-1} + bu_{n-2}$, the matrices $M_n = \begin{pmatrix} u_{n-1} & u_n \\ u_{n-2} & u_{n-1} \end{pmatrix}$ satisfy $M_{n+1} = TM_n$ for the companion matrix $T = \begin{pmatrix} a & b \\ 1 & 0 \end{pmatrix}$, so $\det M_n = (\det T)^{n-1} \det M_1$. See Book 1, field: Linear algebra, topic: companion matrices. Generalised recursion: whenever $\det T = 1$, $u_{n-1}^2 - u_n u_{n-2}$ is the same constant for every n; whenever $\det T = -1$, it alternates sign, recovering Fibonacci's $F_{n-1}F_{n+1} - F_n^2 = (-1)^n$. Any Putnam sequence defined by a quotient of this shape should immediately be tested against this template, with a, b read off from matching the quotient's coefficients.

Uniqueness of solutions to a second order recurrence. Two sequences obeying the same recursion and agreeing on the first two terms are identical for all later terms, by direct induction. See Book 1, field: Sequences and recurrences, topic: recurrence uniqueness.

Degree growth under a dominant linear term. If one term of a linear recurrence has strictly larger degree than the other at every step, no cancellation of leading terms is possible, so the degree grows by exactly the dominant term's degree each step. See Book 1, field: Polynomials, topic: degree induction.

The Laurent phenomenon. Beyond A level: recursions of the shape $u_n u_{n-2} = u_{n-1}^2 - 1$ (and more general exchange relations) are toy instances of the Laurent phenomenon from cluster algebra theory, where iterating such a birational recursion always produces Laurent polynomials, here genuine polynomials, in the initial data. Not needed for the elementary proof, but it is the reason this style of problem recurs: the integrality is not a coincidence of this one recursion, it is a shadow of a much larger structure. See Book 1, field: Abstract algebra, topic: cluster algebras.

Circuit Bank

- **WHEN** a recursion divides (square of the previous term minus a constant) by the term two back **DO** guess the linear recurrence sharing the same seeds and test its Cassini identity via a companion matrix **BECAUSE** such quotients are exactly the fingerprint of a linear recurrence with unit or minus one determinant companion matrix, so the division is guaranteed exact once that identity is confirmed
- **WHEN** two sequences share initial values and a recursive rule **DO** prove them equal by strong induction rather than manipulating either sequence's closed form **BECAUSE** uniqueness of solutions to a well posed recursion makes this the shortest possible route to equality
- **WHEN** a division needs to be justified as exact, or a term needs to be shown nonzero **DO** run a quick degree induction rather than inspecting coefficients **BECAUSE** a strictly dominant term at each step rules out cancellation, giving the degree, and hence nonvanishing, for free

Backtesting

1. First useful cue: the recursion divides a quadratic expression in the previous term by the term two back.
2. Method the expression suggested: match the quotient's shape to the Cassini identity of a guessed linear recurrence sharing the same seeds.
3. Where you would hesitate: unsure why the division is guaranteed exact before proving anything; reinforce that the Cassini identity, once proved for the linear sequence, supplies exact divisibility automatically.
4. The trap the question sets: computing Q_2, Q_3, Q_4 directly and trying to induct on the quotient itself, fighting an increasingly complicated rational expression.
5. What makes you recognise it faster next time: the signature "square minus a constant, divided by two back" as the fixed fingerprint of a Cassini identity, the same fingerprint behind Fibonacci's identity.
6. The reusable decision rule: replace a quotient defined recursion with a guessed linear recursion on the same seeds, prove its Cassini identity via a unit determinant companion matrix, then identify the two sequences by induction.

Mirror drills

1. Prove Fibonacci's identity $F_{n-1}F_{n+1} - F_n^2 = (-1)^n$. *Answer:* same companion matrix argument with $T = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$, $\det T = -1$, so $\det M_n = (-1)^{n-1} \det M_1$ alternates sign.

2. Let $R_0 = 2, R_1 = x, R_n = xR_{n-1} - R_{n-2}$. Find the constant value of $R_{n-1}^2 - R_n R_{n-2}$. *Answer:* the same companion matrix has $\det T = 1$, and $\det M_1 = R_0^2 - R_1 R_{-1} = 4 - x^2$ (using $R_{-1} = x$ from the backward extension), so the constant is $4 - x^2$ for every n.

3. A numerical sequence has $u_0 = 1, u_1 = 2$, $u_n = (u_{n-1}^2 - 1)/u_{n-2}$. Identify the hidden linear recurrence and closed form. *Answer:* matching $u_2 = (4-1)/1 = 3$ to $au_1 - u_0$ gives $a = 2$, so $u_n = 2u_{n-1} - u_{n-2}$, the arithmetic progression recursion, giving $u_n = n + 1$.

9.3 A3. turning an unused zero integral into a sign

Let a and b be real numbers with $a < b$, and let f and g be continuous functions from $[a, b]$ to $(0, \infty)$ such that $\int_a^b f(x)\,dx = \int_a^b g(x)\,dx$ but $f \neq g$. For every positive integer n, define

$$I_n = \int_a^b \frac{(f(x))^{n+1}}{(g(x))^n}\,dx.$$

Show that $I_1, I_2, I_3, \ldots$ is an increasing sequence with $\lim_{n\to\infty} I_n = \infty$.

Read it out loud

Say the hypotheses back to yourself in order. You are told two integrals are equal, and separately that the two functions producing them are not the same function. The first statement, $\int f = \int g$, is algebraically identical to $\int_a^b (f - g)\,dx = 0$, and that is a fact you have been handed for free and have not yet used anywhere. The second statement, $f \neq g$, is currently just a label; it only becomes useful once continuity converts "differs somewhere" into "differs, with one sign, on a whole subinterval". Both hypotheses are inert until you build an expression that actually contains $(f - g)$.

Now look at what you are asked to prove: a sequence indexed by an exponent is increasing and unbounded. Whenever a sequence like $I_n = \int \phi^{n+1}/\psi^n$ is indexed by a power, the natural object to build is not I_n itself but the difference $I_{n+1} - I_n$, because the numerators of two consecutive terms are just one extra factor of f or g apart, and a difference of two things that are "the same shape, one exponent apart" is exactly where the factorisation $a^k - b^k = (a - b)(a^{k-1} + \cdots + b^{k-1})$ lives.

Put the two observations together and the plan writes itself within the first thirty seconds: form $I_{n+1} - I_n$, pull out a common power of f/g, insert the zero you were handed, and watch a difference of equal powers of f and g appear, ready to be factored down to $(f - g)^2$ times something manifestly positive.

Approaches, ranked worst to best

1. **attempt a closed form or a direct size estimate for I_n.** *Cue:* the problem hands you an explicit integral formula. *Circuit:* substitution or crude bounding of f^{n+1}/g^n. (there is no closed form for arbitrary continuous f, g, and this approach never engages with the two hypotheses at all, so it stalls immediately with nothing to say about monotonicity or growth.)

2. **Cauchy-Schwarz on I_n, I_{n+1}, I_{n+2} to get log-convexity.** *Cue:* a sequence indexed by an exponent, resembling a moment sequence. *Circuit:* $I_n I_{n+2} \geq I_{n+1}^2$, then a ratio test using an auxiliary term $I_0 = \int f$. (this works and is a standard powerful circuit, but it needs the extra term I_0, a separate small argument that $I_1 > I_0$, and a ratio telescoping step; more machinery than is needed here.)

3. **insert the zero integral into the difference $I_{n+1} - I_n$ and factor.** *Cue:* $\int (f - g) = 0$ is an unused hypothesis, and the sequence's exponent structure invites a difference of equal powers. *Circuit:* the identity $a^k - b^k = (a - b)(a^{k-1} + \cdots + b^{k-1})$ applied to $f^{n+1} - g^{n+1}$. (best: handles both the increasing claim and, after one more short continuity argument, the divergence claim, with no auxiliary sequence and no inequality beyond positivity of an integral.)

The ideal solution

Step 1: the sequence is increasing. Fix $n \geq 1$. Since $g > 0$ throughout $[a, b]$,

$$I_{n+1} - I_n = \int_a^b \left(\frac{f^{n+2}}{g^{n+1}} - \frac{f^{n+1}}{g^n} \right) dx = \int_a^b \frac{f^{n+1}}{g^{n+1}} (f - g)\,dx.$$

Because $\int_a^b (f-g)\,dx = 0$, subtracting this (zero) quantity changes nothing:

$$I_{n+1} - I_n = \int_a^b \left(\frac{f^{n+1}}{g^{n+1}} - 1\right)(f-g)\,dx = \int_a^b \frac{f^{n+1}-g^{n+1}}{g^{n+1}}(f-g)\,dx.$$

Using $f^{n+1} - g^{n+1} = (f-g)\sum_{k=0}^{n} f^k g^{n-k}$,

$$I_{n+1} - I_n = \int_a^b \frac{(f-g)^2 \sum_{k=0}^{n} f^k g^{n-k}}{g^{n+1}}\,dx.$$

The integrand is continuous (as f, g are continuous and $g > 0$) and nonnegative everywhere, since it is a square times a sum of positive terms divided by a positive quantity. It is not identically zero: as $f \neq g$ on $[a,b]$, some x_0 has $f(x_0) \neq g(x_0)$, so the integrand is strictly positive at x_0, hence (by continuity) on a subinterval of positive length around x_0. A continuous, nonnegative function on $[a,b]$ that is positive on a subinterval of positive length has a strictly positive integral. Hence $I_{n+1} > I_n$ for every $n \geq 1$, so $I_1 < I_2 < I_3 < \cdots$.

Step 2: the sequence diverges. First, it cannot be that $f \leq g$ throughout $[a,b]$: if it were, $h = g - f$ would be continuous, nonnegative, with $\int_a^b h\,dx = \int g - \int f = 0$; by the same positivity fact used above, this forces $h \equiv 0$, contradicting $f \neq g$. So there is some $t \in [a,b]$ with $f(t) > g(t)$. Fix c with $1 < c < f(t)/g(t)$; since f/g is continuous, there is a nondegenerate closed subinterval $J \subseteq [a,b]$ containing t on which $f(x) \geq c\,g(x)$ for all $x \in J$, hence also $f(x)^n \geq c^n g(x)^n$ on J for every positive integer n. Then, discarding the rest of $[a,b]$ (where the integrand is still positive, so only makes the bound weaker),

$$I_n = \int_a^b \frac{f^{n+1}}{g^n}\,dx \geq \int_J \frac{f^{n+1}}{g^n}\,dx = \int_J f\left(\frac{f}{g}\right)^n dx \geq c^n \int_J f\,dx.$$

Since f is continuous and strictly positive on the nondegenerate interval J, $d := \int_J f\,dx$ is a fixed positive number, independent of n. As $c > 1$, $c^n \to \infty$, so

$$I_n \geq c^n d \longrightarrow \infty \qquad \text{as } n \to \infty.$$

This proves both required claims:

$$\boxed{I_1 < I_2 < I_3 < \cdots \quad \text{and} \quad \lim_{n\to\infty} I_n = \infty.}$$

Layer 1: WHAT

Block 1: notice $\int (f-g)\,dx = 0$ is an unused hypothesis waiting to be inserted into a constructed difference. Block 2: form $I_{n+1} - I_n$ and pull out the common factor f^{n+1}/g^{n+1}, reducing to $\int (f^{n+1}/g^{n+1})(f-g)\,dx$. Block 3: insert the zero to rewrite the bracket as $f^{n+1}/g^{n+1} - 1$, then factor $f^{n+1} - g^{n+1}$ to expose $(f-g)^2$ times a manifestly positive sum. Block 4: invoke "continuous, nonnegative, not identically zero implies strictly positive integral" to conclude $I_{n+1} > I_n$. Block 5: reuse the same positivity fact in a proof by contradiction to rule out $f \leq g$ everywhere, producing a point, then (by continuity) an interval J, where $f \geq cg$ for some $c > 1$. Block 6: bound I_n below by discarding everything outside J, giving $I_n \geq c^n d \to \infty$.

The nominal route never leaves Block 1: it tries to bound or estimate I_n directly, by size comparison or a blind inequality, and never builds an expression containing $(f-g)$, so the zero-integral hypothesis sits unused throughout. The bifurcation point is the decision to compute a difference of consecutive terms specifically because the hypothesis is stated as an equality of two integrals, rather than working with a single I_n in isolation.

Layer 2: HOW

Block 1. **Cue.** The hypothesis is phrased as two integrals being equal. **Why natural.** This is algebraically the same as saying the integral of the difference is zero, a fact that can be inserted into any later expression without changing its value. **Link to the next block.** Holding this fact in reserve, the next task is to build an expression that actually contains $(f - g)$.

Block 2. **Cue.** The sequence is indexed by an exponent, and consecutive terms I_n, I_{n+1} share the shape $f^\bullet/g^\bullet$ one power apart. **Why natural.** Subtracting consecutive terms and factoring out the shared power turns the comparison into a single integral of $(f^{n+1}/g^{n+1})(f - g)$, rather than two separate unrelated integrals. **Link to the next block.** This integral has no obvious sign yet; the reserved zero from Block 1 is what will fix that.

Block 3. **Cue.** The bracket f^{n+1}/g^{n+1} has no fixed sign relative to 1 at a glance. **Why natural.** Subtracting the reserved zero converts it to $f^{n+1}/g^{n+1} - 1$, and the numerator $f^{n+1} - g^{n+1}$ always factors as $(f - g)$ times a sum of positive terms, exposing $(f - g)^2$ once multiplied against the outer $(f - g)$. **Link to the next block.** A square is now sitting in the integrand; only its non-identical-vanishing needs to be argued.

Block 4. **Cue.** The integrand is now visibly a square times positive quantities, divided by a positive quantity. **Why natural.** $f \neq g$ guarantees the square is positive somewhere, and continuity upgrades "somewhere" to "on a subinterval", which is exactly what a nonzero integral requires. **Link to the next block.** Monotonicity is settled; divergence still needs a genuinely new idea, since a merely increasing sequence need not be unbounded.

Block 5. **Cue.** Divergence needs more than "somewhere positive"; it needs growth that compounds with n. **Why natural.** Ruling out $f \leq g$ everywhere (by the same positivity fact, in a proof by contradiction) produces a single point where $f > g$, and continuity of f/g upgrades that point to an entire interval J with a fixed ratio bound $c > 1$. **Link to the next block.** An interval with a uniform ratio bound is precisely what lets the exponent n do compounding work.

Block 6. **Cue.** On J, every factor of f/g in the integrand is at least $c > 1$. **Why natural.** Discarding the rest of the domain only weakens a lower bound (the integrand is nonnegative there), so I_n is bounded below by c^n times the fixed constant $\int_J f$. **Link to the next block.** Since $c > 1$, this lower bound tends to infinity, finishing the proof.

Layer 3: WHY

The route is ideal because a hypothesis stated as "two integrals are equal" is never really about equality, it is a licence to insert a specific zero into any expression you build afterward, and the only expressions worth building are ones that already contain $(f - g)$, since that is the only place the licence can be spent. Once you commit to constructing a difference of consecutive sequence terms (forced by the fact that you are asked about monotonicity in the first place), the exponents guarantee a difference of equal powers of f and g appears, and the factorisation of $a^k - b^k$ is the unique elementary tool that turns such a difference into a signed quantity. The discernment mechanism is to treat $\int(f - g) = 0$ as inert until an $(f - g)$ literally appears in your working, and to actively engineer its appearance by subtracting consecutive terms rather than analysing a single term.

The divergence half reuses the very same real analysis fact, positivity of the integral of a nonzero nonnegative continuous function, but in the contrapositive direction: instead of using it to sign an integral, it is used to rule out a global inequality ($f \leq g$ everywhere), which is what manufactures the single strict inequality point that continuity then inflates into an interval. Training this discernment

means recognising that this one lemma about continuous nonnegative functions is doing all the real work in the problem twice over, and that whenever a "differs somewhere" hypothesis needs to become "differs substantially, on a set of positive length", continuity of the relevant ratio or difference is the only tool that makes the upgrade.

Revolving concepts

Positivity of the integral of a nonnegative continuous function. If h is continuous and nonnegative on $[a, b]$ with $h(t_0) > 0$ for some t_0, then $h > \frac{1}{2}h(t_0)$ on a subinterval of positive length around t_0, so $\int_a^b h\,dx > 0$; equivalently, a nonnegative continuous function with zero integral is identically zero. See Book 1, field: Real analysis, topic: positivity of integrals.

Difference of like powers. For real a, b and integer $k \geq 1$, $a^k - b^k = (a-b)(a^{k-1} + a^{k-2}b + \cdots + b^{k-1})$. See Book 1, field: Polynomials, topic: factorisation identities. Generalised recursion: whenever a difference of two equal, high powers of two quantities appears or can be engineered to appear, this identity converts it into (the base difference) times (a manifestly signed sum when the quantities share a sign), the standard route to manufacturing a squared, hence signed, quantity from a bare difference.

Continuity upgrades a point to an interval. If ϕ is continuous at t and $\phi(t) > c$, then $\phi(x) > c$ throughout some subinterval around t (one sided if t is an endpoint), since nearby values cannot jump away from $\phi(t)$. See Book 1, field: Real analysis, topic: local behaviour of continuous functions.

Cauchy-Schwarz and log-convexity of parametrised integrals. For positive integrands, Cauchy-Schwarz applied to $\sqrt{f^{n+1}/g^n} \cdot \sqrt{f^{n+3}/g^{n+2}} = f^{n+2}/g^{n+1}$ gives $I_n I_{n+2} \geq I_{n+1}^2$, so $\log I_n$ is convex in n and the ratios I_{n+1}/I_n are nondecreasing; this is the mechanism behind the alternate solution and a standard route to monotonicity or growth results for any sequence of integrals indexed by an exponent. See Book 1, field: Inequalities, topic: log-convexity via Cauchy-Schwarz.

Circuit Bank

- **WHEN** a hypothesis states two integrals (or sums) are equal **DO** immediately rewrite it as "the integral (or sum) of the difference is zero" and hold it in reserve **BECAUSE** that reserved zero can be inserted into any later expression built from the same difference without changing its value, which is otherwise the only use such a hypothesis has

- **WHEN** a sequence of integrals is indexed by an exponent and monotonicity is asked for **DO** compute the difference of consecutive terms and factor out the shared power **BECAUSE** consecutive terms of an exponent indexed sequence differ by exactly one extra factor, which is precisely the setting where a difference of equal powers, and hence the factorisation $a^k - b^k = (a-b)(\cdots)$, becomes available

- **WHEN** a difference of two equal powers of positive quantities appears **DO** factor it as $(a-b)$ times a sum of positive cross terms **BECAUSE** this is the one identity that turns a bare power difference into a manifestly signed quantity, and combined with an outer $(a-b)$ it produces a square, the cheapest possible guaranteed sign

- **WHEN** a growth or divergence claim needs more than a single point of strict inequality **DO** upgrade the point to a subinterval via continuity, then bound the integral below using only that subinterval **BECAUSE** a single point contributes nothing to an integral, but continuity guarantees the strict inequality persists on a set of positive length, which is enough to build a genuine geometric lower bound

Backtesting

1. First useful cue: the hypothesis states two integrals are equal, an unused zero waiting to be inserted somewhere.
2. Method the expression suggested: form the difference of consecutive terms of the exponent indexed sequence and factor out the shared power of f/g.
3. Where you would hesitate: after reaching $\int (f^{n+1}/g^{n+1})(f-g)\,dx$, unsure how to pin down a sign; reinforce that inserting the reserved zero and factoring $f^{n+1} - g^{n+1}$ always exposes a square.
4. The trap the question sets: trying to bound I_n directly by size comparisons or a blind inequality, which leaves the zero integral hypothesis completely unused and the monotonicity claim unreachable.
5. What makes you recognise it faster next time: seeing "two integrals equal, functions not identical" as a fixed signature that wants a difference built and a zero inserted, with the continuity upgrade reused whenever a single point of strict inequality needs to become an interval.
6. The reusable decision rule: whenever $\int (f-g) = 0$ is given, build the next expression as a difference containing $(f-g)$, insert the zero, factor, and reach for continuity the moment a single point of strict inequality needs to grow into an interval.

Mirror drills

1. Let h be continuous and nonnegative on $[a,b]$ with $h(t_0) > 0$ for some $t_0 \in [a,b]$. Show $\int_a^b h\,dx > 0$, and deduce that a nonnegative continuous function with zero integral is identically zero. *Answer:* by continuity $h > \frac{1}{2}h(t_0)$ on a subinterval of positive length around t_0, so $\int h$ exceeds $\frac{1}{2}h(t_0)$ times that length; the second claim is the contrapositive.
2. With positive reals $a_1, \ldots, a_m$ and $b_1, \ldots, b_m$ satisfying $\sum a_i = \sum b_i$ but $(a_i) \neq (b_i)$, show $\sum_i a_i^{n+1}/b_i^n$ is strictly increasing in n. *Answer:* the identical computation with sums replacing integrals: the difference of consecutive terms telescopes to $\sum_i (a_i - b_i)^2 (\text{positive terms})/b_i^{n+1}$, positive since not all $a_i = b_i$.
3. Under the hypotheses of the main problem, show directly that $\int_a^b (f-g)^2\,dx > 0$. *Answer:* $f \neq g$ gives a point of strict inequality, continuity upgrades it to a subinterval, and a nonnegative continuous function positive on a subinterval has positive integral.

9.4 A4. A sliding window splits the class

A class with $2N$ students took a quiz, on which the possible scores were $0, 1, \ldots, 10$. Each of these scores occurred at least once, and the average score was exactly 7.4. Show that the class can be divided into two groups of N students in such a way that the average score for each group was exactly 7.4.

Read it out loud

Say the structure before you say the numbers. You are handed a multiset of $2N$ integers drawn from the block $\{0, 1, \ldots, 10\}$, told that every value in that block is actually used, and told that the total is pinned at $7.4 \cdot 2N$. You are asked to cut that multiset into two halves of equal size and equal sum. So this is an existence statement about an exact value, and existence statements about exact values are almost never proved by building the object. They are proved by moving a parameter and catching the target as it goes past.

The fields wired into it: a scrap of elementary number theory (the average is not an integer, so it is quietly doing arithmetic work on N), order combinatorics (sorting is the only structure a bare multiset has), and the discrete intermediate value theorem, which is what is really being tested.

Within thirty seconds three lines should be on your paper. First, the total is $7.4 \cdot 2N = \frac{74N}{5}$, and it is a sum of integers, so 5 divides N and the per group target $7.4N = \frac{37N}{5}$ is itself an integer. Second, it is enough to find N of the scores summing to $7.4N$, because the complementary N then sum to $14.8N - 7.4N = 7.4N$ for free; that halves the problem and costs nothing. Third, sort.

Now look at the hypothesis that reads like scene setting: each of the scores 0 to 10 occurred at least once. That is not scene setting, it is the engine. Take thirteen students scoring 0 and thirty seven scoring 10. That is 50 students with total 370, average exactly 7.4, and no valid split exists at all, because every group sum is then a multiple of 10 while the target is 185. The fact you must use is that the set of achieved values is a block of consecutive integers. Any proof of yours that never uses it is wrong, and you should hunt for the error rather than celebrate.

Approaches, ranked worst to best

1. **Classify by the eleven multiplicities.** *Cue:* the scores only run from 0 to 10, so "there are finitely many shapes". *Circuit:* case analysis on the score distribution. You are staring at an eleven dimensional lattice of multiplicity vectors cut by one linear equation, with N unbounded. There is no finite check to run. Induction on N dies for the same reason: deleting two students can destroy "every score occurs" and it moves the target, so the hypothesis does not survive the induction step.

2. **Generating function coefficient extraction.** *Cue:* "choose a subset with a prescribed sum". *Circuit:* read off $[y^N x^{7.4N}] \prod_j (1 + yx^{a_j})$. To finish you must prove that one coefficient is positive, and there is no positivity mechanism available here: no unimodality you can invoke, no symmetry that forces a nonzero term. The generating function restates the problem in heavier notation and hands you nothing.

3. **Reserve one student of each score, then fine tune.** *Cue:* "each of these scores occurred at least once" reads as "you have been given a full set of small change". *Circuit:* park the eleven compulsory students, run a window on the rest, repair the remainder with a small subset of the parked ones. This works, and it is essentially the second official route. The cost is an extra lemma (every integer from 15 to 40 is a sum of five distinct elements of $\{1, \ldots, 10\}$) plus a page of index bookkeeping. More ink, same conclusion.

4. **Exchange argument.** *Cue:* "two groups, equal sums". *Circuit:* descend on the integer potential $|\Sigma A - \Sigma B|$. Start from any split into halves A and B. The potential is a nonnegative integer

with the same parity as the total, hence even. If it is positive, then $\Sigma A > \Sigma B$ forces some $a \in A$ to exceed some $b \in B$; take such a pair with $a - b$ minimal, and the consecutive block hypothesis forces $a - b = 1$, since otherwise the value $a - 1$ occurs somewhere in the class and produces a strictly smaller pair. Swap that pair and the potential drops by exactly 2. Descent in $\mathbb{N}$ terminates, at 0. This is a genuinely good solution and it generalises well; it sits below the winner only because the minimal pair step is a second argument bolted on.

5. **Sliding window plus discrete intermediate value theorem.** *Cue:* exact target, and the only structure available is order. *Circuit:* parametrise a family of candidate groups that changes by one student at a time, and catch the target on the way past. Sort, slide a window of N consecutive scores along the sorted list, and observe that the two extreme windows average to the target. Monotonicity does the searching. One inequality and one deletion finish it.

The ideal solution

Write $a_1 \le a_2 \le \cdots \le a_{2N}$ for the scores in nondecreasing order, so every a_j lies in $\{0, 1, \ldots, 10\}$ and every element of $\{0, 1, \ldots, 10\}$ occurs among them. Put $\Sigma = \sum_{j=1}^{2N} a_j = 7.4 \cdot 2N = \frac{74N}{5}$.

Step 0 (integrality, and halving the goal). Σ is a sum of integers, so 5 divides $74N$ and hence 5 divides N. Therefore

$$T := 7.4N = \frac{37N}{5} \in \mathbb{Z}, \qquad \Sigma = 2T.$$

It is enough to produce N of the scores with sum exactly T: the remaining N scores then sum to $\Sigma - T = T$, and each group has average $T/N = 7.4$.

Step 1 (the window family). For $0 \le i \le N$ let

$$s_i = \sum_{j=i+1}^{i+N} a_j,$$

the sum of the N consecutive terms starting at position $i + 1$. Then

$$s_{i+1} - s_i = a_{i+N+1} - a_{i+1} \ge 0$$

by sortedness, so $s_0 \le s_1 \le \cdots \le s_N$. Also $s_0 + s_N = \Sigma = 2T$, since the two extreme windows are the bottom half and the top half. Hence $s_0 \le T \le s_N$.

Step 2 (the ends are distinct). The scores are not all equal, because 0 and 10 both occur. Suppose $s_0 = s_N$. Then every s_i is equal, so $a_{j+N} = a_j$ for $1 \le j \le N$. In particular $a_1 = a_{N+1} \ge a_N \ge a_1$, so $a_1 = a_2 = \cdots = a_{N+1}$, and then $a_{N+j} = a_j = a_1$ for $1 \le j \le N$ makes all $2N$ scores equal. Contradiction, so $s_0 < s_N$.

Step 3 (discrete intermediate value theorem). Let i be the largest index in $\{0, 1, \ldots, N\}$ with $s_i \le T$; it exists because $s_0 \le T$. If $i = N$ then $s_N \le T \le s_N$ gives $s_N = T$, whence $s_0 = 2T - s_N = T = s_N$, contradicting Step 2. So $i \le N - 1$, and by maximality

$$s_i \le T < s_{i+1} = s_i + a_{i+N+1} - a_{i+1}.$$

Step 4 (the value that must be deleted). Consider the $N + 1$ consecutive terms $a_{i+1}, \ldots, a_{i+N+1}$, whose total is $s_i + a_{i+N+1}$. If we delete one term of value v we are left with N terms of total T precisely when

$$v = s_i + a_{i+N+1} - T,$$

which is an integer by Step 0. The two inequalities of Step 3 now pin it down: $s_i \le T$ gives $v \le a_{i+N+1}$, and $T < s_i + a_{i+N+1} - a_{i+1}$ gives $v > a_{i+1}$. Thus

$$a_{i+1} < v \le a_{i+N+1}.$$

Step 5 (the block lemma).

Lemma 9.4.1. *For any $1 \le p \le q \le 2N$, every integer w with $a_p \le w \le a_q$ occurs among $a_p, a_{p+1}, \dots, a_q$.*

Proof. Since $0 \le a_p \le w \le a_q \le 10$, the integer w lies in $\{0, 1, \dots, 10\}$ and therefore occurs in the class, say $w = a_t$. If $t < p$ then $a_t \le a_p \le w = a_t$, so $a_p = w$ and w occurs at position p. If $t > q$ then symmetrically $a_q = w$. Otherwise $p \le t \le q$ already. In every case w occurs in the run. □

This is the only place the hypothesis "each score occurred at least once" is used, and it is exactly the place where it is indispensable.

Step 6 (finish). Apply the lemma with $p = i + 1$ and $q = i + N + 1$: by Step 4 the integer v satisfies $a_{i+1} \le v \le a_{i+N+1}$, so $v = a_t$ for some t with $i + 1 \le t \le i + N + 1$. Let the first group consist of the N students at positions $\{i + 1, \dots, i + N + 1\} \setminus \{t\}$; their total is

$$(s_i + a_{i+N+1}) - v = T.$$

The remaining N students have total $\Sigma - T = T$. Both groups therefore have average $\boxed{7.4}$, as required.

Layer 1: WHAT

Block 1. Clear the decimal: $\Sigma = \frac{74N}{5}$ is an integer, so $5 \mid N$ and $T = 7.4N$ is an integer.

Block 2. Halve the goal: find one group of N with sum T; the complement is then automatic.

Block 3. Sort, because the only structure a multiset carries is order, and the special hypothesis is a statement about the sorted list having no gaps.

Block 4. Build the window sums $s_0 \le \cdots \le s_N$. Their two ends add to $2T$, so the target is trapped between them.

Block 5. Take the last window at or below T. The step to the next window is a single swap of size $a_{i+N+1} - a_{i+1}$, so the shortfall $T - s_i$ is smaller than that swap.

Block 6. Widen the window to $N + 1$ terms and ask which single value has to be deleted. It is forced: $v = s_i + a_{i+N+1} - T$, and the two inequalities put v strictly inside the range of the run.

Block 7. The block lemma says the run realises every integer between its endpoints, so v is actually there. Delete it and finish.

Juxtaposition. The nominal route fixes the target and then tries to build a group that hits it, greedily or by case analysis on the multiplicities, or attempts induction on N. Every version of that spends its effort on the wrong object. The bifurcation point is Block 4: the zombie chooses *a subset*, the ideal route chooses *a one parameter family of subsets* and lets monotonicity do the choosing. Everything after Block 4 is bookkeeping.

Layer 2: HOW

Block 1. **Cue.** An average stated as 7.4, a non-integer, attached to an integer valued quantity. **Why natural.** A non-integer average is never decoration. Multiply out at once: $\Sigma = \frac{74N}{5}$ must be an integer, so $5 \mid N$. That single line is what later makes v an integer, and without it Step 4 produces a fractional value and the whole proof collapses. **Link to the next block.** Knowing T is an integer, you can state the goal purely in integers.

Block 2. **Cue.** "Divided into two groups of N ... average for each group". **Why natural.** Two groups of equal size partitioning a fixed total is one condition, not two: fix one half and the other is determined. Always strip a partition condition down to a single subset condition before you start work. **Link to the next block.** You now need one subset of size N with a prescribed sum, which is a search over a structured family.

Block 3. **Cue.** A multiset of integers with a hypothesis about *which values occur*. **Why natural.** Sorting is free and it converts "which values occur" into "the sorted list has no gaps", which is a usable local statement about consecutive terms. Sorting also makes any window sum monotone in its starting index, which is the property the whole proof runs on. **Link to the next block.** With the list sorted, a family of subsets indexed by one integer becomes available.

Block 4. **Cue.** You need one subset of size N hitting an exact value, and you have a total order. **Why natural.** Take the windows of N consecutive terms. Consecutive windows differ by exactly one swap, so the sums move monotonically and in controlled steps; and the first and last windows are the bottom half and the top half, whose sums add to $\Sigma = 2T$. Hence $s_0 \le T \le s_N$ with no computation at all. This is the discrete intermediate value theorem being set up. **Link to the next block.** The target lies between the two ends of a monotone integer sequence, so some step straddles it.

Block 5. **Cue.** A monotone sequence crossing a target. **Why natural.** Choose the last index at or below the target. That is the only choice that gives you a two sided bound: $s_i \le T$ from the definition, $T < s_{i+1}$ from maximality. Also check the degenerate end, $i = N$, since a proof that silently assumes $i < N$ is incomplete; the symmetry $s_0 + s_N = 2T$ kills that case in one line. **Link to the next block.** You now have $0 \le T - s_i < a_{i+N+1} - a_{i+1}$, which is a bound of exactly one swap.

Block 6. **Cue.** A shortfall smaller than one swap. **Why natural.** A window of N terms cannot be adjusted; a window of $N + 1$ terms with one term deleted can. Widening by one is the cheapest possible extra degree of freedom, and the deleted value is then forced rather than chosen. The two inequalities translate directly into $a_{i+1} < v \le a_{i+N+1}$, which is the statement that the required value lies inside the range of the run. **Link to the next block.** It remains to know that the run contains every integer in its own range.

Block 7. **Cue.** "Each of these scores occurred at least once", not yet used. **Why natural.** The achieved values form the block $\{0, 1, \ldots, 10\}$, so a value missing from a run would have to be missing from the whole class, and it is not. Sandwiching the position of an occurrence against the ends of the run finishes it. This is where the decorative looking hypothesis pays for itself. **Link to the next block.** Delete one occurrence of v and the two groups are built.

Layer 3: WHY

Three mathematical truths sit underneath this route.

The first is the discrete intermediate value theorem: if $s_0, \ldots, s_m$ are integers with $s_0 \le T \le s_m$ and $|s_{i+1} - s_i| \le d$ for all i, then some i has $s_i \le T < s_{i+1}$ and hence $0 \le T - s_i < d$. You cannot hope for equality in general, only for "within one step". That is the correct expectation to carry into the arena, and it tells you in advance that you will need one further degree of freedom to close the last gap.

The second is where that degree of freedom comes from. Enlarging the window from N to $N + 1$ terms turns "the window sum is close to T" into "the window sum minus a deletable term equals T", and the value to be deleted is then determined, not chosen. What remains is a pure availability question, and availability is exactly what a block of consecutive values guarantees. The setters supplied that block and gave it to you as a sentence about a quiz. The counterexample with only the scores 0 and 10 shows that no proof can avoid it.

The third is the cheapest of the three and the most often forgotten: an equal split of a fixed total is a single condition. Half the candidates in the arena will carry two symbols ΣA and ΣB through the whole proof.

Discernment mechanism. Ask three questions in order. Is the required object exact rather than approximate? Then do not construct it, parametrise a family. Does the family move in bounded steps? Then a discrete intermediate value theorem gives you "within one step". Is there a hypothesis in the question that supplies precisely one step of slack? If yes, that hypothesis is what the last line of your proof will consume.

How to train it. After every problem you solve, list the hypotheses and mark the line of your proof that uses each one. An unused hypothesis is either a signal that your proof is wrong or a signal that you have proved a stronger theorem, and you must know which. Second habit: whenever you sort, immediately ask what the gaps in the sorted list can be, because "monotone with gaps at most 1" is a far stronger object than "monotone".

Revolving concepts

Discrete intermediate value theorem. If integers $s_0, \dots, s_m$ satisfy $s_0 \le T \le s_m$ and $s_{i+1} - s_i \le d$ for all i, then there is an i with $0 \le T - s_i < d$; if moreover every step is 0 or 1, then some $s_i = T$ exactly. This last case is worth memorising: unit steps give exact landing, and much of combinatorics is arranging for unit steps. See Book 1, field: Combinatorics, topic: discrete intermediate value theorem.

Sliding windows and the general swap recursion. The family s_i obeys the first order recursion $s_{i+1} = s_i + a_{i+N+1} - a_{i+1}$, whose increments are single element swaps. Generalised form: if $X_0, X_1, \dots, X_m$ are finite sets with $|X_{i+1} \triangle X_i| = 2$ (one element out, one element in) and f is a sum over the set, then $f(X_{i+1}) - f(X_i)$ is a difference of two element values, so the sequence $f(X_i)$ has steps bounded by the spread of the values. Any such family plus a sign change at the ends yields a near solution, and the same recursion is the engine behind necklace splitting arguments and behind the standard proof that a cyclic sequence of partial sums must cross its own mean. See Book 1, field: Combinatorics, topic: exchange and window families.

Blocks of consecutive values. If the value set of a finite multiset of integers is a block of consecutive integers, then every run of its sorted list realises every integer between the endpoints of that run. Generalisation: if the value set is contained in an arithmetic progression of common difference d and contains every term of that progression between its extremes, the same statement holds for values congruent to a_p modulo d. This is the "no gaps" property, and it is the standard partner of any window argument that needs to land exactly.

Descent on an integer potential. The exchange approach uses that $|\Sigma A - \Sigma B|$ is a nonnegative integer decreasing by exactly 2 at each swap; a strictly decreasing sequence in $\mathbb{N}$ terminates. General recursion: any local search with a potential Φ : states $\to \mathbb{N}$ that strictly decreases at every legal move terminates, and the terminal state satisfies the local optimality condition you want. Parity is what tells you the terminal value is 0 rather than 1: here $\Sigma A - \Sigma B \equiv \Sigma A + \Sigma B \pmod 2$ and the total is even. See Book 1, field: Combinatorics, topic: monovariants and descent.

Integrality from a rational average. An average of p/q in lowest terms over n integers forces $q \mid n$. Here $7.4 = 37/5$ over $2N$ students gives $5 \mid 2N$, hence $5 \mid N$. See Book 1, field: Number theory, topic: divisibility from means.

Circuit Bank

- **WHEN** an average or mean given as a non-integer **DO** clear the denominator immediately and read off the divisibility it forces **BECAUSE** the exact value of the target is what makes an integer argument possible, and the divisibility is usually load bearing later
- **WHEN** a partition of a fixed total into two parts with a prescribed property **DO** throw away one part and impose the condition on a single subset **BECAUSE** the complement is determined, so two symbols where one will do is pure cost

- **WHEN** an exact target and a total order on the data **DO** build a one parameter family of candidate sets that changes by one element at a time, and apply the discrete intermediate value theorem **BECAUSE** a monotone integer sequence with bounded steps crossing a target must come within one step of it
- **WHEN** a shortfall smaller than one step **DO** enlarge the candidate set by one element and delete the forced value instead **BECAUSE** widening by one converts a near miss into an exact hit, and the value to delete becomes determined rather than chosen
- **WHEN** a hypothesis that looks like scene setting **DO** find the single line of your proof that fails without it, or construct the counterexample **BECAUSE** setters do not plant free hypotheses, and an unused hypothesis usually means a broken proof

Backtesting

1. First useful cue: the non-integer average 7.4 attached to integer scores. It forces $5 \mid N$ and an integer target, and it is also the reason no student can score the average.
2. Method the expression suggested: sort and slide a window of N consecutive scores, because an exact target plus a total order is the standard trigger for a discrete intermediate value argument.
3. Where you would hesitate, and the thought to reinforce: at the moment the window sum lands strictly below the target, you feel stuck because a window of N terms cannot be nudged. The thought to install is "take $N+1$ terms and delete one", which is the cheapest available extra degree of freedom.
4. The trap the question sets: treating "each of these scores occurred at least once" as flavour. Without it the statement is false, as the class of thirteen zeros and thirty seven tens shows.
5. What makes you recognise it faster next time: the pairing of an exactness demand with a hypothesis that the achieved values form a consecutive block. That pairing is the signature of a window argument that must land exactly.
6. The reusable decision rule: for an exact subset sum, parametrise rather than construct, get within one step by monotonicity, and spend the "no gaps" hypothesis on the final step.

Mirror drills

1. Let $2N$ integers lie in $\{0, 1, \ldots, 10\}$, let every one of those eleven values occur, and let the total be even. Show the multiset splits into two halves of equal sum. *Answer:* identical proof with $T = \Sigma/2$; nothing used 7.4 beyond the integrality of T, which is now a hypothesis.
2. Let $a_1 \leq \cdots \leq a_{2N}$ be integers in $\{0, 1, \ldots, d\}$. Show that some N of them have sum within $d/2$ of half the total. *Answer:* window sums have steps at most d and satisfy $s_0 + s_N = \Sigma$, so the last s_i at or below $\Sigma/2$ is within d of it; the better constant follows by comparing s_i and s_{i+1} and taking the closer one.
3. Find a multiset of four integers with even total that cannot be split into two pairs of equal sum, and identify which hypothesis of the problem it violates. *Answer:* $\{1, 1, 1, 3\}$ has total 6 but pair sums only 2 and 4; its value set $\{1, 3\}$ is not a block of consecutive integers.

9.5 A5. Three card players and a rotating lead

Each of the integers from 1 *to* n *is written on a separate card, and then the cards are combined into a deck and shuffled. Three players,* A*,* B*, and* C*, take turns in the order* $A, B, C, A, \ldots$ *choosing one card at random from the deck. (Each card in the deck is equally likely to be chosen.) After a card is chosen, that card and all higher-numbered cards are removed from the deck, and the remaining cards are reshuffled before the next turn. Play continues until one of the three players wins the game by drawing the card numbered* 1*.*

Show that for each of the three players, there are arbitrarily large values of n *for which that player has the highest probability among the three players of winning the game.*

Read it out loud

Read the process, not the players. A deck of n cards; someone draws card k uniformly; the deck becomes $\{1, \ldots, k-1\}$. So the state of the game is a single integer that strictly decreases, the transition is "replace n by a uniform element of $\{0, 1, \ldots, n-1\}$", and the game ends when the state hits 0. The three players are not really three objects: they are one object, namely the number of draws taken so far, read modulo 3. That is the sentence to say out loud, and it is the whole problem.

The fields wired in: probability (first step analysis on a self similar process), generating functions (the number of draws is the only statistic that matters, so mark it with a variable), complex numbers (a residue modulo 3 is extracted by a roots of unity filter), and a scrap of real analysis at the end (a divergent series with vanishing terms).

Notice what the conclusion is really asking. It is not asking who wins. It is asking for infinitely many sign changes in a three way comparison, that is, for a quantity that keeps rotating. The moment you read "arbitrarily large values of n for which that player has the highest probability", you should expect an angle that grows without bound in steps that shrink to zero, because that is the only cheap mechanism that produces infinitely many rotations.

Within thirty seconds you should have written the first step recursion with the roles rotated,

$$a_n = \frac{1}{n}\sum_{k=1}^{n} c_{k-1}, \quad b_n = \frac{1}{n}\sum_{k=1}^{n} a_{k-1}, \quad c_n = \frac{1}{n}\sum_{k=1}^{n} b_{k-1},$$

with $a_0 = b_0 = 0$ and $c_0 = 1$, where a_n, b_n, c_n are the winning probabilities of the player to move, the next player and the third player. The convention $c_0 = 1$ says that when the deck empties the player who has just drawn (the third player in the rotated labelling) has won. Do not then start computing terms. Look at what you have: three coupled sequences with a cyclic symmetry, each an average of the previous ones.

Approaches, ranked worst to best

1. **Compute and observe.** *Cue:* "show there are arbitrarily large n". *Circuit:* tabulate a_n, b_n, c_n and watch the lead change. This is not a proof, and here it is actively misleading. The lead changes at $n = 3$, then 14, then 145, then 1608: each handover needs n to be multiplied by roughly 11, so a table up to $n = 100$ shows two handovers and then a long flat stretch that looks like convergence. A candidate who trusts the table concludes the wrong thing.

2. **Direct estimates on the recursion.** *Cue:* three coupled sequences. *Circuit:* bound $a_n - b_n$ by hand and hunt for sign changes. You are trying to control a rotation with inequalities in one real variable at a time. Every bound you prove is a projection of a two dimensional spiral onto a line, so the estimates fight each other and nothing closes.

3. **Order type state machine.** *Cue:* "at most one of the three differences vanishes". *Circuit:* define the six possible orderings of (a_n, b_n, c_n) and prove the transitions cycle. This is the third official

route, and it works with no complex numbers at all. It costs several preliminary lemmas (that none of the three partial sums can diverge or converge to a nonzero limit) and roughly two pages. Fully elementary, fully rigorous, expensive.

4. **Normalise the difference vector and rotate it.** *Cue:* $x_n + y_n + z_n = 0$ for the three differences. *Circuit:* project onto a circle and show the angle increments are a null sequence with divergent sum. This is the first official route and it is the right picture. It reaches the answer by inventing the circle by hand rather than by letting algebra hand it to you.

5. **Generating function in the number of draws, evaluated at a cube root of unity.** *Cue:* the winner is determined by the number of draws modulo 3. *Circuit:* mark the number of draws with X, telescope the averaging recursion, then apply a roots of unity filter. The recursion for the generating function collapses to $P_n = \frac{X+n-1}{n} P_{n-1}$, so $P_n(X) = X(X+1)\cdots(X+n-1)/n!$ in one line, and substituting a primitive cube root of unity turns the whole triple into a single complex number whose argument is a visible sum of arctangents. The rotation is then not a picture to be invented but a product of complex numbers to be read off.

The ideal solution

Let M_n be the number of draws in the game played with a deck of n cards, and let

$$P_n(X) = \mathbb{E}\left[X^{M_n}\right] = \sum_{m \geq 0} \Pr[M_n = m]\, X^m,$$

with $P_0(X) = 1$. The game always terminates, since the deck strictly shrinks at every draw. Player A takes draws $1, 4, 7, \ldots$, player B takes draws $2, 5, 8, \ldots$ and player C takes draws $3, 6, 9, \ldots$, and the winner is the player who takes the final draw, so with

$$a_n = \Pr[M_n \equiv 1], \quad b_n = \Pr[M_n \equiv 2], \quad c_n = \Pr[M_n \equiv 0] \pmod 3$$

the three winning probabilities are a_n, b_n, c_n and $a_n + b_n + c_n = 1$.

Step 1 (the generating function). With n cards, the first draw is card k with probability $1/n$, after which the deck is exactly $\{1, \ldots, k-1\}$ and the remaining play is an independent copy of the game with $k-1$ cards. Hence $M_n = 1 + M_{k-1}$ in distribution, conditionally on the first card being k, and

$$P_n(X) = \frac{X}{n} \sum_{k=1}^{n} P_{k-1}(X) \qquad (n \geq 1).$$

Multiply by n and subtract the same identity for $n-1$ multiplied by $n-1$:

$$nP_n(X) - (n-1)P_{n-1}(X) = XP_{n-1}(X),$$

so $P_n(X) = \frac{X+n-1}{n} P_{n-1}(X)$ for $n \geq 2$; and $P_1(X) = XP_0(X) = X$ agrees with the same formula at $n = 1$. Therefore

$$P_n(X) = \prod_{j=1}^{n} \frac{X+j-1}{j} = \frac{X(X+1)\cdots(X+n-1)}{n!}.$$

As a check, $P_n(1) = 1$.

Step 2 (roots of unity filter). Let $\omega = e^{2\pi i/3}$, so $\omega^3 = 1$ and $1 + \omega + \omega^2 = 0$. Put

$$z_n = P_n(\omega) = \mathbb{E}\left[\omega^{M_n}\right] = c_n + a_n\omega + b_n\omega^2.$$

Using $\operatorname{Im}\omega = \frac{\sqrt{3}}{2}$ and $\operatorname{Im}\omega^2 = -\frac{\sqrt{3}}{2}$, and $\omega^3 = 1$,

$$\operatorname{Im}(z_n) = \tfrac{\sqrt{3}}{2}(a_n - b_n), \quad \operatorname{Im}(\omega z_n) = \tfrac{\sqrt{3}}{2}(c_n - a_n), \quad \operatorname{Im}(\omega^2 z_n) = \tfrac{\sqrt{3}}{2}(b_n - c_n),$$

the last two because $\omega z_n = b_n + c_n\omega + a_n\omega^2$ and $\omega^2 z_n = a_n + b_n\omega + c_n\omega^2$. Every factor $\omega + j$ with j a nonnegative integer is nonzero, since ω is not real, so $z_n \neq 0$ and $\theta_n := \arg z_n$ is defined. Reading the three displayed identities as statements about which half planes z_n, ωz_n, $\omega^2 z_n$ lie in:

$$a_n > b_n \iff \theta_n \in (0, \pi), \quad c_n > a_n \iff \theta_n \in (-\tfrac{2\pi}{3}, \tfrac{\pi}{3}), \quad b_n > c_n \iff \theta_n \in (\tfrac{2\pi}{3}, \tfrac{5\pi}{3}),$$

all modulo 2π. Intersecting the pairs of conditions,

$$A \text{ strictly leads} \iff \theta_n \in \left(\tfrac{\pi}{3}, \pi\right), \quad B \text{ strictly leads} \iff \theta_n \in \left(\pi, \tfrac{5\pi}{3}\right), \quad C \text{ strictly leads} \iff \theta_n \in \left(-\tfrac{\pi}{3}, \tfrac{\pi}{3}\right),$$

three open arcs of length $\frac{2\pi}{3}$ each, again modulo 2π.

Step 3 (the argument grows without bound in vanishing steps). From $z_1 = \omega$ and $z_{n+1} = \frac{\omega+n}{n+1} z_n$, and since $n + 1 > 0$ and $\omega + n = \left(n - \frac{1}{2}\right) + \frac{\sqrt{3}}{2} i$ has positive real part for $n \geq 1$,

$$\theta_n = \frac{2\pi}{3} + \sum_{j=1}^{n-1} \delta_j, \qquad \delta_j = \arg(\omega + j) = \arctan \frac{\sqrt{3}}{2j - 1} \in \left(0, \tfrac{\pi}{2}\right],$$

is a valid choice of $\arg z_n$, because the argument of a product is the sum of the arguments modulo 2π. The increments satisfy $\delta_j \to 0$; and for $j \geq 2$ we have $0 < \frac{\sqrt{3}}{2j-1} \leq 1$, so by concavity of arctan on $[0, 1]$,

$$\delta_j \geq \frac{\pi}{4} \cdot \frac{\sqrt{3}}{2j - 1} \geq \frac{\sqrt{3}\,\pi}{8j},$$

and $\sum_j \delta_j$ diverges by comparison with the harmonic series. Thus (θ_n) is strictly increasing, tends to $+\infty$, and has increments tending to 0.

Step 4 (the landing lemma).

Lemma 9.5.1. *Let (θ_n) be real, increasing, with $\theta_n \to +\infty$ and $\theta_{n+1} - \theta_n \to 0$. Then for every $\alpha \in \mathbb{R}$ and every $\varepsilon > 0$ there are infinitely many n with $\theta_n \in (\alpha + 2\pi k, \alpha + 2\pi k + \varepsilon)$ for some integer k; that is, $\theta_n \bmod 2\pi$ lies in the arc $(\alpha, \alpha + \varepsilon)$ for infinitely many n.*

Proof. Choose M with $\theta_{n+1} - \theta_n < \varepsilon$ for all $n \geq M$. Let k be any integer with $\alpha + 2\pi k > \theta_M$. Since $\theta_n \to +\infty$ there is a least index $n(k)$ with $\theta_{n(k)} > \alpha + 2\pi k$, and $n(k) > M$ because $\theta_M \leq \alpha + 2\pi k$. Minimality gives $\theta_{n(k)-1} \leq \alpha + 2\pi k$, and $n(k) - 1 \geq M$ gives $\theta_{n(k)} < \theta_{n(k)-1} + \varepsilon$. Hence $\alpha + 2\pi k < \theta_{n(k)} < \alpha + 2\pi k + \varepsilon$. Letting $k \to \infty$ makes $\theta_{n(k)} \to \infty$, so the indices $n(k)$ are unbounded and there are infinitely many of them. □

Step 5 (conclusion). Apply the lemma to each of the three arcs of Step 2, each of length $\varepsilon = \frac{2\pi}{3} > 0$. For each player there are infinitely many n with θ_n in that player's arc, and hence infinitely many n at which that player's winning probability is strictly the largest of the three. In particular such n are arbitrarily large. □

Two checks worth doing in the arena. At $n = 3$ the formula gives $P_3(X) = \frac{X(X+1)(X+2)}{6} = \frac{X^3+3X^2+2X}{6}$, so $(a_3, b_3, c_3) = (\frac{1}{3}, \frac{1}{2}, \frac{1}{6})$, matching the recursion directly, and $\theta_3 = \frac{2\pi}{3} + \frac{\pi}{3} + \frac{\pi}{6} = \frac{7\pi}{6}$, which lies in B's arc, as it should. At $n = 2$, $\theta_2 = \pi$ sits exactly on a boundary ray, and indeed $a_2 = b_2 = \frac{1}{2}$ is a tie; boundary rays are ties, which is why the arcs were taken open.

Layer 1: WHAT

Block 1. Identify the state: a deck of size n, transition to a uniform smaller size, absorbing at 0. First step analysis with the roles rotated.

Block 2. Refuse to carry three sequences. The winner is a function of one integer, the number of draws, read modulo 3.

Block 3. Mark that integer with X and form $P_n(X) = \mathbb{E}[X^{M_n}]$. The averaging recursion telescopes after multiplying by n, giving $P_n = \frac{X+n-1}{n} P_{n-1}$ and hence the rising factorial $X(X + 1) \cdots (X + n - 1)/n!$.

Block 4. Extract residues modulo 3 by evaluating at ω. The triple (a_n, b_n, c_n) becomes the single complex number $z_n = c_n + a_n\omega + b_n\omega^2$.

Block 5. Translate "who leads" into "which 120 degree sector contains z_n".

Block 6. The argument of a product is the sum of arguments, so θ_n is a sum of arctangents: increasing, increments to zero, sum divergent.

Block 7. A monotone divergent sequence with vanishing steps enters every arc infinitely often. Done.

Juxtaposition. The nominal route sets up the same recursion, computes twenty terms, sees A then B then C, and then tries to prove sign changes for $a_n - b_n$ by direct estimates on the coupled recursion. It dies because the object it is estimating is the projection of a rotation. The bifurcation point is Block 2: the decision to stop tracking three probabilities and track instead the one integer statistic that determines all three. Everything downstream is forced by that decision, including the appearance of ω, which is simply the standard tool for reading an integer modulo 3.

Layer 2: HOW

Block 1. **Cue.** "that card and all higher-numbered cards are removed" and "the remaining cards are reshuffled". **Why natural.** Reshuffling is the setters telling you the process is memoryless: the future depends on the deck size alone. So write the one step recursion at once, and note the roles rotate, since the player who has just drawn becomes the third player of the new game. **Link to the next block.** You now have three coupled averaging recursions with cyclic symmetry.

Block 2. **Cue.** Three players in a fixed cyclic order, and a winner determined by whose turn the last draw was. **Why natural.** The player index is the draw count modulo 3. Carrying three sequences is carrying the same information three times. Ask instead for the distribution of the draw count M_n, from which all three probabilities follow. **Link to the next block.** One scalar random variable replaces the triple.

Block 3. **Cue.** A recursion of the shape $u_n = \frac{1}{n}\sum_{k<n} u_k$, and a random variable whose distribution you want. **Why natural.** Two moves, both standard. First, an averaging recursion is cleared by multiplying by n and subtracting the previous relation; that always turns a Cesàro type recursion into a first order one. Second, a distribution supported on the nonnegative integers is carried by its generating function, and $M_n = 1 + M_{k-1}$ becomes multiplication by X. The product $\prod_j \frac{X+j-1}{j}$ then also tells you that M_n is a sum of independent Bernoulli variables with parameters $1/j$, which is worth noticing. **Link to the next block.** You have an exact closed form for the whole distribution, valid for every n.

Block 4. **Cue.** You want probabilities of residues modulo 3, and you hold a polynomial. **Why natural.** That is precisely the roots of unity filter. Evaluating at ω compresses the three residue classes into one complex number, and it is the only evaluation that keeps all the information you need while discarding everything you do not. **Link to the next block.** The state of the game at size n is now a single point of the complex plane.

Block 5. **Cue.** A triple of nonnegative reals summing to 1, mapped linearly to $\mathbb{C}$. **Why natural.** The map sends the centroid to 0 and the three extreme cases to $\omega, \omega^2, 1$; comparisons between the coordinates therefore become half plane conditions on z_n, ωz_n, $\omega^2 z_n$, and intersecting pairs of half planes gives sectors. There is nothing to invent: multiplication by ω is exactly the cyclic relabelling of the players. **Link to the next block.** "Each player leads infinitely often" has become "the argument visits each of three arcs infinitely often".

Block 6. Cue. A product formula and a question about arguments. **Why natural.** Arguments add over products, and the factors $\omega + j$ have positive real part, so their arguments are honest arctangents in $(0, \pi/2]$ with no branch anxiety. The size $\arctan \frac{\sqrt{3}}{2j-1} \approx \frac{\sqrt{3}}{2j}$ tells you the whole story: the steps shrink like $1/j$, so they tend to zero, and their sum diverges like $\frac{\sqrt{3}}{2} \log n$. **Link to the next block.** A monotone divergent angle with vanishing steps cannot skip an arc.

Block 7. Cue. "arbitrarily large values of n". **Why natural.** That phrasing asks for infinitely many indices, not for a limit, so a soft argument suffices: a sequence which climbs past every multiple of 2π in steps eventually smaller than the arc length must land inside every translate of the arc. Write the lemma out separately; it is short and it is the only analysis in the solution.

Layer 3: WHY

The first truth is that a cyclic three way comparison is a statement about the characters of $\mathbb{Z}/3$. A probability vector (a, b, c) with $a + b + c = 1$ carries exactly two degrees of freedom, and the natural coordinates on that two dimensional space are the values of the two nontrivial characters, that is, $c + a\omega + b\omega^2$ and its conjugate. In those coordinates the cyclic relabelling of the players becomes multiplication by ω, a rotation by 120 degrees. Any argument phrased in terms of $a_n - b_n$ alone is fighting this structure; any argument phrased in terms of z_n inherits it for free.

The second truth is that an averaging recursion becomes a first order recursion after one multiplication and one subtraction, and a first order recursion in the complex plane is a spiral: $z_{n+1} = \frac{\omega+n}{n+1} z_n$ multiplies the modulus by $\frac{\sqrt{n^2-n+1}}{n+1} < 1$ and adds $\arctan \frac{\sqrt{3}}{2n-1}$ to the argument. The lead rotates because the multiplier $\omega + n$ has positive argument for every n; the rotation never stops because $\sum \frac{1}{n}$ diverges; and it slows down because the argument increments shrink like $1/n$. All three features of the answer are visible in one line of the recursion.

The third truth is a soft one that is worth naming because it appears constantly: divergence with vanishing steps forces recurrence. You do not need equidistribution, you do not need any measure theory, you need only that a sequence which increases past every bound in steps smaller than the target arc cannot jump over the arc. Reach for it whenever a problem asks for infinitely many n with a sign or an order reversed.

Discernment mechanism. When a process has k symmetric roles and the outcome depends on a step count modulo k, pair the state with the characters of $\mathbb{Z}/k$: that is, evaluate the generating function at k-th roots of unity. When the answer must be "infinitely often", look for an unbounded angle with vanishing increments. When a recursion averages all earlier terms, clear it by n and subtract.

What the setters nudged, and how. They gave three players rather than two, because with two players the same generating function gives $P_n(-1) = 0$ for every $n \geq 2$ and the game is exactly fair, so nothing to prove. They reshuffled the deck, to tell you the process is memoryless. They asked for "arbitrarily large n" rather than "all large n", which is a direct instruction not to look for a limit. And the numbers punish the impatient: the handovers occur at $n = 3, 14, 145, 1608, \ldots$, each roughly $e^{4\pi/(3\sqrt{3})} \approx 11.2$ times the last, so a table of the first hundred values suggests a false conclusion.

Revolving concepts

First step analysis. For an absorbing Markov chain, condition on the first transition and write $u_n = \sum_k p_{nk} u_k$. Here the extra content is the role rotation, encoded by the convention $a_0 = b_0 = 0$, $c_0 = 1$. See Book 1, field: Probability, topic: first step analysis.

Cesàro recursions. Any recursion of the form $nu_n = \sum_{k=0}^{n-1} f(u_k)$ is converted to a first order recursion by writing the same identity at $n-1$ and subtracting, giving $nu_n - (n-1)u_{n-1} = f(u_{n-1})$. This is the single most useful manipulation for recursions defined by averages, and it applies

verbatim to sequences, to generating functions and to matrices. See Book 1, field: Sequences and recurrences, topic: averaging recursions.

Roots of unity filter. For $f(X) = \sum_m \alpha_m X^m$ and $\zeta = e^{2\pi i/k}$,

$$\sum_{m \equiv r \ (k)} \alpha_m = \frac{1}{k} \sum_{j=0}^{k-1} \zeta^{-jr} f(\zeta^j).$$

Here $k = 3$ and only $j = 1$ carries information beyond $f(1) = 1$. See Book 1, field: Complex numbers, topic: roots of unity filter.

Rising factorials, Stirling numbers and random permutations. $P_n(X) = \frac{X(X+1)\cdots(X+n-1)}{n!} = \prod_{j=1}^{n} \left(\frac{j-1}{j} + \frac{X}{j}\right)$. The second form says M_n is a sum of independent Bernoulli variables with parameters $1, \frac{1}{2}, \ldots, \frac{1}{n}$; the first says the coefficients are unsigned Stirling numbers of the first kind divided by $n!$. So the number of draws in this game has the distribution of the number of cycles of a uniformly random permutation of $\{1, \ldots, n\}$, with mean the harmonic number $H_n \approx \log n$ and variance also about $\log n$. That is the honest explanation of the slow rotation: the draw count is concentrated near $\log n$, so its residue modulo 3 drifts as $\log n$ advances. See Book 1, field: Combinatorics, topic: Stirling numbers of the first kind.

Generalised recursion. The complex recursion $z_{n+1} = \frac{\omega+n}{n+1} z_n$ with $z_1 = \omega$ has the exact solution $z_n = \frac{\Gamma(n+\omega)}{\Gamma(\omega)\,\Gamma(n+1)}$, and the standard asymptotic $\Gamma(n+\alpha)/\Gamma(n+\beta) \sim n^{\alpha-\beta}$ gives $z_n \sim n^{\omega-1}/\Gamma(\omega)$. Since $\omega - 1 = -\frac{3}{2} + \frac{\sqrt{3}}{2} i$, the modulus decays like $n^{-3/2}$ and the argument grows like $\frac{\sqrt{3}}{2} \log n$: a logarithmic spiral. The same pattern, $\prod_{j=1}^{n} \frac{j+\alpha-1}{j} = \binom{n+\alpha-1}{n}$, is the general solution of any recursion $u_n = \frac{n+\alpha-1}{n} u_{n-1}$ and is worth installing once and for all. This is a knowledge gap for you: Gamma function asymptotics are not in the Further Mathematics syllabus, and the finite product plus arctangent sum used in the ideal solution is exactly the elementary substitute.

Divergence with vanishing steps. If $\theta_n \uparrow \infty$ and $\theta_{n+1} - \theta_n \to 0$, then $\{\theta_n \bmod 2\pi\}$ is dense in the circle and meets every arc infinitely often. This is much weaker than equidistribution, which for $\theta_n = \frac{\sqrt{3}}{2} \log n$ actually fails in the usual Weyl sense. Know the difference and claim only what you need. See Book 1, field: Real analysis, topic: recurrence of slowly varying sequences.

Circuit Bank

- **WHEN** a process with k symmetric roles taken in cyclic order, the winner decided by the number of steps modulo k **DO** track the number of steps, form its generating function, and evaluate at k-th roots of unity **BECAUSE** a residue class is extracted by characters, and the cyclic relabelling of the roles becomes multiplication by a root of unity
- **WHEN** a recursion in which the new term is the average of all previous terms **DO** multiply by n, write the same relation at $n-1$, and subtract **BECAUSE** averaging recursions telescope into first order recursions, and first order recursions have product solutions
- **WHEN** a triple of nonnegative reals summing to 1 whose ordering you must compare **DO** map it to $c + a\omega + b\omega^2$ in the complex plane **BECAUSE** the map turns the three comparisons into three half planes and the three "who leads" regions into 120 degree sectors
- **WHEN** a demand for "arbitrarily large n" with some order reversed **DO** find an angle that increases without bound with increments tending to zero **BECAUSE** such a sequence enters every arc infinitely often, which is exactly infinitely many reversals and needs no equidistribution
- **WHEN** a table of small cases that seems to settle the behaviour **DO** estimate the scale on which the phenomenon operates before trusting it **BECAUSE** here the handovers are spaced geometrically with ratio about 11, so any finite table is silent about what follows

Backtesting

1. First useful cue: the deck is reshuffled and only the top card matters, so the state is the deck size alone and the winner is the draw count modulo 3.
2. Method the expression suggested: the averaging recursion $u_n = \frac{1}{n}\sum_{k<n} u_k$ demanded the multiply and subtract move, and the residue modulo 3 demanded a cube root of unity.
3. Where you would hesitate, and the thought to reinforce: after obtaining $z_n = P_n(\omega)$ you may not see what to do with a complex number. The thought to install is that a complex number is a modulus and an argument, that the modulus is irrelevant to a comparison, and that the argument is a sum because z_n is a product.
4. The trap the question sets: computing a table and believing it. The first two handovers are at $n = 3$ and $n = 14$, the third is at $n = 145$ and the fourth at $n = 1608$.
5. What makes you recognise it faster next time: any cyclic competition between three symmetric agents is a $\mathbb{Z}/3$ problem, and $\mathbb{Z}/3$ problems are done with ω, not with three sequences.
6. The reusable decision rule: compress a symmetric multi agent state into one complex number via a character, convert the recursion into complex multiplication, and read the conclusion off the argument.

Mirror drills

1. Two players A and B play the same card game with n cards. Who is favoured? *Answer:* now A wins if and only if the draw count is odd, so $b_n - a_n = \mathbb{E}[(-1)^{M_n}] = P_n(-1) = \frac{(-1)\cdot 0\cdot 1\cdots(n-2)}{n!} = 0$ for every $n \geq 2$, so the game is exactly fair for all $n \geq 2$; only $n = 1$ favours A.
2. Show that the number of draws in the n card game has the same distribution as the number of cycles of a uniformly random permutation of $\{1, \ldots, n\}$. *Answer:* both have probability generating function $X(X+1)\cdots(X+n-1)/n!$; equivalently both are sums of independent Bernoulli variables with parameters $1/j$ for $j = 1, \ldots, n$.
3. Let $\theta_n = \sum_{j=1}^{n} \arcsin\frac{1}{j}$. Show that $e^{i\theta_n}$ enters every arc of the unit circle infinitely often. *Answer:* the increments tend to 0 and $\arcsin\frac{1}{j} \geq \frac{1}{j}$ so the sum diverges; apply the landing lemma.

9.6 A6. Icosahedron edge colourings via linear algebra

The 30 edges of a regular icosahedron are distinguished by labelling them $1, 2, \ldots, 30$. *How many different ways are there to paint each edge red, white, or blue such that each of the 20 triangular faces of the icosahedron has two edges of the same colour and a third edge of a different colour? (The top matter on each exam paper included the logo of the Mathematical Association of America, which is itself an icosahedron.)*

Read it out loud

Say what the object is. There are 3^{30} colourings, roughly 2×10^{14}, and 20 constraints, one per face, each involving only three of the thirty edges. So this is a constraint satisfaction count with a fixed sparse incidence structure: a solid, a set of 30 variables in a 3 element set, and 20 local conditions. Nothing about it is asking you to be clever about icosahedra. It is asking you what the local condition really says.

Now say the local condition out loud. "Two edges of the same colour and a third of a different colour" is the negation of "all three the same or all three different". Those two forbidden patterns are the two orbits of the colour permutation group on triples that are somehow uniform, and any time you meet "all equal or all distinct" with exactly three colours, you should try to make the colours into the field $\mathbb{F}_3$ and look at the sum. Over $\mathbb{F}_3$, all equal gives $3u = 0$, and all distinct gives $0 + 1 + 2 = 0$, while two equal and one different, say u, u, w with $w \neq u$, gives $2u + w = w - u \neq 0$. The condition is exactly "the sum of the three edge labels is nonzero".

That is the entire content of the problem, and the rest is linear algebra. The fields wired in: finite fields and vector spaces over them, rank and nullity, and a small amount of polyhedral combinatorics ($V = 12$, $E = 30$, $F = 20$, every vertex has degree 5 and its five neighbours form a pentagon, every edge lies in exactly two faces).

Within thirty seconds you should have written the equivalence above, the map

$$T : \mathbb{F}_3^E \to \mathbb{F}_3^F, \qquad T(x)_f = \sum_{e \in f} x_e,$$

and the sentence "count the admissible targets, then multiply by the size of a fibre". And you should have noticed the trap: the edges are labelled 1 to 30, so nothing is to be counted up to symmetry. The icosahedron in the logo is decoration.

Approaches, ranked worst to best

1. **Burnside and the rotation group.** *Cue:* the word icosahedron, and a note about a logo. *Circuit:* count orbits of colourings under the symmetry group. This answers a different question. The edges carry labels 1 to 30, so a colouring is a function on a labelled set and two colourings that differ by a rotation are different. Any candidate who divides by 60 has thrown away the sentence that was put there to stop them.

2. **Layer by layer transfer matrix.** *Cue:* the icosahedron is a pentagonal antiprism with two pyramids on it. *Circuit:* propagate a state vector over 3^5 states through five layers. This is a genuine algorithm, and by hand it is a page of 243 dimensional bookkeeping to compute what one rank computation gives you. You would in effect be doing linear algebra without admitting it.

3. **Inclusion and exclusion over the bad faces.** *Cue:* "each of the 20 faces" is a conjunction of conditions. *Circuit:* sum over subsets S of faces with sign, counting colourings whose faces in S are all bad. Each term requires the number of solutions of a subsystem, which depends on the rank of that subsystem, and the ranks are not uniform across the 2^{20} subsets. The sum does not collapse.

4. **Peel the two polar caps.** *Cue:* an icosahedron splits as five faces, a pentagon, ten faces, a pentagon, five faces. *Circuit:* colour the equatorial band freely, then complete each ring. Colour the ten equatorial edges freely, note that each of the five faces containing exactly one edge of a polar pentagon then determines that edge in 2 ways, and finally show each polar fan of five spokes admits exactly 2^5 completions. It reaches $3^{10} \cdot 2^{20}$ correctly, but the last step is the same odd cycle fact that the winning route uses, so this is the winning route with extra scaffolding.
5. **Recode into $\mathbb{F}_3$ and count fibres.** *Cue:* three colours, and a condition invariant under permuting the colours. *Circuit:* make the condition linear, prove the linear map is onto, and count as (number of admissible images) times (size of the kernel). The condition becomes $T(x)_f \neq 0$ for every f; there are 2^{20} admissible images; T is onto, so every fibre has 3^{30-20} elements. Two lines of counting once surjectivity is proved, and surjectivity is one local gadget.

The ideal solution

Let E be the set of the 30 edges and F the set of the 20 faces. Identify the three colours with the three elements of $\mathbb{F}_3$, the field with three elements, in any fixed way, so that a colouring is a vector $x \in \mathbb{F}_3^E$. Define

$$T : \mathbb{F}_3^E \longrightarrow \mathbb{F}_3^F, \qquad T(x)_f = \sum_{e \subset f} x_e,$$

the sum being over the three edges of the face f. Each coordinate of $T(x)$ is a sum of coordinates of x, so T is $\mathbb{F}_3$-linear.

Lemma 9.6.1. *A face f has two edges of one colour and a third edge of a different colour if and only if $T(x)_f \neq 0$.*

Proof. The three edge colours of f fall into exactly one of three mutually exclusive cases. If all three are equal to u, then $T(x)_f = 3u = 0$. If all three are distinct, they are $0, 1, 2$ in some order and $T(x)_f = 0 + 1 + 2 = 0$. Otherwise exactly two are equal, say the colours are u, u, w with $w \neq u$, and then $T(x)_f = 2u + w = w - u \neq 0$, because $2 = -1$ in $\mathbb{F}_3$ and $w \neq u$. So the required pattern holds exactly when the sum is nonzero. □

Write $\mathbb{F}_3^\times = \{1, 2\}$ for the two nonzero elements. The colourings we must count are therefore

$$\mathcal{N} = \left| \left\{ x \in \mathbb{F}_3^E : T(x) \in (\mathbb{F}_3^\times)^F \right\} \right| = \left| T^{-1}\left((\mathbb{F}_3^\times)^F \right) \right|.$$

Lemma 9.6.2. *T is surjective.*

Proof. It suffices to show that every standard basis vector of $\mathbb{F}_3^F$ lies in the image, since those span.

Fix a vertex v. In the icosahedron v has degree 5 and its five neighbours form a pentagon, so the five edges at v can be listed as $e_1, \ldots, e_5$ in cyclic order in such a way that the five faces containing v are exactly $f_1, \ldots, f_5$, where f_i has edges e_i, e_{i+1} and one edge of that pentagon (indices modulo 5). Every edge at v lies in exactly two faces, and both of them contain v; hence if x is supported on $\{e_1, \ldots, e_5\}$ then $T(x)$ is supported on $\{f_1, \ldots, f_5\}$ and

$$T(x)_{f_i} = x_{e_i} + x_{e_{i+1}} \qquad (i = 1, \ldots, 5).$$

Take $x_{e_1} = 2$, $x_{e_2} = 1$, $x_{e_3} = 2$, $x_{e_4} = 1$, $x_{e_5} = 2$ and $x_e = 0$ for every other edge. Then

$$T(x)_{f_1} = 2 + 1 = 0, \quad T(x)_{f_2} = 1 + 2 = 0, \quad T(x)_{f_3} = 2 + 1 = 0, \quad T(x)_{f_4} = 1 + 2 = 0,$$

while $T(x)_{f_5} = x_{e_5} + x_{e_1} = 2 + 2 = 1$. So $T(x)$ is the standard basis vector at the face f_5.

Finally, let f be any face and v any vertex of f. The two edges of f at v are consecutive in the cyclic order at v, so the labelling above may be started so that they are e_5 and e_1, that is, so that $f = f_5$. Hence every standard basis vector of $\mathbb{F}_3^F$ is in the image, and T is surjective. □

The alternating pattern $2, 1, 2, 1, 2$ is not a lucky guess: on a cycle of odd length the assignment that alternates cannot close up, and the defect is forced to appear at exactly one place. Formally, the map $\mathbb{F}_3^5 \to \mathbb{F}_3^5$ sending $(x_1, \ldots, x_5)$ to $(x_1 + x_2, \ldots, x_5 + x_1)$ has matrix $I + S$ with S the cyclic shift, whose determinant is $\prod_{\zeta^5=1}(1+\zeta) = 1 - (-1)^5 = 2 \neq 0$ in $\mathbb{F}_3$. So the five spokes at a vertex can realise *any* prescribed values on the five faces at that vertex, and in particular a single 1.

Now finish. Since T is a surjective linear map from a 30 dimensional space to a 20 dimensional space, rank and nullity give $\dim \ker T = 30 - 20 = 10$, so $|\ker T| = 3^{10}$. Every fibre $T^{-1}(w)$ with $w \in \mathbb{F}_3^F$ is a coset of $\ker T$ and therefore has exactly 3^{10} elements. The set of admissible targets has $|(\mathbb{F}_3^\times)^F| = 2^{20}$ elements. Hence

$$\mathcal{N} = 2^{20} \cdot 3^{10} = \boxed{61917364224}.$$

Layer 1: WHAT

Block 1. Read the face condition as the negation of "all equal or all distinct".

Block 2. Three colours plus a condition invariant under permuting them: recode the colours as $\mathbb{F}_3$ and test the sum. Both forbidden patterns have sum 0, the allowed pattern has sum nonzero.

Block 3. The condition is now $T(x)_f \neq 0$ for all f, with T linear. The problem has become: how many vectors does a linear map send into a prescribed product set.

Block 4. Fibres of a linear map are cosets of the kernel, so the count is (number of admissible targets in the image) times $|\ker T|$. All that is missing is the rank.

Block 5. Prove surjectivity by hitting one standard basis vector with a local gadget: the five spokes at a vertex, alternating $2, 1, 2, 1, 2$ around an odd cycle.

Block 6. Rank and nullity, then arithmetic: $2^{20} \cdot 3^{10}$.

Juxtaposition. The nominal route treats this as a hard enumeration: peel the solid into layers, define a state on each pentagon, and push a transfer matrix through five stages, or worse, start worrying about the symmetry group because the word icosahedron and a logo were mentioned. The bifurcation point is Block 2. Before it you have a combinatorial condition on three coloured objects; after it you have a system of 20 linear inequations over a field, and the only remaining question in the whole problem is the rank of a 20×30 matrix. Notice what the ideal route never does: it never enumerates a single face pattern, never uses a symmetry group, and never draws the solid beyond one vertex.

Layer 2: HOW

Block 1. **Cue.** "two edges of the same colour and a third edge of a different colour". **Why natural.** A condition on a triple that does not name any particular colour is invariant under all 6 permutations of the colours, so it is a union of orbits of unordered patterns. There are only three such orbits: all equal, all distinct, exactly two equal. Say them out loud and the condition becomes a complement, which is nearly always easier to make algebraic than the original. **Link to the next block.** You now want one algebraic function of a triple that vanishes on the two forbidden orbits.

Block 2. **Cue.** Exactly three colours, and a symmetric condition. **Why natural.** The cheapest colour invariant functions are symmetric functions, and the cheapest of those is the sum. The sum only becomes a colour invariant statement once the colours live in a ring, so put them in $\mathbb{F}_3$. Then $3 = 0$ kills the monochromatic case, and $0 + 1 + 2 = 0$ kills the rainbow case; that these two coincide is special to $\mathbb{F}_3$, so check it rather than assume it. The remaining case gives $w - u \neq 0$. **Link to the next block.** The 20 face conditions are now 20 linear inequations.

Block 3. **Cue.** Twenty conditions, each a linear form in the edge variables, each forbidding one value. **Why natural.** Do not solve the system. Name the map T that packages all 20 forms at once,

so that the condition reads "$T(x)$ has no zero coordinate". Packaging is what lets you count instead of solve. **Link to the next block.** The count is now a statement about a preimage.

Block 4. **Cue.** A preimage of a set under a linear map between finite spaces. **Why natural.** Fibres of a linear map are cosets of the kernel, hence all of the same size; so $|T^{-1}(S)| = |S \cap \operatorname{im} T| \cdot |\ker T|$. Every counting question of this shape reduces to two numbers: how many admissible targets are hit, and how large the kernel is. Both are easy once the rank is known, which is why the rank is now the only open question. **Link to the next block.** You need to decide whether T is onto.

Block 5. **Cue.** You need one standard basis vector in the image, and the incidence structure is local and highly symmetric. **Why natural.** Surjectivity means hitting every basis vector, and by the symmetry of the solid it is enough to hit one, provided the construction can be positioned at any face. So look for the smallest gadget whose image is supported on few faces: the five edges at a single vertex, because every one of them lies in two faces that both contain that vertex. On those five faces the map becomes "sum of cyclically adjacent pairs" on a 5 cycle, and the alternating vector $2, 1, 2, 1, 2$ cancels four of the five sums. It cannot cancel all five, and that is the point: 5 is odd. **Link to the next block.** Surjectivity gives the rank, and the rank gives the kernel.

Block 6. **Cue.** A surjective linear map $\mathbb{F}_3^{30} \to \mathbb{F}_3^{20}$. **Why natural.** Rank and nullity give a kernel of dimension 10; there are 2^{20} vectors in $\mathbb{F}_3^{20}$ with all coordinates nonzero; multiply. State the answer as $2^{20}3^{10}$ and give the decimal only as a courtesy.

Layer 3: WHY

The first truth is a coincidence of $\mathbb{F}_3$ that you must verify and then remember: for three elements u, v, w of $\mathbb{F}_3$, the sum $u + v + w$ vanishes precisely when they are all equal or all distinct. Over $\mathbb{F}_5$ the analogous statement is false, and over $\mathbb{F}_2$ there is nothing to say. This is exactly the fact behind the card game SET, where three cards form a set when each attribute is all equal or all distinct across the three cards, that is, when the attribute vectors sum to zero in $\mathbb{F}_3^4$. The problem is a SET condition on the faces of a solid, negated.

The second truth is the counting principle. If T is linear over a finite field and S is any subset of the target, then $|T^{-1}(S)| = |S \cap \operatorname{im} T| \cdot |\ker T|$, because nonempty fibres are cosets of the kernel. This turns a hard looking count over 3^{30} objects into two easy counts. The whole difficulty of such problems concentrates into deciding $\operatorname{im} T$, and here $\operatorname{im} T$ is everything.

The third truth is why the rank is full, and it is a parity statement. The natural obstruction to surjectivity of a face and edge incidence map is that each edge lies in exactly two faces, so

$$\sum_{f \in F} T(x)_f = \sum_{e \in E} 2x_e.$$

In characteristic 2 the right hand side vanishes identically, the image lies in a hyperplane, and the rank drops to 19; the two colour version of this problem would be governed by that obstruction. In characteristic 3 the factor 2 is invertible and no such relation exists. A second potential obstruction is a two colouring of the faces: if the faces could be split into two classes so that every edge meets one face of each class, then the sum over one class would always equal the sum over the other and the rank would again drop. That is precisely what happens for the octahedron, whose dual graph is the cube and hence bipartite. The dual of the icosahedron is the dodecahedron, which contains 5 cycles and is not bipartite, so that obstruction is absent too. Both obstructions are about even structures, and both are defeated by the same feature: the icosahedron has odd vertex degree and odd dual girth.

Discernment mechanism. When a colouring condition is local and invariant under permuting the colours, ask whether the colour set can be made into a group or a field so that the condition becomes

linear. When a count is "how many x with $T(x)$ avoiding something", never solve for x; count the targets and multiply by the kernel. When you need a linear map defined by an incidence structure to be surjective, look for the smallest local gadget whose image is supported on a single basis vector, and always check the characteristic first, because incidence maps carry parity relations for free.

How to train it. Take every counting problem you meet with a fixed small colour set and ask what the colours would have to be for the condition to be a linear equation. Then take every incidence matrix you meet and compute its rank over $\mathbb{F}_2$ and over $\mathbb{F}_3$ separately; the difference between the two is where the interesting structure lives.

Revolving concepts

The field $\mathbb{F}_3$ and the SET condition. $\mathbb{F}_3 = \mathbb{Z}/3\mathbb{Z}$ with $2 = -1$. For $u, v, w \in \mathbb{F}_3$: $u + v + w = 0$ if and only if $u = v = w$ or $\{u, v, w\} = \{0, 1, 2\}$. Generalisation: in $\mathbb{F}_3^d$, three vectors sum to zero if and only if in every coordinate they are all equal or all distinct; this is the rule of the game SET with $d = 4$, and the maximum size of a SET free collection is the cap set problem. See Book 1, field: Abstract algebra, topic: small finite fields.

Fibres of a linear map over a finite field. For $T : \mathbb{F}_q^m \to \mathbb{F}_q^n$ linear and S a subset of $\mathbb{F}_q^n$, $|T^{-1}(S)| = |S \cap \operatorname{im} T| \cdot q^{m - \operatorname{rank} T}$. This single formula covers a very large family of Putnam counting problems, including counting solutions of linear systems over $\mathbb{F}_p$ and counting tuples with a prescribed weighted sum modulo a prime. See Book 1, field: Linear algebra, topic: counting over finite fields.

Rank and nullity, and the two standard obstructions. $\operatorname{rank} T + \dim \ker T = \dim$ of the source. For a face and edge incidence map on a triangulated surface, the two obstructions to full rank are the characteristic 2 relation $\sum_f T(x)_f = 2 \sum_e x_e$ and a bipartition of the faces in which every edge meets one face of each part. For the icosahedron over $\mathbb{F}_3$ neither occurs and the rank is 20; over $\mathbb{F}_2$ the rank is 19; for the octahedron over $\mathbb{F}_3$ the dual graph is bipartite and the rank is 7 rather than 8.

The odd cycle recursion, generalised. Around a cycle of length n the system $x_i + x_{i+1} = t_i$ for $i = 1, \ldots, n$ (indices modulo n) is solved by the recursion $x_{i+1} = t_i - x_i$, which after going once around gives

$$x_1 = (t_n - t_{n-1} + \cdots \pm t_1) + (-1)^n x_1.$$

If n is odd this determines x_1 uniquely in any field of characteristic other than 2, so the system has exactly one solution for every right hand side, which is the same statement as $\det(I + S) = 1 - (-1)^n \neq 0$. If n is even the map is singular and the right hand sides must satisfy the alternating sum condition. This is the general form of the local gadget, it is the reason the pentagonal vertex figure of the icosahedron is exactly what the proof needs, and it is worth installing on its own because "odd cycles are invertible, even cycles have an alternating obstruction" recurs constantly in combinatorics. See Book 1, field: Linear algebra, topic: circulant matrices.

Icosahedron combinatorics. $V = 12$, $E = 30$, $F = 20$, $V - E + F = 2$; every vertex has degree 5 with the five neighbours forming a pentagon; every edge lies in exactly two faces; the dual is the dodecahedron. General identity for a triangulation: $3F = 2E$, so the count in the ideal solution reads $2^F 3^{E-F} = 2^F 3^{F/2} = (2\sqrt{3})^F$ for any triangulation of a surface on which the analogous T is surjective. See Book 1, field: Discrete structures and graphs, topic: polyhedral combinatorics.

Circuit Bank

- **WHEN** a local condition on three objects coloured from a set of three colours, invariant under permuting the colours **DO** identify the colours with $\mathbb{F}_3$ and compute the sum **BECAUSE** all equal and all distinct both give sum zero over $\mathbb{F}_3$, so the condition becomes a single linear inequation

- **WHEN** a count of the form "how many x with $T(x)$ in a prescribed set", T linear over a finite field **DO** count the admissible targets inside the image and multiply by the size of the kernel **BECAUSE** nonempty fibres are cosets of the kernel and so all have the same size
- **WHEN** a need for surjectivity of a map defined by an incidence structure **DO** construct one local gadget whose image is a single standard basis vector, then move it by relabelling **BECAUSE** surjectivity is exactly the statement that every basis vector is hit, and incidence maps are local so gadgets are small
- **WHEN** any face and edge incidence map **DO** check the characteristic before doing anything else **BECAUSE** each edge lies in two faces, so in characteristic 2 the face sums satisfy a universal relation and the map cannot be onto
- **WHEN** objects in a counting problem explicitly labelled, as in "the edges are distinguished by labelling them 1 to 30" **DO** count functions and never quotient by a symmetry group **BECAUSE** labelled counting and orbit counting are different questions, and the labelling sentence is there to tell you which one is being asked

Backtesting

1. First useful cue: "two edges of the same colour and a third edge of a different colour" with exactly three colours available. That is a colour symmetric condition, hence a candidate for an $\mathbb{F}_3$ recoding.
2. Method the expression suggested: recode the colours as $\mathbb{F}_3$, convert the 20 face conditions into $T(x)_f \neq 0$, and count by fibres.
3. Where you would hesitate, and the thought to reinforce: at surjectivity. The instinct is to build a Hamiltonian path in the dual graph and prescribe values along it, which works but is long. The thought to install is that surjectivity only needs one basis vector plus the freedom to reposition it, so look for the smallest local gadget first.
4. The trap the question sets: the word icosahedron and the note about the logo invite a symmetry argument, but the edges are labelled and no quotient is wanted. A second trap is to forget that the count of admissible target vectors is 2^{20} and not $2 \cdot 20$ or $3^{20} - 2^{20}$.
5. What makes you recognise it faster next time: three colours plus "all equal or all distinct" is always $\mathbb{F}_3$; and a sparse local constraint over a small field is always a rank computation.
6. The reusable decision rule: make the condition linear, then count the image and the kernel rather than the solutions.

Mirror drills

1. Show that the analogous map for two colours cannot be surjective on any polyhedron. *Answer:* every edge lies in exactly two faces, so $\sum_f T(x)_f = 2\sum_e x_e = 0$ over $\mathbb{F}_2$ and the image lies in a hyperplane; for the icosahedron the rank over $\mathbb{F}_2$ is 19 rather than 20.
2. The same colouring question for the regular octahedron (12 edges, 8 faces). Why does the counting shortcut break, and what is the answer? *Answer:* the dual graph is the cube, which is bipartite, so the sum of the four face constraints in one part always equals the sum in the other and the rank is 7, not 8; the kernel has size 3^5 and exactly 86 of the 2^8 all nonzero targets lie in the image, giving $86 \cdot 3^5 = 20898$, which is not $2^8 3^4$.
3. Prove that for odd n the system $x_i + x_{i+1} = t_i$, indices modulo n, has exactly one solution over $\mathbb{F}_3$ for every right hand side, and describe what happens for even n. *Answer:* substitute $x_{i+1} = t_i - x_i$ around the cycle to get $x_1 = A + (-1)^n x_1$; for odd n this determines x_1 since 2

is invertible, and for even n it is solvable only when the alternating sum A vanishes, and then there is a one parameter family.

9.7 B1. why a dilation always finds the meeting point

Let L_1 and L_2 be distinct lines in the plane. Prove that L_1 and L_2 intersect if and only if, for every real number $\lambda \neq 0$ and every point P not on L_1 or L_2, there exist points A_1 on L_1 and A_2 on L_2 such that $\overrightarrow{PA_2} = \lambda \overrightarrow{PA_1}$.

Read it out loud

Two distinct lines in the plane, a point off both of them, a nonzero real number, and a vector equation linking a point on each line back to that outside point. Say it in plain terms: for every centre P you could name and every nonzero scaling factor λ you could name, you can find a point on L_1 and a point on L_2 so that the second is obtained from the first by scaling about P by λ. That is not a sentence about lines meeting somewhere out in the plane, it is a sentence about a transformation, because output minus centre equals λ times input minus centre is not a clue pointing at a transformation, it is the transformation, written out in vectors instead of in the word dilation.

The fields wired into this problem are plane geometry, parallelism and intersection, and affine transformations, dilations, also called homotheties. The universal quantifiers for every λ and for every P are doing real work: they tell you the claim must survive an arbitrary choice of centre and an arbitrary nonzero ratio, which is exactly the freedom a dilation has. Within the first thirty seconds you should have written down that $\overrightarrow{PA_2} = \lambda \overrightarrow{PA_1}$ means A_2 is the image of A_1 under the dilation centred at P with ratio λ. Everything else follows from what dilations do to lines.

Approaches, ranked worst to best

1. **Coordinate bash.** *Cue:* explicit line equations and an explicit point $P = (p, q)$. *Circuit:* solve two simultaneous linear equations in the parameter of A_1. (why it ranks here: you must case split on vertical against non-vertical lines to avoid dividing by an undefined slope, the algebra for the two directions of the iff gets written out twice with different letters, and nothing about the argument explains why the statement is true, it only checks that it is).

2. **Normal-vector linear system.** *Cue:* a line is the solution set of $\vec{v} \cdot \vec{x} = c$. *Circuit:* write both membership conditions as one linear system in the unknown displacement and read off solvability from linear independence of the two normal vectors. (why it ranks here: it is coordinate-free and correct, and it makes the link to not parallel explicit through linear independence, but it still asks you to set up and solve a genuine linear system rather than simply naming a transformation whose properties you already know).

3. **Dilation, also called a homothety, centred at P.** *Cue:* the shape of the vector equation itself, output minus centre equals a scalar times input minus centre. *Circuit:* name the transformation, then use the one property of dilations that matters here, a dilation sends a line not through its centre to a parallel line. (why it ranks here: the forward direction becomes two sentences, the backward direction becomes one sentence by choosing the single easiest value $\lambda = 1$, and both directions lean on the same one fact about dilations instead of two separate pieces of machinery).

The ideal solution

Recall the basic dichotomy for two distinct lines in the plane: L_1 and L_2 either intersect in exactly one point, or are parallel, in which case, being distinct, they are disjoint. You will prove the two directions of the biconditional separately, and both will turn on a single fact about the map $h(X) = P + \lambda(X - P)$, the dilation centred at P with ratio $\lambda \neq 0$: it sends any line L with $P \notin L$ to a

line $h(L)$ parallel to L, and it is invertible, with inverse $h^{-1}(Y) = P + \lambda^{-1}(Y - P)$, itself a dilation centred at P.

Forward direction. Suppose L_1 and L_2 intersect. Fix any $\lambda \neq 0$ and any point P not on L_1 or L_2. Let h be the dilation centred at P with ratio λ, and consider $h(L_1)$. Since $P \notin L_1$, the line $h(L_1)$ is parallel to L_1. Because L_1 and L_2 intersect, they are not parallel, so L_1 and L_2 have different direction vectors; consequently $h(L_1)$, sharing its direction with L_1, also has a different direction from L_2, so $h(L_1)$ is not parallel to L_2 either, and the two lines $h(L_1)$ and L_2 meet in exactly one point. Call that point A_2, and set $A_1 = h^{-1}(A_2)$. Then $A_1 \in L_1$, because $A_2 \in h(L_1)$, and by the defining equation of h,

$$A_2 = P + \lambda(A_1 - P), \qquad \text{that is} \qquad \overrightarrow{PA_2} = \lambda\overrightarrow{PA_1},$$

exactly as required. Since P and λ were arbitrary subject only to the stated restrictions, this proves the forward direction in full.

Backward direction, by contrapositive. Suppose L_1 and L_2 do not intersect, that is, since they are distinct, suppose they are parallel and hence disjoint, $L_1 \cap L_2 = \varnothing$. Pick any point P not on L_1 or L_2 (such a point exists, since two lines cannot cover the whole plane) and take $\lambda = 1$. The dilation centred at P with ratio 1 is the identity map, so the required equation $\overrightarrow{PA_2} = 1 \cdot \overrightarrow{PA_1}$ reads $A_2 - P = A_1 - P$, that is $A_2 = A_1$. For points $A_1 \in L_1$ and $A_2 \in L_2$ to satisfy this you would need a common point of L_1 and L_2, but $L_1 \cap L_2 = \varnothing$. So for this choice of P and λ, no such A_1, A_2 exist, and the right-hand side of the biconditional fails. This proves the contrapositive of the backward direction, hence the backward direction itself.

Both directions are now established, so L_1 and L_2 intersect if and only if the stated property holds. ■

Layer 1: WHAT

Block 1: read the vector equation $\overrightarrow{PA_2} = \lambda\overrightarrow{PA_1}$ as the definition of a dilation centred at P with ratio λ, not as two coordinate equations to be solved. Block 2: recall that a dilation sends a line missing its centre to a parallel line, and that it is invertible for $\lambda \neq 0$. Block 3, forward direction: apply the dilation to L_1, use that not parallel is preserved under taking a parallel image, to force $h(L_1)$ to meet L_2, and pull the intersection point back through h^{-1}. Block 4, backward direction: specialise to the single value $\lambda = 1$, where the dilation collapses to the identity and the required equation collapses to $A_1 = A_2$, which is impossible on disjoint lines.

The nominal route sets up explicit coordinates for L_1, L_2 and P, writes A_1 with a parameter, imposes $A_2 = P + \lambda(A_1 - P) \in L_2$, and solves for the parameter, splitting into cases according to whether either line is vertical, then repeating a mirror computation for the converse. The bifurcation point is the very first line of work: whether you translate $\overrightarrow{PA_2} = \lambda\overrightarrow{PA_1}$ into coordinates or into the single word dilation. Naming the transformation is what lets both directions of the proof finish in a few lines with no case split at all.

Layer 2: HOW

Block 1. Cue. The expression $\overrightarrow{PA_2} = \lambda\overrightarrow{PA_1}$ has the exact shape displacement of output from a fixed point equals a scalar times displacement of input from the same fixed point. **Why natural.** That shape is not similar to the definition of a dilation, it is the definition of a dilation; there is no gap between the given equation and the transformation, so naming it costs nothing and buys the whole toolkit of known dilation properties. **Link to the next block.** Once A_2 is understood as $h(A_1)$, the question of whether A_1 exists becomes the question of whether $h(L_1)$ meets L_2, a question about two lines, which is what you already know how to answer.

Block 2. **Cue.** L_1 and L_2 intersect, that is, are not parallel, that is, have different direction vectors. **Why natural.** A dilation scales every displacement vector by the same factor λ, so it scales a line's direction vector by λ and leaves the direction unchanged up to that scalar; a line and its dilated image are always parallel to each other. **Link to the next block.** Since $h(L_1)$ keeps L_1's direction, and L_1's direction differs from L_2's, $h(L_1)$ and L_2 have different directions too, so they meet in exactly one point, which is exactly the pair of points the problem asks you to produce.

Block 3. **Cue.** The problem demands A_1 on L_1 itself, not merely a point whose image lies on L_2. **Why natural.** $\lambda \neq 0$ guarantees h is invertible, with inverse the dilation of ratio $1/\lambda$ at the same centre P, so pulling the found intersection point back through h^{-1} lands on L_1 automatically. **Link to the next block.** This closes the forward direction for an arbitrary P, λ, so the natural next question is whether the converse needs the same generality, or whether one well-chosen instance suffices.

Block 4. **Cue.** The property to be falsified is a for every λ, for every P statement. **Why natural.** Negating a universal quantifier only needs one witness, so instead of repeating a perpendicular-component argument for a general λ, you should ask which single value of λ makes the equation collapse to something trivially false; $\lambda = 1$ turns the dilation into the identity, and the identity's fixed condition $A_1 = A_2$ is visibly impossible on disjoint lines. **Link to the next block.** There is no further block: the single witness P, with $\lambda = 1$, already breaks the property, completing the contrapositive and the proof.

Layer 3: WHY

The truth underneath this problem is that intersect and parallel are not two independent facts about a pair of distinct lines, they are the two branches of a single dichotomy governed entirely by direction vectors, and every affine transformation that scales vectors by a nonzero constant, which is what a dilation is by definition, respects that dichotomy exactly, because it multiplies every direction vector by the same nonzero number and so can never turn a different directions pair into a same direction pair or the reverse. That is why the forward direction needs no case work: parallelism is dilation invariant, full stop.

The discernment mechanism to train is this: whenever a problem statement is built from a vector equation of the shape output minus a fixed point equals λ times input minus the same fixed point, with the fixed point and scalar both allowed to range freely, treat the fixed point as a candidate centre and the scalar as a candidate ratio of a named transformation before doing anything else. The examiners chose to write the condition in vectors rather than say the word dilation outright precisely so that recognising the transformation is the content of the problem; once you see it, the rest is bookkeeping. The second habit to train is quantifier judo: a for all claim you must prove needs the general argument, but a for all claim you must refute needs only its worst instance, and hunting for the value of the free parameter that trivialises the defining equation, here $\lambda = 1$, turning a dilation into the identity, is almost always less ink than adapting the general construction into a nonexistence argument.

Revolving concepts

Dilation, or homothety: the map $h_{P,\lambda}(X) = P + \lambda(X - P)$ for a centre P and ratio $\lambda \neq 0$. It fixes P, scales every displacement from P by λ, sends lines not through P to parallel lines and lines through P to themselves, composes with another dilation of the same centre by multiplying ratios, $h_{P,\lambda} \circ h_{P,\mu} = h_{P,\lambda\mu}$, and is therefore invertible with inverse $h_{P,1/\lambda}$. See Book 1, field: Geometry, topic: affine transformations.

Parallel against intersecting lines in the plane: two distinct lines either share a direction vector up to scaling, parallel, hence disjoint, or have linearly independent direction vectors, intersecting in

exactly one point; this is the coordinate-geometry fact underlying every step of both directions here. See Book 1, field: Geometry, topic: lines and direction vectors.

Lines as level sets of a linear functional: $L = \{\vec{x} : \vec{v} \cdot \vec{x} = c\}$ for a nonzero normal $\vec{v}$; two such lines are parallel exactly when their normals are scalar multiples of each other, and the alternative reinterpretation route solves the problem's system by checking that the two normals are linearly independent, which is the same dichotomy stated in the language of linear algebra rather than transformations. See Book 1, field: Linear algebra, topic: rank and linear independence in two dimensions.

There is no recursive or self-referential structure in this problem: nothing here is defined in terms of earlier terms of itself, so there is no recursion to generalise for this particular question.

Circuit Bank

- **WHEN** a vector equation has the shape output minus a named fixed point equals a nonzero scalar times input minus the same fixed point **DO** name it immediately as a dilation centred at that point with that ratio, and reach for the known dilation-to-line properties rather than coordinates **BECAUSE** the equation is not evidence of a dilation, it is the definition of one, so recognising it is free, and skipping straight to coordinates throws away that toolkit
- **WHEN** you must disprove a claim that begins for every $\lambda \neq 0$ and every point P **DO** search first for the single easiest value of the free parameter that makes the defining condition collapse to something visibly impossible, here $\lambda = 1$ collapsing a dilation to the identity, rather than adapting the general-case construction **BECAUSE** one witness refutes a universal statement, and the trivialising value of a parameter usually costs one line instead of several
- **WHEN** a dilation's image of a line needs to be compared with another line for parallelism **DO** compare directions, not equations, since a dilation multiplies every direction vector by the same nonzero scalar and so preserves the parallel or not-parallel status of any pair of lines it is applied to **BECAUSE** direction-vector comparison is coordinate-free and immune to the vertical-line edge case that plagues slope-based coordinate arguments

Backtesting

1. First useful cue: the vector equation $\overrightarrow{PA_2} = \lambda \overrightarrow{PA_1}$ with P and λ both universally quantified.
2. Method the expression suggested: rename A_2 as the image of A_1 under the dilation centred at P with ratio λ, and work with what dilations do to lines.
3. Where you would hesitate, and the thought to reinforce: wondering whether the backward direction also needs to handle a general λ; reinforce that negating for every λ only needs one value, and $\lambda = 1$ is always worth trying first because it turns the transformation into the identity.
4. The trap the question sets: it invites a coordinate case split on vertical against non-vertical lines, which never actually resolves cleanly and hides the one-line argument behind unnecessary algebra.
5. What makes you recognise it faster next time: seeing the syntactic pattern output minus a named point equals scalar times input minus the same point, and reading it as a transformation's defining equation on sight, before any other processing of the problem.
6. The reusable decision rule: when a fixed point and a free nonzero scalar act uniformly on the whole plane inside a vector identity, default to transformation language, dilation here, translation or rotation for other shapes of equation, over raw coordinates.

Mirror drills

1. Two distinct circles have centres $O_1 \neq O_2$ and radii $r_1 \neq r_2$. Show there is a point P and a ratio λ so that the dilation centred at P with ratio λ sends the first circle onto the second. *Answer:* take $\lambda = r_2/r_1$ and solve $\overrightarrow{PO_2} = \lambda \overrightarrow{PO_1}$ for P on the line through O_1 and O_2; the same output-minus-centre-equals-scalar-times-input pattern pins down the external centre of similitude.

2. For which nonzero values of λ does the dilation $X \mapsto P + \lambda(X - P)$ send every line through P to itself as a set? *Answer:* every $\lambda \neq 0$, since points collinear with the centre stay collinear with the centre after scaling; this is the companion fact to a line missing the centre goes to a parallel line.

3. With $L_1 : x = 0$ and $L_2 : y = 1$, $P = (2, 2)$, and $\lambda = 3$, find $A_1 \in L_1$ and $A_2 \in L_2$ with $\overrightarrow{PA_2} = 3\overrightarrow{PA_1}$. *Answer:* write $A_1 = (0, t)$, so $A_2 = P + 3(A_1 - P) = (-4, 3t - 4)$; forcing the y-coordinate to be 1 gives $t = 5/3$, so $A_1 = (0, 5/3)$ and $A_2 = (-4, 1)$.

9.8 B2. sums of consecutive integers and divisor counting

Suppose that a positive integer N can be expressed as the sum of k consecutive positive integers

$$N = a + (a+1) + (a+2) + \cdots + (a+k-1)$$

for $k = 2017$ but for no other values of $k > 1$. Considering all positive integers N with this property, what is the smallest positive integer a that occurs in any of these expressions?

Read it out loud

Read this: a positive integer N has a representation as a sum of 2017 consecutive positive integers, and that representation is the only one, for any run length $k > 1$, that N possesses. The question does not want a single example, it wants the smallest starting value a across every N with this exact uniqueness property. The phrase for $k = 2017$ but for no other values of $k > 1$ is the whole problem: it is an exact-count condition, exactly one valid run length, dressed up as a sum. The field wired in here is elementary number theory, specifically the arithmetic of factorising $2N$ and counting divisors; underneath the summation this is a divisor-counting problem, not a series problem.

Within the first thirty seconds you should have converted $N = a + (a+1) + \cdots + (a+k-1)$ into the algebraic identity $2N = k(2a+k-1)$, because every subsequent idea, the parity of the two factors, the bijection with divisors, the uniqueness count, lives inside that one rewritten equation. The specific numeral 2017 is not decoration either; a run length that is a large prime is exactly the kind of number that can only occupy one very restricted role in a factor pair, and noticing that is most of the route to the answer.

Approaches, ranked worst to best

1. **Fix $k = 2017$ and search.** *Cue:* the problem names a specific run length. *Circuit:* substitute $k = 2017$ into $N = a + \cdots + (a + 2016)$, then test small values of a by hand to see when no other k seems to work. (why it ranks here: checking no other $k > 1$ works for even one candidate N means checking infinitely many other values of k individually, which is not a finite computation and never becomes a proof, only a list of unverified examples).
2. **Parity of the two factors of $2N$.** *Cue:* $2N = k(2a+k-1)$ splits into a pair of factors of opposite parity. *Circuit:* for the fixed value $k = 2017$, deduce that the complementary factor $2a + 2016$ must have no odd divisor greater than one, that is, must be a pure power of two. (why it ranks here: this is close to the fastest possible route once stated, but stated on its own it does not explain why no odd divisor greater than one is the correct translation of no other k works, it asserts the punchline rather than deriving it from a count).
3. **Bijection between valid k and divisors of the odd part of N.** *Cue:* exactly one k works is an exact-count statement. *Circuit:* split $2N = 2^s \cdot u$ with u odd, show every opposite-parity factor pair of $2N$ corresponds to exactly one divisor of u, and translate the hypothesis into a statement about how many divisors u has. (why it ranks here: it derives the previous approach's punchline instead of asserting it, turns an infinite case check into a single divisor count, and hands you both the necessary condition and the reason it is also sufficient in one pass).

The ideal solution

You will show the answer is $a = 16$.

Step 1: rewrite the sum as a factorisation of $2N$. If $N = a + (a+1) + \cdots + (a+k-1)$ with $a \geq 1$ and $k \geq 2$, then $N = ka + \binom{k}{2}$, so

$$2N = k(2a+k-1).$$

Write $m = 2a + k - 1$. Since $a \geq 1$, $m \geq k + 1 > k$; since $m - k = 2a - 1$ is odd, k and m have opposite parity. Conversely, given any factorisation $2N = km$ with $1 \leq k < m$ and k, m of opposite parity, setting $a = (m - k + 1)/2$ recovers an integer $a \geq 1$, the numerator is even because $m - k$ is odd, and positive because $m > k$, and this a satisfies $2N = k(2a + k - 1)$. So the valid run lengths $k \geq 2$ for a fixed N correspond exactly, one for one, to the ways of splitting $2N$ into two factors of opposite parity with the smaller factor called k; the case $k = 1$ corresponds to the trivial split $m = 2N$, $k = 1$, and is excluded by hypothesis.

Step 2: count those splittings by counting divisors. Write $2N = 2^s u$ with u odd and $s \geq 1$, the exponent of 2 in $2N$ is at least 1 since $2N$ is even. In any opposite-parity factorisation $2N = km$, exactly one of k, m is odd and the other even; the odd one, being coprime to 2, must be a divisor d of u, and the even one is then forced to be $2^s(u/d)$, since it must absorb every factor of 2 in $2N$. So the opposite-parity factorisations of $2N$ correspond exactly to the divisors d of u, via $\{k, m\} = \{d, 2^s u/d\}$ and $k = \min(d, 2^s u/d)$.

For $d = 1$: $k = \min(1, 2^s u) = 1$, the excluded trivial case. For any divisor $d \geq 2$ of u: since $d \leq u$, the complementary factor satisfies $2^s u/d \geq 2^s \geq 2$, so $k = \min(d, 2^s u/d) \geq 2$ is a genuinely valid run length. Different divisors $d \geq 2$ give different values of k: if k is odd then $k = d$, the odd member of the pair, which determines d; if k is even then $k = 2^s u/d$, which likewise determines $d = 2^s u/k$. So the map from d to k is a bijection from the set of divisors of u that are at least 2 onto the set of valid run lengths $k > 1$. This set has size $\tau(u) - 1$, where $\tau(u)$ is the number of positive divisors of u.

Step 3: impose the hypothesis. You are told the valid run lengths $k > 1$ form the single-element set $\{2017\}$, so $\tau(u) - 1 = 1$, that is, $\tau(u) = 2$: the odd part u of $2N$ is prime. The run length $k = 2017$ arises from some divisor d of u with $\min(d, 2^s u/d) = 2017$; since 2017 is odd, it can only be the odd member of the pair, the other member $2^s u/d$ is even because $s \geq 1$, so $d = 2017$, forcing $2017 \mid u$. Combined with u prime, this gives $u = 2017$ exactly. You should check 2017 is itself prime: since $2017 < 45^2 = 2025$, it suffices to test the primes up to 43, namely $2, 3, 5, 7, 11, 13, 17, 19, 23, 29, 31, 37, 41, 43$; direct division shows none of them divides 2017.

Step 4: solve for a and minimise. With $u = 2017$ and $d = 2017$ giving $k = 2017$, the complementary factor is $m = 2^s u/d = 2^s$, and $k < m$ requires $2017 < 2^s$; the least such s is $s = 11$, since $2^{10} = 1024 < 2017 < 2048 = 2^{11}$. Then

$$a = \frac{m - k + 1}{2} = \frac{2^s - 2016}{2} = 2^{s-1} - 1008,$$

which is strictly increasing in s, so it is minimised at the least admissible $s = 11$:

$$a = 2^{10} - 1008 = 1024 - 1008 = \boxed{16}.$$

At $s = 11$: $2N = 2^{11} \cdot 2017 = 2048 \cdot 2017$, $k = 2017$, $m = 2048$, and indeed $N = 2017 \cdot 1024$ with $a = 16$ gives exactly one representation as a sum of more than one consecutive positive integer, the length-2017 one.

Layer 1: WHAT

Block 1: convert the consecutive sum into $2N = k(2a + k - 1)$ and read off that valid k's correspond to opposite-parity factor pairs of $2N$. Block 2: split $2N = 2^s u$ and see that an opposite-parity factor pair is exactly a choice of divisor d of the odd part u. Block 3: turn exactly one $k > 1$ works, namely 2017, into the divisor count $\tau(u) - 1 = 1$, hence u prime, hence, since $2017 \mid u$, $u = 2017$. Block 4: solve $2^s > 2017$ for the least s, giving $a = 2^{s-1} - 1008$ minimised at $s = 11$, so $a = 16$.

The nominal route fixes $k = 2017$ from the start and tries to rule out every competitor run length $k = 2, 3, 4, \ldots$ one at a time by direct divisibility checks on N, an approach that can produce examples of N that work for small cases but can never certify that no other k works, because there are infinitely many candidates to rule out. The bifurcation point sits right after writing

$2N = k(2a + k - 1)$: do you keep k fixed and hunt through values of a, or do you fix the arithmetic of $2N$, its power-of-two part and its odd part, and count, all at once, every k that could possibly work. The reroute is to stop asking whether this particular k fails and start asking how many k succeed in total, which is a single divisor count rather than an unbounded sequence of checks.

Layer 2: HOW

Block 1. **Cue.** The problem phrases a sum of consecutive positive integers with an explicit run length k and starting value a. **Why natural.** Expanding the arithmetic series and doubling to clear the fraction is the standard first move for any sum of consecutive integers statement, and it immediately exposes $2a + k - 1$, a quantity whose parity is forced, opposite to k's, purely because $2a - 1$ is odd. **Link to the next block.** Once $2N = k(2a + k - 1)$ is written down, the natural next question is which pairs of positive integers can appear as k and $2a + k - 1$, which is a question about factor pairs of the single fixed number $2N$.

Block 2. **Cue.** The two factors k and $m = 2a + k - 1$ are forced to have opposite parity, and $2N$ is a specific even number. **Why natural.** Any even number splits uniquely into a power of two and an odd part, and an opposite-parity factor pair must put the entire power-of-two part on one side, leaving only the odd part free to be divided between the two factors; that freedom is exactly a choice of divisor of the odd part. **Link to the next block.** This turns how many valid k are there into how many divisors does the odd part have, a completely different and finite kind of question from the one you started with.

Block 3. **Cue.** The hypothesis says the count of valid $k > 1$ is exactly one. **Why natural.** A set of divisors of u that are at least 2 has exactly one element precisely when u has exactly two divisors in total, which is the definition of u being prime; and the given $k = 2017$, being odd, can only have arisen from the divisor $d = 2017$ of u, pinning u down completely once you know it is prime. **Link to the next block.** With $u = 2017$ fixed, every remaining unknown, a, and the free exponent s, is now determined by a single inequality and a single formula, so the problem has become pure optimisation over one integer parameter.

Block 4. **Cue.** a is expressed as an increasing function of the single remaining free parameter s, subject to the constraint $2^s > 2017$. **Why natural.** A strictly increasing function of an integer parameter is minimised at the smallest admissible value of that parameter, so the whole optimisation collapses to solving one inequality, $2^s > 2017$, by comparing powers of two you already know. **Link to the next block.** There is no further block: substituting the least admissible $s = 11$ gives the numeric answer directly.

Layer 3: WHY

The fact underneath every step is a named classical result, sometimes called the polite number theorem: the number of ways to write a positive integer N as a sum of two or more consecutive positive integers equals the number of divisors of the odd part of N, minus one; in particular N has no such representation at all exactly when N is a power of two. This problem is that theorem wearing a disguise, asking not how many representations in general but for which N is that count equal to exactly one, achieved at the specific length 2017. Once you know the theorem exists, you know in advance that the answer must reduce to a statement about the odd part of N having very few divisors, and you go looking for the bijection that proves it rather than inventing case-by-case divisibility arguments.

The discernment mechanism to train is this: whenever a problem asks about the number of ways to express N as a sum, a product, or a partition of some constrained shape, and then attaches

an exact count or a uniqueness condition to that number of ways, expect the true content to be a divisor-counting identity for some auxiliary integer built from N, here the odd part u of $2N$. The examiners nudge you toward this by making the target run length a specific prime, 2017; that choice is not decorative, a prime run length is exactly the kind of number that can only occupy the role of the one and only nontrivial divisor of the auxiliary odd part, which is what forces u itself to be exactly that prime once you know u has just two divisors. Recognising a specific numeral in a competition problem as chosen because it is prime is itself a trainable reflex: check primality of any distinguished constant before doing anything else with it.

Revolving concepts

Sum of consecutive positive integers as a factor pair: $N = a + \cdots + (a + k - 1)$ for $a \geq 1$, $k \geq 2$, if and only if $2N = km$ for some factorisation into $1 \leq k < m$ of opposite parity, via $m = 2a + k - 1$ and $a = (m - k + 1)/2$. See Book 1, field: Number theory, topic: consecutive integer sums.

The polite number theorem: the count of representations of N as a sum of two or more consecutive positive integers equals $\tau(u) - 1$, where u is the odd part of N, equivalently of $2N$, and τ counts positive divisors; N is representable in no such way exactly when N is a power of two. See Book 1, field: Number theory, topic: polite numbers and odd divisors.

Splitting an integer into its power-of-two part and odd part, $n = 2^s u$ with u odd: every factorisation of n into factors of prescribed opposite parity is obtained by choosing which divisor of u plays the odd role, with the even role forced; this all the twos go to one side idea recurs whenever a problem mixes parity constraints with factorisation. See Book 1, field: Number theory, topic: two-adic valuation.

The divisor-counting function τ and the fact that $\tau(n) = 2$ exactly when n is prime: the bridge between exactly one nontrivial representation and the auxiliary number is prime. See Book 1, field: Number theory, topic: the divisor function.

There is no recursive sequence inside this problem itself, the run $a, a + 1, \ldots, a + k - 1$ is consecutive integers, not a recursively defined sequence, so there is no recursion to generalise here beyond noting that the same split into power-of-two part and odd part, then count divisors of the odd part method reappears verbatim in any problem about the number of ways to write N as a sum, or a difference of two squares, or a product of two factors of prescribed parity.

Circuit Bank

- **WHEN** a problem talks about writing N as a sum of k consecutive positive integers, for one or several values of k **DO** rewrite immediately as $2N = k(2a + k - 1)$ and read the two factors as an opposite-parity pair **BECAUSE** this single identity converts every question about consecutive-integer sums into a question about factorisations of the fixed number $2N$
- **WHEN** a problem attaches an exact count, or a uniqueness statement, to the number of ways some representation of N exists **DO** look for a bijection between the valid representations and the divisors of an auxiliary integer built from N, very often its odd part, then translate the count into a statement about that auxiliary integer's divisor count **BECAUSE** exactly one, or exactly some small number, is almost always secretly a statement that this integer has exactly two, or a few, divisors, and the divisor function is the only standard tool that produces exact small counts
- **WHEN** an even number needs to be split into two factors of specified, opposite parity **DO** factor out the full power of two first, $n = 2^s u$ with u odd, then note the even factor must swallow the entire 2^s, leaving only divisors of u free to distribute **BECAUSE** this avoids ever having to case split on how many twos end up on which side; there is only ever one place for them to go

- **WHEN** a distinguished numeral in a competition problem, here 2017, needs to be identified as prime or composite before you can use it **DO** trial-divide by every prime up to its square root and state the check explicitly, rather than assuming primality because the number looks like it should be prime **BECAUSE** a full-marks proof cannot rest on an unverified numerical claim, and the size of Putnam numerals is always small enough for a short, explicit trial division

Backtesting

1. First useful cue: sum of k consecutive positive integers, for $k = 2017$ but no other $k > 1$.
2. Method the expression suggested: rewrite as $2N = k(2a + k - 1)$, an opposite-parity factor pair of the fixed number $2N$.
3. Where you would hesitate, and the thought to reinforce: not seeing how to convert no other k works into something finite; reinforce that the polite number theorem turns representation counts into divisor counts of the odd part, so hunt for that bijection rather than testing individual k's.
4. The trap the question sets: it invites you to try to rule out $k = 2, 3, 4, \ldots$ one at a time, which is an unbounded search that never becomes a completed proof.
5. What makes you recognise it faster next time: seeing sum of consecutive positive integers and a count or uniqueness condition together, and firing the divisor-of-the-odd-part reflex before writing anything else.
6. The reusable decision rule: whenever a competition problem fixes a fussy-looking specific numeral, a large prime such as 2017, inside a divisibility or factorisation context, check whether that numeral's primality is the entire point, and verify it explicitly by trial division.

Mirror drills

1. How many ways can 45 be written as a sum of two or more consecutive positive integers? *Answer:* 45 is odd so all six of its divisors, $1, 3, 5, 9, 15, 45$, are odd, giving $6 - 1 = 5$ representations.
2. Show that a positive integer N has no representation as a sum of two or more consecutive positive integers if and only if N is a power of two. *Answer:* the odd part of N has only the divisor 1 exactly when N is a power of two, so the representation count $\tau(u) - 1$ is zero exactly then.
3. Find the smallest N that can be written as a sum of consecutive positive integers, length greater than 1, in exactly three different ways. *Answer:* you need the odd part of N to have exactly four divisors; the smallest odd number with four divisors is $15 = 3 \times 5$, and $N = 15$ itself works: $15 = 7 + 8 = 4 + 5 + 6 = 1 + 2 + 3 + 4 + 5$.

9.9 B3. power series digits and a denominator clash

Suppose that $f(x) = \sum_{i=0}^{\infty} c_i x^i$ is a power series for which each coefficient c_i is 0 or 1. Show that if $f(2/3) = 3/2$, then $f(1/2)$ must be irrational.

Read it out loud

Read the hypothesis literally: every coefficient of this power series is a 0 or a 1, nothing else. That single sentence tells you $f(1/2) = \sum c_i 2^{-i}$ is not merely some real number built from a series, it is the binary expansion of a real number, digit for digit, with c_i sitting in the 2^{-i} place. The problem is not really about power series at all beneath the surface, it is about binary expansions and the arithmetic fact that governs which of them represent rational numbers. The two evaluation points, $2/3$ and $1/2$, are chosen so that one of them, $1/2$, reads off the digits directly, and the other, $2/3$, is where the actual numerical information, the given value $3/2$, lives; your job is to move information from one point to the other.

Because the conclusion is must be irrational, the shape of the whole solution is fixed before you compute anything: this will be a proof by contradiction, since there is no way to directly construct or bound an irrational number from a series about which you know almost nothing except its value at a different point. The fields wired in are real analysis, base expansions and rationality, and generating functions, turning a periodic coefficient sequence into a genuine rational function of x. Within the first thirty seconds you should have written down that if $f(1/2)$ is rational then its binary digit sequence (c_i) is eventually periodic, because that is the only way rational ever manifests itself as a concrete, usable structural fact about a digit sequence.

Approaches, ranked worst to best

1. **Guess a specific sequence.** *Cue:* the hypothesis $f(2/3) = 3/2$ looks like it should pin down (c_i). *Circuit:* try to construct, digit by digit, one sequence of 0s and 1s achieving $f(2/3) = 3/2$, then compute $f(1/2)$ for that sequence. (why it ranks here: the sequence achieving $f(2/3) = 3/2$ is not unique, so even a successful computation for one example proves nothing about every sequence satisfying the hypothesis; this cannot become a proof of a universal claim).

2. **Direct estimation of $f(1/2)$.** *Cue:* $f(1/2)$ is a sum of a series with bounded terms. *Circuit:* bound $f(1/2)$ between two nearby rationals using the constraint $f(2/3) = 3/2$, hoping to squeeze it away from every rational number. (why it ranks here: bounding a number between two rationals that are close together never rules out that number itself being rational, so this line of attack has no natural way to finish and stalls before reaching a contradiction).

3. **Contrapositive via eventual periodicity of the binary expansion.** *Cue:* coefficients restricted to 0 or 1 is exactly a binary digit sequence, and must be irrational calls for contradiction. *Circuit:* assume $f(1/2)$ is rational, invoke that a real number is rational if and only if its base-2 expansion is eventually periodic, rewrite $f(x)$ as a genuine rational function of x using that periodicity, then evaluate at $x = 2/3$ and compare the parity of denominators against the given value $3/2$. (why it ranks here: it replaces an infinite series with a finite algebraic expression, and the contradiction it produces is a clean, checkable fact about odd against even denominators rather than an open-ended estimate).

The ideal solution

Suppose, for contradiction, that $f(1/2)$ is rational.

Step 1: extract periodicity. The number $f(1/2) = \sum_{i=0}^{\infty} c_i 2^{-i}$, with each $c_i \in \{0, 1\}$, is precisely the number whose base-2 expansion has digit c_i in position i. A real number is rational if and

only if its base-2 expansion is eventually periodic: the remainders that occur in the long-division algorithm for a fraction with denominator q lie in the finite set $\{0, 1, \ldots, q-1\}$, so some remainder must recur, and from that point on the digits repeat exactly as they did after the first occurrence of that remainder. Since $f(1/2)$ is assumed rational, there exist integers $n \geq 0$ and $m \geq 1$ such that

$$c_i = c_{i+m} \qquad \text{for all } i \geq n.$$

Step 2: convert periodicity into a rational function. Split off the pre-period terms and sum the repeating block as a geometric series in x^m:

$$f(x) = \sum_{i=0}^{n-1} c_i x^i + x^n \sum_{j=0}^{\infty} x^{jm} \sum_{i=0}^{m-1} c_{n+i} x^i = P(x) + \frac{x^n Q(x)}{1 - x^m},$$

where $P(x) = \sum_{i=0}^{n-1} c_i x^i$ and $Q(x) = \sum_{i=0}^{m-1} c_{n+i} x^i$ are honest polynomials with $0/1$ coefficients, and the identity is valid for $|x| < 1$, in particular at $x = 2/3$.

Step 3: evaluate at $x = 2/3$ and track denominators. The value $P(2/3) = \sum_{i=0}^{n-1} c_i (2/3)^i$, once written over a common denominator, equals an integer divided by 3^{n-1}; in lowest terms its denominator divides 3^{n-1}, hence is odd. Similarly $Q(2/3) = \sum_{i=0}^{m-1} c_{n+i} (2/3)^i$ equals an integer divided by 3^{m-1}. The second summand of $f(2/3)$ is

$$\frac{(2/3)^n Q(2/3)}{1 - (2/3)^m} = \frac{2^n 3^m}{3^{n+m-1}(3^m - 2^m)} \sum_{i=0}^{m-1} c_{n+i} 2^i 3^{m-1-i},$$

whose denominator, before any cancellation, is $3^{n+m-1}(3^m - 2^m)$. Since 3^m is odd and 2^m is even for every $m \geq 1$, the quantity $3^m - 2^m$ is odd; and 3^{n+m-1} is a power of an odd number. So this denominator is a product of two odd numbers, hence odd, and remains odd after any cancellation, since cancelling only removes factors that were already present in both numerator and denominator, never introduces the prime 2 into the denominator.

So $f(2/3) = P(2/3) + (\text{second summand})$ is a sum of two rational numbers each with odd denominator in lowest terms. Writing both over the common denominator $3^{n+m-1}(3^m - 2^m)$, itself odd, shows the sum, before reduction, again has odd denominator; reduction cannot turn an odd denominator into an even one. So $f(2/3)$, written in lowest terms, has odd denominator.

Step 4: contradiction. You are given $f(2/3) = 3/2$, and $3/2$ is already in lowest terms with denominator 2, which is even. A single rational number cannot simultaneously have odd denominator, from Step 3, and even denominator, from the hypothesis, in its own unique lowest-terms representation. This contradiction shows the assumption of Step 1 was false: $f(1/2)$ is irrational. ■

Layer 1: WHAT

Block 1: read $c_i \in \{0, 1\}$ as this is a binary expansion, so $f(1/2)$ is a specific real number's base-2 digit string. Block 2: since the conclusion is must be irrational, commit to a proof by contradiction and assume $f(1/2)$ is rational. Block 3: invoke the rational if and only if eventually periodic lemma to get $c_i = c_{i+m}$ for $i \geq n$. Block 4: turn that periodicity into a closed-form rational function $f(x) = P(x) + x^n Q(x)/(1 - x^m)$. Block 5: evaluate the closed form at $x = 2/3$ and show every term, hence the whole sum, has odd denominator. Block 6: contradict the given even denominator of $3/2$.

The nominal route tries to pin down an explicit sequence (c_i) satisfying $f(2/3) = 3/2$, perhaps by a greedy digit-by-digit construction reminiscent of a non-integer base expansion, and then attempts to read off properties of $f(1/2)$ directly from that one sequence. The bifurcation point comes immediately after writing suppose $f(1/2)$ is rational: the zombie move is to try to solve for the digits themselves, which spirals into an underdetermined, non-terminating construction, while

the reroute is to extract only the structural consequence of rationality, eventual periodicity, and carry that structure to the other evaluation point, where a concrete number is already known, rather than trying to pin down the sequence completely.

Layer 2: HOW

Block 1. **Cue.** Every coefficient of the power series is restricted to $\{0,1\}$, nothing else. **Why natural.** A series with only $0/1$ coefficients evaluated at $1/2$ is not an arbitrary real number built from a sum, it is the literal definition of a base-2 expansion with those digits, so any question about $f(1/2)$ is secretly a question about binary expansions. **Link to the next block.** Since the target conclusion is a rationality statement about a digit string, the natural tool is the standard fact linking rationality of a number to periodicity of its digit string.

Block 2. **Cue.** The problem demands you show a quantity must be irrational. **Why natural.** Irrationality is a negative, unbounded statement, a number is not expressible as any ratio of integers, and negative unbounded statements are proved by assuming the opposite and deriving a contradiction with something you can compute, since there is no positive construction of not a fraction. **Link to the next block.** Assuming $f(1/2)$ is rational immediately hands you, via the periodicity lemma, a finite amount of combinatorial data, the numbers n and m and the finitely many digits between them, to work with instead of an infinite unknown sequence.

Block 3. **Cue.** The periodicity you now have, $c_i = c_{i+m}$ for $i \geq n$, describes the coefficient sequence, not yet a usable number. **Why natural.** An eventually periodic sequence's generating function is always exactly a polynomial, the pre-period part, plus a geometric-series tail, because summing a periodic block infinitely many times is precisely what the identity for a geometric series in x^m computes. **Link to the next block.** This closed form $f(x) = P(x) + x^n Q(x)/(1 - x^m)$ can now be evaluated at any point inside the radius of convergence, in particular at the point $x = 2/3$ where the problem has already told you the exact value.

Block 4. **Cue.** The two rational evaluation points, $2/3$, denominator a power of 3, and the target value $3/2$, denominator 2, involve different primes in their denominators. **Why natural.** Every term in the closed form, evaluated at $2/3$, produces a denominator built only from powers of 3 and from $3^m - 2^m$, and $3^m - 2^m$ is odd because 3^m is odd and 2^m is even; no term can ever contribute a factor of 2 to a denominator, since $2/3$ itself has no 2 in its denominator to begin with. **Link to the next block.** Once every term is confirmed odd-denominatored, the sum is odd-denominatored, and this collides head-on with the given value $3/2$, whose denominator is unavoidably even; that collision is the entire content of the contradiction.

Layer 3: WHY

The mathematical truth beneath this problem is that rationality is not a property you can see directly in an infinite sum, it is a property of the structure of the coefficient sequence, periodicity, and structure is exactly the kind of thing that survives being transported to a different evaluation point, whereas a raw numerical value does not. Assuming $f(1/2)$ is rational buys you periodicity; periodicity buys you a rational-function formula for f as a function of x, valid everywhere inside the disc of convergence; and a rational-function formula is the one kind of object whose behaviour at $x = 2/3$ you can fully control and compare against a known target. The deeper reason the contradiction lands is arithmetic: $2/3$ only ever introduces the prime 3 into denominators, its own denominator, and the denominators $3^m - 2^m$ that arise from summing its powers, so nothing forces a factor of 2 into any denominator along the way, yet the hypothesis $f(2/3) = 3/2$ insists that a

factor of 2 must be there. The clash is unavoidable once periodicity is assumed, which is exactly why the contradiction is airtight rather than merely suggestive.

The discernment mechanism to train: whenever a problem gives you a series' value at two different rational points and asks you to deduce the rational or irrational nature of one from the given value at the other, expect the mechanism to be a denominator mismatch, most often a mismatch of which primes divide the denominator, obtained by assuming the structural consequence of rationality at the unknown point, periodicity, or more generally that the object is a rational function, and pushing that structure through to the known point. Whenever coefficients are restricted to a small finite set like $\{0, 1\}$, read that restriction immediately as these are digits in some base, because that reading is what makes the rationality lemma available at all; without it there is no route from rational value to periodic sequence.

Revolving concepts

Rationality and eventually periodic base-b expansions: a real number is rational exactly when its expansion in any fixed integer base is eventually periodic; the proof is a pigeonhole argument on the finitely many possible remainders in long division by the denominator. See Book 1, field: Real analysis, topic: base expansions of rational numbers.

Generating function of an eventually periodic sequence: if $c_i = c_{i+m}$ for all $i \geq n$, then the generating function of (c_i) equals a polynomial plus x^n times a polynomial over $1 - x^m$, built from the pre-period and one period block; more generally, any sequence satisfying a linear recurrence from some point on has a generating function equal to a polynomial divided by the reversed characteristic polynomial of that recurrence, obtained the same way every time, multiply the recurrence by x^i, sum over all valid i, and solve the resulting equation for the generating function. Eventual periodicity is exactly the special case of the recurrence $c_{i+m} = c_i$, whose characteristic polynomial $x^m - 1$ has every m-th root of unity as a root, giving the denominator $1 - x^m$. See Book 1, field: Generating functions, topic: rational generating functions from linear recurrences.

Denominator bookkeeping by prime: a sum or product of rational numbers each having odd denominator, more generally each having denominator coprime to a fixed prime p, again has denominator coprime to p, because a common denominator built from odd numbers is odd, and reducing a fraction never introduces a new prime factor into the denominator that was not already dividing the original denominator. See Book 1, field: Number theory, topic: valuations and denominators.

The identity $3^m - 2^m$ is always odd for $m \geq 1$: a special case of a power of an odd number minus a power of an even number is odd, used here as the one nonobvious denominator factor that must be checked by hand. See Book 1, field: Number theory, topic: parity arguments.

Power series with $0/1$ coefficients as indicator generating functions: $f(x) = \sum_{i \in A} x^i$ for $A = \{i : c_i = 1\}$, a subset of the nonnegative integers, so $f(1/2)$ is literally the real number whose binary expansion marks the elements of A. See Book 1, field: Functional equations, topic: generating functions of sets.

Circuit Bank

- **WHEN** a power series has coefficients restricted to $\{0, 1\}$ **DO** read $f(1/b)$ for any integer base $b \geq 2$ as the literal base-b digit expansion of a real number with those digits, not as an abstract sum **BECAUSE** the restriction to two symbols is exactly the definition of a digit string in that base, and every fact about rationality of digit strings becomes available the instant you make this identification
- **WHEN** you must prove a stated quantity must be irrational **DO** argue by contradiction: assume it is rational, extract the strongest available structural consequence, periodicity of a digit string, algebraicity of a series, and push that structure to wherever a concrete numerical

value is already known **BECAUSE** irrationality has no positive constructive proof in general, so the standard route is always to assume rationality, extract structure, and collide that structure with a fact you can compute

- **WHEN** a coefficient sequence is shown to be eventually periodic **DO** split the generating function into a finite pre-period polynomial plus a period-block polynomial times $x^n/(1-x^m)$ **BECAUSE** this is the unique way to sum an eventually periodic series in closed form, converting an infinite object into two polynomials and one geometric factor
- **WHEN** two rational evaluations of the same object need to be compared for a contradiction **DO** track which prime appears in each side's denominator rather than compute an exact common denominator **BECAUSE** the contradiction usually needs only one bit of information, whether a fixed prime divides the denominator or not, and full computation is unnecessary ink

Backtesting

1. First useful cue: coefficients restricted to $\{0,1\}$, combined with a given exact value at one point and a rationality question at another.
2. Method the expression suggested: contrapositive, plus the rational if and only if eventually periodic base expansion lemma.
3. Where you would hesitate, and the thought to reinforce: wondering whether rational implies eventually periodic needs its own proof inside the write-up; reinforce that this is a standard, nameable lemma about long division remainders, and it should be stated as such rather than waved through as obvious.
4. The trap the question sets: it tempts you to try to construct or guess the actual sequence (c_i) satisfying $f(2/3) = 3/2$, which is neither unique nor necessary for the proof.
5. What makes you recognise it faster next time: seeing each coefficient is 0 or 1 and immediately relabelling the series as a base-2 digit string rather than as an unstructured sequence.
6. The reusable decision rule: whenever an irrationality conclusion must follow from a given rational value at a different point, hunt for a prime that can appear in one side's denominator but not the other's, after first extracting the periodicity or rational-function structure that rationality would force.

Mirror drills

1. Prove the converse direction used in Step 2: if (c_i) is eventually periodic with period m from index n, then $\sum c_i 2^{-i}$ is rational. *Answer:* group into blocks of length m exactly as in Step 2; at $x = 1/2$ the closed form is manifestly a ratio of integers, since $P(1/2)$ and $Q(1/2)$ are rational and $1 - 2^{-m}$ is a nonzero rational.
2. If $g(x) = \sum d_i x^i$ has $d_i \in \{0,1\}$ and $g(1/2) = g(1/3)$, and this common value is rational, what primes can appear in its denominator? *Answer:* at $x = 1/2$ the closed form only ever produces denominators that are powers of 2 or factors of $2^m - 1$; at $x = 1/3$ it only ever produces powers of 3 or factors of $3^m - 1$; a common rational value forces the denominator to divide both kinds simultaneously, a strong restriction worth chasing with the same bookkeeping used above.
3. True or false: if f has coefficients in $\{0,1\}$ and $f(1/2)$ is rational, then f is a rational function of x. *Answer:* true, this is exactly the periodic-to-rational-function lemma of Step 2; the converse, that a rational function with a power series expansion having $0/1$ coefficients must

have eventually periodic coefficients, follows from the theory of linear recurrences via partial fractions.

9.10 B4. Evaluating a period four logarithmic series

Evaluate the sum

$$\sum_{k=0}^{\infty}\left(3\cdot\frac{\ln(4k+2)}{4k+2}-\frac{\ln(4k+3)}{4k+3}-\frac{\ln(4k+4)}{4k+4}-\frac{\ln(4k+5)}{4k+5}\right)$$
$$=3\cdot\frac{\ln 2}{2}-\frac{\ln 3}{3}-\frac{\ln 4}{4}-\frac{\ln 5}{5}+3\cdot\frac{\ln 6}{6}-\frac{\ln 7}{7}-\frac{\ln 8}{8}-\frac{\ln 9}{9}+3\cdot\frac{\ln 10}{10}-\cdots.$$

(As usual, $\ln x$ *denotes the natural logarithm of* x*.)*

Read it out loud

There is one sequence here and one weight. The sequence is $b_n=\dfrac{\ln n}{n}$, evaluated at every positive integer in turn. The weight is a pattern that repeats with period 4: weight 3 when $n\equiv 2 \pmod 4$, weight -1 on the other three residues. Say that sentence to yourself before you write anything else, because the second display in the question is the honest form of the object and the first display is only a bracketing of it. In symbols, set

$$\epsilon_n=\begin{cases}3 & n\equiv 2 \pmod 4\\ -1 & \text{otherwise,}\end{cases}$$

and the series is $\sum_n \epsilon_n b_n$, started at $n=2$. It costs nothing to start at $n=1$ instead, because $b_1=\ln 1=0$, and starting at $n=1$ is what makes the weight a genuinely periodic sequence rather than a periodic sequence with a hole in it. That is the first thing you should have on paper inside thirty seconds.

The second thing on paper is $3-1-1-1=0$. The weight has mean zero over one period. That single fact is doing all the work: it is why the series converges at all (the terms b_n only decay like $\ln n/n$, so no weight of nonzero mean could give a convergent series), and it is why the bracketed version converges absolutely while the unbracketed version does not. The fields wired into this problem are therefore real analysis first (conditional versus absolute convergence, and the discipline of never rearranging a conditionally convergent series) and analytic number theory second (a Dirichlet series with periodic coefficients, evaluated by differentiating at $s=1$).

The third thing on paper is a question, not a calculation: where can a closed form possibly come from? The only structural identity available to ln is $\ln(mn)=\ln m+\ln n$. Since the modulus is 4 and the special residue is 2, the only multiplicative relation in sight is doubling. Compute what doubling does to b:

$$b_{2m}=\frac{\ln(2m)}{2m}=\frac{\ln 2}{2m}+\frac{1}{2}\cdot\frac{\ln m}{m}=\frac{\ln 2}{2m}+\frac{1}{2}b_m.$$

That is an exact self-similarity: the doubling map sends b to half of itself plus a harmonic term carrying a factor $\ln 2$. So $\ln 2$ can enter the answer in exactly one way, through that harmonic term, and the harmonic term will have to be summed against an alternating sign to produce anything finite. Alternating harmonic sums to $\ln 2$. So before you have proved anything you already expect $(\ln 2)^2$, and a two second numerical check on the first few brackets (0.4805 to four places against $(\ln 2)^2=0.48045\ldots$) confirms it. The rest of the work is to get there without committing a rearrangement crime.

What is really being tested is whether you can hold a conditionally convergent object still. The graders on this problem were not looking for the value; the value is guessable. They were looking for a candidate who manipulates only finite partial sums and takes limits exactly once, at the end.

Approaches, ranked worst to best

1. **Numerical reconnaissance and recognition.** *Cue:* "Evaluate the sum" with no free parameter, so the answer is one number. *Circuit:* compute, recognise, then go and prove. Summing a few thousand brackets gives 0.48045, and $\sqrt{0.48045} = 0.6931 = \ln 2$. This is worth zero marks as a proof and is nevertheless compulsory: you should never spend twenty minutes proving a value you have not first checked. It ranks last only as a route to a written solution.

2. **Expand every logarithm and hope.** *Cue:* $\ln(4k+2) = 2\ln 2 + \ln(2k+1)$, $\ln(4k+4) = 2\ln 2 + \ln(k+1)$, and so on. *Circuit:* split every term into its $\ln 2$ part and its residual part. This is the zombie route. You end up with a heap of pieces, each of which is individually divergent ($\sum 1/n$, $\sum \ln n/n$), and you must track the cancellation between divergent objects by hand across a page of algebra. It can be made to work with asymptotic expansions and the Euler to Mascheroni constant, but the ink cost is enormous and every regrouping is a place to lose the marks.

3. **Telescoping the block.** *Cue:* the block has four terms whose weights sum to zero, and any mean zero block is a combination of consecutive differences. *Circuit:* write $a_k = b_k - b_{k+1}$ and express the block in the a basis. You find $3b_{4k+2} - b_{4k+3} - b_{4k+4} - b_{4k+5} = 3a_{4k+2} + 2a_{4k+3} + a_{4k+4}$, note that $\sum_{k\geq 1} a_k$ telescopes to 0 and converges absolutely, and then grind out the remaining $\ln 2$ by pairing $a_{4k+2} + a_{4k+3}$. This is a complete and correct route and it is the one the official solution takes first. It ranks third because it needs two separate ideas (the difference basis, and then a second regrouping to release the $\ln 2$) where the winning route needs one.

4. **Dirichlet series and differentiation at $s = 1$.** *Cue:* a periodic weight of mean zero times $\ln n/n$ is exactly $-\frac{d}{ds}$ of a Dirichlet series at $s = 1$. *Circuit:* build $L(s) = \sum \epsilon_n n^{-s}$, factor it, differentiate. This is the best explanation of the answer and you must know it (see Layer 3). As a written solution it ranks fourth because of the analysis rent: you owe the grader convergence of $L(s)$ for $s > 0$, the identity $L(s) = -\zeta(s)(1 - 2^{1-s})^2$ proved for $s > 1$ and then extended to $s = 1$, and a justification of term by term differentiation. That is a page of standard but unavoidable analysis for a value you can get in five lines.

5. **Decompose the weight, not the terms.** *Cue:* the weight is a period 4 integer sequence, and the doubling self-similarity $b_{2m} = \frac{\ln 2}{2m} + \frac{1}{2}b_m$ is the only multiplicative structure available. *Circuit:* write ϵ as an alternating pattern plus twice an alternating pattern pulled back along $n \mapsto 2n$. This is the ideal route. You never touch an infinite sum until the last line, the unknown value of $\sum(-1)^{n-1}b_n$ cancels against itself and never has to be evaluated, and the $(\ln 2)^2$ appears as a product of two separate copies of $\ln 2$, one from $\ln(2m) = \ln 2 + \ln m$ and one from the alternating harmonic series.

The ideal solution

Write $b_n = \dfrac{\ln n}{n}$ for $n \geq 1$, so that $b_1 = 0$, and let

$$\epsilon_n = \begin{cases} 3, & n \equiv 2 \pmod 4, \\ -1, & \text{otherwise.} \end{cases}$$

The Kth partial sum of the given series is

$$T_K = \sum_{k=0}^{K-1} \left(3b_{4k+2} - b_{4k+3} - b_{4k+4} - b_{4k+5}\right) = \sum_{n=2}^{4K+1} \epsilon_n b_n = \sum_{n=1}^{4K+1} \epsilon_n b_n,$$

the last equality because $b_1 = 0$.

Claim 9.10.1. *For every $n \geq 1$,*

$$\epsilon_n \;=\; -(-1)^{n-1} \;+\; \begin{cases} 2\,(-1)^{m-1}, & n = 2m, \\ 0, & n \text{ odd.} \end{cases}$$

Proof. Three cases. If n is odd the right side is -1, and $n \not\equiv 2 \pmod 4$, so $\epsilon_n = -1$. If $n = 2m$ with m odd, then $n \equiv 2 \pmod 4$ and the right side is $-(-1)^{2m-1} + 2(-1)^{m-1} = 1 + 2 = 3 = \epsilon_n$. If $n = 2m$ with m even, then $n \equiv 0 \pmod 4$ and the right side is $1 - 2 = -1 = \epsilon_n$. □

The even indices n with $1 \leq n \leq 4K+1$ are exactly $n = 2m$ with $1 \leq m \leq 2K$, so the Claim gives the finite identity

$$T_K \;=\; -\sum_{n=1}^{4K+1} (-1)^{n-1} b_n \;+\; 2\sum_{m=1}^{2K} (-1)^{m-1} b_{2m}.$$

Now use $b_{2m} = \dfrac{\ln 2}{2m} + \dfrac{1}{2} b_m$, which is just $\ln(2m) = \ln 2 + \ln m$ divided by $2m$:

$$2\sum_{m=1}^{2K} (-1)^{m-1} b_{2m} \;=\; (\ln 2) \sum_{m=1}^{2K} \frac{(-1)^{m-1}}{m} \;+\; \sum_{m=1}^{2K} (-1)^{m-1} b_m.$$

Abbreviate $A_N = \sum_{n=1}^{N} (-1)^{n-1} b_n$ and $H_N = \sum_{m=1}^{N} \frac{(-1)^{m-1}}{m}$. Combining the last two displays,

$$T_K \;=\; -A_{4K+1} \;+\; A_{2K} \;+\; (\ln 2)\, H_{2K}, \qquad K \geq 1. \tag{$*$}$$

Every step so far is an identity between finite sums; nothing has been rearranged.

It remains to take limits in $(*)$. The function $x \mapsto \frac{\ln x}{x}$ has derivative $\frac{1 - \ln x}{x^2} < 0$ for $x > e$, so the sequence $(b_n)_{n \geq 3}$ is strictly decreasing, and $b_n \to 0$. By the alternating series test applied from $n = 3$ onwards (the terms $n = 1, 2$ form a finite head and do not affect convergence), A_N converges to a finite limit A. Also $H_N \to \ln 2$, the alternating harmonic series. Therefore

$$\lim_{K \to \infty} T_K \;=\; -A + A + (\ln 2)(\ln 2) \;=\; \boxed{(\ln 2)^2}.$$

Two points a grader will want addressed explicitly, both of which are cheap.

First, $\lim_K T_K$ is exactly what the question asks for, since the bracketing displayed in the problem *is* the definition of the sum. In fact the bracketed series converges absolutely, so the value is bracket independent in the strongest sense: writing the block as

$$3b_{4k+2} - b_{4k+3} - b_{4k+4} - b_{4k+5} = (b_{4k+2} - b_{4k+3}) + (b_{4k+2} - b_{4k+4}) + (b_{4k+2} - b_{4k+5}),$$

each difference is at most $3 \max_{x \geq 4k+2} \left| \frac{d}{dx} \frac{\ln x}{x} \right| = O\left(\frac{\ln k}{k^2} \right)$ by the mean value theorem, and $\sum_k \frac{\ln k}{k^2} < \infty$.

Second, the value A of the alternating series $\sum_{n \geq 1} (-1)^{n-1} \frac{\ln n}{n}$ was never needed. It is a genuine constant (it equals $\gamma \ln 2 - \frac{(\ln 2)^2}{2}$, which you are not expected to know and did not use); all that mattered was that it exists, so that $-A_{4K+1}$ and A_{2K} have the same limit and cancel.

Layer 1: WHAT

Block 1. Name the object: one sequence $b_n = \ln n / n$, one period 4 weight ϵ_n of mean zero, sum $= \sum \epsilon_n b_n$ with $b_1 = 0$ so that the sum may start at $n = 1$.

Block 2. Ask where $\ln 2$ can come from. Only from $\ln(2m) = \ln 2 + \ln m$. So record the doubling self-similarity $b_{2m} = \frac{\ln 2}{2m} + \frac{1}{2} b_m$ and decide to build the solution around the map $n \mapsto 2n$.

Block 3. Decompose the *weight* in terms of that map: $\epsilon_n = -(-1)^{n-1}$ plus $2(-1)^{m-1}$ on the even indices $n = 2m$. Verify by three residue cases.

Block 4. Substitute. The $\frac{1}{2}b_m$ half of the self-similarity regenerates the same alternating sum you subtracted; the $\frac{\ln 2}{2m}$ half becomes $\ln 2$ times an alternating harmonic sum.

Block 5. Take limits of the three finite sequences in $(*)$, each of which you have proved converges. The unknown constant cancels, the answer is $(\ln 2)^2$.

Juxtaposition. The nominal route also starts by splitting logarithms, but it splits them *inside the terms*: $\ln(4k+2) = 2\ln 2 + \ln(2k+1)$, $\ln(4k+3)$ stays, $\ln(4k+4) = 2\ln 2 + \ln(k+1)$, $\ln(4k+5)$ stays. You then have four families of terms and a pile of $\ln 2$ multiples, none of which sums separately, and you attempt to reassemble $\sum_n \ln n/n$ out of the pieces while the harmonic parts diverge underneath you. The ideal route splits the same logarithm but only after deciding which indices to apply it to, and it decides that by decomposing the weight.

Bifurcation point. The exact line where the routes split is the line after you have written ϵ_n down. The zombie asks "what are the terms?". You ask "what is the weight, as a sequence, in terms of the maps under which b is self-similar?". Everything downstream is forced.

Layer 2: HOW

Block 1. Cue. Two displays are given, and the second one has no brackets. That is the setter telling you the object is a weighted sum over all n, and that the bracketing is a convergence courtesy rather than part of the definition. **Why natural.** Whenever a series is presented in blocks of equal length, the honest object is (weight sequence) times (term sequence), and the block length is the period of the weight. Writing ϵ_n separates the two so that you can work on each independently. Recording $b_1 = 0$ is not cosmetic: it is what lets the weight be a clean periodic sequence starting at $n = 1$, which is what every later step needs. **Link to the next block.** With the two factors separated, the next question is forced: which of the two carries the structure that could produce a closed form?

Block 2. Cue. The answer must be a closed form, and the only closed form constants available from logarithms of integers are ln of small integers. The modulus is 4, so the small integer in play is 2. **Why natural.** ln turns multiplication into addition. Therefore the only maps on indices that interact usefully with $b_n = \ln n/n$ are the multiplications $n \mapsto dn$, under which $b_{dn} = \frac{\ln d}{dn} + \frac{1}{d}b_n$. This is not a trick; it is the defining property of ln applied to the only place it can be applied. Note the shape of the result: an exact affine self-similarity, with a harmonic remainder that carries the constant $\ln d$. **Link to the next block.** The self-similarity is stated in terms of $n \mapsto 2n$, so if you want to use it you must arrange for the weight to be expressed in terms of $n \mapsto 2n$ too.

Block 3. Cue. ϵ is -1 almost everywhere and $+3$ on one residue class, so $\epsilon_n = -1 + 4 \cdot [\, n \equiv 2 \pmod 4 \,]$; and the condition $n \equiv 2 \pmod 4$ says exactly "$n = 2m$ with m odd". **Why natural.** That reading of the residue class is the whole move. "$n \equiv 2 \pmod 4$" looks like a statement about n; it is really a statement about $m = n/2$, namely that m is odd. Once the special class is described in terms of m, the alternating sign $(-1)^{m-1}$ appears by itself, because "m odd" is the support of $\frac{1+(-1)^{m-1}}{2}$. Matching constants then gives $\epsilon_n = -(-1)^{n-1} + 2(-1)^{m-1}[n = 2m]$, which you confirm in three lines. **Link to the next block.** Now both factors are expressed through the same map, so substitution will make the two alternating sums collide.

Block 4. Cue. You have $-\sum(-1)^{n-1}b_n$ and $+2\sum(-1)^{m-1}b_{2m}$ side by side, and you know what b_{2m} is. **Why natural.** Substituting the self-similarity is the only available move, and it is a good one because the coefficient 2 in front is exactly what turns $2 \cdot \frac{1}{2}b_m$ into b_m, restoring the alternating sum you subtracted. That is not luck: the 2 came from ϵ, and ϵ was built to make the two pieces match, because you chose the decomposition with the doubling identity already in view. **Link to the next block.** What survives is $2 \cdot \frac{\ln 2}{2m}$ summed with alternating signs, which is $\ln 2$ times the alternating harmonic series.

Block 5. Cue. Three finite sums, three separate limits. **Why natural.** Because you kept everything finite, taking limits is legal the instant you prove each sequence converges, and the proofs are one line each (alternating series test for A_N; the standard alternating harmonic value for H_N). Had you rearranged the infinite series instead, you would have needed absolute convergence of a series that does not converge absolutely, and the Riemann rearrangement theorem says the result could have been anything. **Link to the next block.** Nothing follows; you are done. Then check the value numerically, which you had already done before starting.

Layer 3: WHY

The mathematical truth underneath is that periodic weights against n^{-s} are Dirichlet series, and multiplying a Dirichlet series by a factor of the form $1 - c\,d^{-s}$ is exactly the coefficient level operation "subtract c times the value at index n/d". That is the operation you performed in Block 3, in the opposite direction.

Concretely, set $L(s) = \sum_{n\geq 1} \epsilon_n n^{-s}$. For $s > 1$ everything converges absolutely and you may split by residue class:

$$L(s) = -\zeta(s) + 4\sum_{j\geq 0}(4j+2)^{-s} = -\zeta(s) + 4\cdot 2^{-s}(1-2^{-s})\zeta(s) = \zeta(s)\big(-1 + 2^{2-s} - 2^{2-2s}\big),$$

using $\sum_{j\geq 0}(2j+1)^{-s} = (1-2^{-s})\zeta(s)$. Now put $u = 2^{1-s}$: the bracket is $-1 + 2u - u^2 = -(1-u)^2$. Hence

$$L(s) = -\zeta(s)\big(1-2^{1-s}\big)^2 = -\eta(s)\big(1-2^{1-s}\big), \qquad \eta(s) := \sum_{n\geq 1}\frac{(-1)^{n-1}}{n^s} = (1-2^{1-s})\zeta(s).$$

Since $\frac{d}{ds}n^{-s} = -(\ln n)n^{-s}$, the sum you want is $S = -L'(1)$. The factor $1 - 2^{1-s}$ vanishes at $s = 1$ with derivative $\ln 2$, and $\eta(1) = \ln 2$, so

$$L'(1) = -\eta'(1)\cdot 0 - \eta(1)\ln 2 = -(\ln 2)^2, \qquad S = (\ln 2)^2.$$

Read the same computation through ζ instead: ζ has a simple pole at $s = 1$ with residue 1, and $(1-2^{1-s})^2$ has a double zero there with leading coefficient $(\ln 2)^2$; pole times double zero is a simple zero, and $-L'(1)$ picks out (residue) times (leading coefficient) $= (\ln 2)^2$. The answer is a perfect square because the weight is, up to sign, a Dirichlet convolution square.

That is the discernment mechanism, and it generalises cleanly. Given $\sum_n \epsilon_n \frac{\ln n}{n}$ with ϵ periodic of period q and mean zero, form $L(s) = \sum \epsilon_n n^{-s}$ and ask whether $L(s)/\zeta(s)$ factors into terms $1 - c\,d^{-s}$ with $d \mid q$. If it factors with a *double* zero at $s = 1$ you will get an elementary answer with no Euler to Mascheroni constant, and the elementary proof is the coefficient level shadow of the factorisation; if it has only a *simple* zero, γ will appear (for the period 3 weight $(-1,-1,2)$ you get $L(s) = \zeta(s)(3^{1-s}-1)$, a single zero, and the sum is $\gamma\ln 3 - \frac{(\ln 3)^2}{2}$). So the factorisation tells you in advance how hard the answer will be.

To train the discernment: take periodic patterns of mean zero and practise writing them as integer combinations of the constant weight **1**, the alternating weight $(-1)^{n-1}$, and their pullbacks along $n \mapsto n/d$ for the divisors d of the period. Ten minutes of that makes Block 3 automatic. The examiners nudged toward it in the only way available on a printed paper: they wrote the second, unbracketed display so that you would see the pattern $3, -1, -1, -1$ repeating, and they chose the weights so that the pattern is -1 plus a spike, which is the easiest possible pattern to decompose.

Revolving concepts

The sequence $\ln n/n$**.** Definition level facts: $\frac{d}{dx}\frac{\ln x}{x} = \frac{1-\ln x}{x^2}$, so it increases on $(0,e)$ and decreases on (e,∞) with maximum $1/e$ at $x = e$; among integers the maximum is at $n = 3$. Hence $(b_n)_{n\geq 3}$

decreases to 0, which is precisely the hypothesis of the alternating series test. See Book 1, field: Real analysis, topic: monotonicity and the alternating series test.

Absolute versus conditional convergence. $\sum|\epsilon_n b_n|$ diverges (it dominates $\sum\frac{\ln n}{n}$ up to a constant), so the series is conditionally convergent at best; the bracketed series is absolutely convergent. The Riemann rearrangement theorem says a conditionally convergent real series can be rearranged to any real value or to $\pm\infty$, so a solution that rearranges without justification is not merely informal, it is wrong. See Book 1, field: Real analysis, topic: rearrangement.

Dirichlet's test and the convergence of $\sum\epsilon_n b_n$. If ϵ is periodic with mean zero then its partial sums are bounded, and $b_n \downarrow 0$ eventually, so $\sum\epsilon_n b_n$ converges. This is the general statement of which the alternating series test is the period 2 case. See Book 1, field: Real analysis, topic: Dirichlet's test.

Alternating harmonic series. $\sum_{m\geq 1}\frac{(-1)^{m-1}}{m} = \ln 2$. From the Maclaurin series of $\ln(1+x)$ on $(-1,1)$ plus Abel's theorem at $x=1$, or directly from $H_{2N} = \sum_{n=N+1}^{2N}\frac{1}{n} \to \int_0^1\frac{dt}{1+t}$. See Book 1, field: Real analysis, topic: alternating harmonic series.

Dirichlet series with periodic coefficients. $L(s) = \sum\epsilon_n n^{-s}$ converges for $s > 0$ when ϵ has mean zero and for $s > 1$ always; $\zeta(s) = \sum n^{-s}$ has a simple pole at $s = 1$ with residue 1; $\eta(s) = (1-2^{1-s})\zeta(s)$; $\sum_{n\text{ odd}} n^{-s} = (1-2^{-s})\zeta(s)$. The move $\frac{d}{ds}n^{-s} = -(\ln n)n^{-s}$ is why every "$\ln n$ over n" sum is a disguised derivative. See Book 1, field: Number theory, topic: Dirichlet series.

The self-similarity, generalised. There is no recursion in the sequence sense here, but there is an exact self-similarity under index scaling, and it is the engine, so generalise it fully. For any $d \geq 2$ and any real s,

$$\frac{1}{(dn)^s} = d^{-s}\cdot\frac{1}{n^s}, \qquad \frac{\ln(dn)}{(dn)^s} = d^{-s}\left(\frac{\ln n}{n^s} + \frac{\ln d}{n^s}\right),$$

and more generally $\frac{(\ln dn)^r}{(dn)^s} = d^{-s}\sum_{j=0}^{r}\binom{r}{j}(\ln d)^{r-j}\frac{(\ln n)^j}{n^s}$. In words: the family $\{n^{-s},\ (\ln n)n^{-s},\ (\ln n)^2 n^{-s},\dots\}$ is closed under index scaling, with a triangular matrix of coefficients. That closure is the structural reason Dirichlet series, and not power series, are the correct transform for any sum whose index appears inside a logarithm. The same generalisation solves every problem of the form "periodic weight against $(\ln n)^r/n^s$": decompose the weight along the divisors of the period, then apply the binomial expansion above. See Book 1, field: Number theory, topic: index scaling and Dirichlet convolution.

Telescoping, the alternative engine. $\sum_{n=1}^{N}(g(n)-g(n+1)) = g(1)-g(N+1)$, so $\sum_{n\geq 1}(g(n)-g(n+1)) = g(1)$ whenever $g(n)\to 0$. With $g = b$ this gives $\sum_{k\geq 1}a_k = 0$ for $a_k = b_k - b_{k+1}$, the fact powering the third ranked approach. See Book 1, field: Sequences and recurrences, topic: telescoping.

Circuit Bank

- **WHEN** a series is printed in equal length blocks, or in two forms one of which is bracketed **DO** separate it into (periodic weight) times (term sequence), extend the weight back to $n = 1$ if a term vanishes there, and check whether the weight has mean zero **BECAUSE** the block length is the period of the weight, and mean zero is what makes the thing converge and what makes bracketing matter
- **WHEN** $\ln n$ appears divided by n or by n^s **DO** write down $b_{dn} = d^{-s}(b_n + \frac{\ln d}{n^s})$ for the divisors d of the period before doing anything else **BECAUSE** ln converts multiplication to addition, so index scaling is the only structural operation the expression admits, and it is where every $\ln d$ in the final answer must come from
- **WHEN** a residue class such as $n \equiv 2 \pmod 4$ singles out the special terms **DO** restate it as a condition on $m = n/2$, here "m odd" **BECAUSE** a condition on n/d is what lets you pull the weight back along the scaling map, which is the only way the weight and the terms can be made to talk to each other

- **WHEN** you are tempted to rearrange, regroup or split an infinite sum that is not absolutely convergent **DO** work with the Nth partial sum, keep every identity finite, and take limits exactly once at the end **BECAUSE** Riemann rearrangement means an unjustified regrouping of a conditionally convergent series is not a shortcut, it is an error, and the finite version costs one extra subscript
- **WHEN** an unknown constant appears twice with opposite signs and shifted indices **DO** name it, prove only that it converges, and let it cancel **BECAUSE** evaluating it is usually a much harder problem than the one you were set, and convergence is all the cancellation needs

Backtesting

1. First useful cue: the second, unbracketed display, showing the weights $3, -1, -1, -1$ repeating with period 4 against the single sequence $\ln n/n$; and immediately after it, $3-1-1-1=0$.
2. Method the expression suggested: separate weight from terms; note the only structure $\ln n/n$ has is $b_{2m} = \frac{\ln 2}{2m} + \frac{1}{2}b_m$; therefore decompose the weight along the doubling map.
3. Where you would hesitate, and the thought to reinforce: at the moment of matching ϵ_n to $-(-1)^{n-1} + 2(-1)^{m-1}[n = 2m]$, which can feel like it was pulled from nowhere. Reinforce: it was not guessed, it was forced. $\epsilon = -1 + 4[n \equiv 2 \bmod 4]$, and $n \equiv 2 \pmod 4$ means $n = 2m$ with m odd, and "m odd" carries the sign $(-1)^{m-1}$. Two constants then have to be matched, and there is only one way to match them.
4. The trap the question sets: the problem hands you two displays, one bracketed and one not, so that you will treat them as interchangeable and start regrouping. The unbracketed series is only conditionally convergent. Any solution that shuffles it without a finite partial sum argument is exposed.
5. What makes you recognise it faster next time: the pairing "periodic mean zero weight" with "$\ln n$ over n" is the fingerprint of $-L'(1)$ for a Dirichlet series L. Having once seen that $L(s) = -\zeta(s)(1-2^{1-s})^2$ here, you will recognise the family instantly, and you will know before computing whether the answer is clean (double zero at $s=1$) or contaminated by γ (simple zero).
6. The reusable decision rule: when a sum mixes a periodic weight with a sequence that is self-similar under index scaling, decompose the weight along the scaling maps, keep the algebra finite, and take limits once.

Mirror drills

1. Evaluate $\displaystyle\sum_{k=0}^{\infty}\left(\frac{3}{4k+2} - \frac{1}{4k+3} - \frac{1}{4k+4} - \frac{1}{4k+5}\right)$. *Answer:* 0. Same weight, terms $1/n$. The partial sum is $-\sum_{n\le 4K+1}\frac{(-1)^{n-1}}{n} + 2\sum_{m\le 2K}\frac{(-1)^{m-1}}{2m} \to -\ln 2 + \ln 2 = 0$. This is the statement $L(1)=0$, visible in the factorisation $L(s) = -\zeta(s)(1-2^{1-s})^2$.
2. Let $\epsilon_n = 2$ if $3 \mid n$ and $\epsilon_n = -1$ otherwise. Evaluate $\sum_{n\ge 1}\epsilon_n/n$. *Answer:* $-\ln 3$. Here $\epsilon_n = -1 + 3[3 \mid n]$, so $\sum_{n\le 3N}\epsilon_n/n = -H_{3N} + 3\sum_{m\le N}\frac{1}{3m} = -(H_{3N} - H_N) \to -\ln 3$. Note the contrast with drill 1: the weight is not built from an alternating character, so nothing cancels and the answer is a single ln.
3. Show that $\displaystyle\sum_{m=1}^{\infty}(-1)^{m-1}\left(\frac{\ln(2m)}{2m} - \frac{\ln m}{2m}\right) = \frac{(\ln 2)^2}{2}$. *Answer:* the bracket is $\frac{\ln 2}{2m}$ exactly, so the sum is $\frac{\ln 2}{2}\sum_{m\ge 1}\frac{(-1)^{m-1}}{m} = \frac{(\ln 2)^2}{2}$. This is the engine of B4 in isolation: one $\ln 2$ from splitting the logarithm, one from the alternating harmonic series.

9.11 B5. Triangles with exactly two equalizer lines

A line in the plane of a triangle T is called an equalizer *if it divides T into two regions having equal area and equal perimeter. Find positive integers $a > b > c$, with a as small as possible, such that there exists a triangle with side lengths a, b, c that has exactly two distinct equalizers.*

Read it out loud

A line that cuts a triangle in two cuts across two of its three sides. So every dividing line is described by three pieces of data: which vertex the two cut sides share, and the two distances from that vertex to the cut points. Call the vertex V, call the two sides through it u and v, call the third side w, and call the distances x and y. That is the whole coordinate system, and you should have it on paper within thirty seconds, because the alternative coordinate system (put the triangle in the plane, write the line as $y = mx + k$) has three unknowns instead of two and no relationship to either constraint.

Now read the two constraints in those coordinates. Area: the corner triangle cut off at V has area $\frac{1}{2}xy\sin V$ and the whole triangle has area $\frac{1}{2}uv\sin V$, so equal area says $xy = \frac{1}{2}uv$. A *product*. Perimeter: the corner region has perimeter $x + y + \ell$ where ℓ is the length of the cut, and the other region has perimeter $(u - x) + (v - y) + w + \ell$, so the cut length ℓ cancels and equal perimeter says $x + y = \frac{1}{2}(u + v + w) = s$, the semiperimeter. A *sum*. Two symmetric conditions on the same pair of numbers, one giving their sum and one giving their product. That is a quadratic, and the entire problem is now about how many roots of that quadratic land in the allowed window.

The fields wired in are plane geometry (area from two sides and the included angle; medians; the incentre), elementary convexity (the function $x + k/x$, and AM to GM as its minimum), and at the very end a small piece of number theory (when is $2ab$ a perfect square). The command term "exactly two" is the guiding light: a convex function meets a horizontal level in zero, one or two points, and "exactly one" happens only at tangency. Any problem that asks for an exact count in the presence of a convex function is asking you to find the tangency case.

One more reading, worth the ten seconds it costs. The conditions are symmetric in x and y and involve only the two sides through V and the semiperimeter. Nothing about the angles survives. That is a strong hint that the answer will be a relation purely between the side lengths, and it is: $8ab = (a + b + c)^2$.

Approaches, ranked worst to best

1. **Coordinate bash.** *Cue:* a line in the plane of a triangle. *Circuit:* place the triangle at $(0, 0)$, $(a, 0)$, (p, q) and write the line as $y = mx + k$. Two unknowns for the line, then integrals or shoelace formulae for the area and a distance computation for the perimeter, then a two variable system in m and k with a case split on which sides are cut. This is the zombie route: it throws away the fact that the natural parameters are the two cut distances, and it reintroduces the angles the problem does not care about.

2. **Numerical search over small integer triples.** *Cue:* "find positive integers $a > b > c$ with a as small as possible". *Circuit:* write a loop, count equalizers numerically, report the first hit. It produces $(9, 8, 7)$ and proves nothing, because "exactly two" has not been characterised and no minimality argument exists. Ranks second last: useful only as a check after the real work.

3. **Quadratic with root location conditions.** *Cue:* $x + y = s$ and $xy = uv/2$ make x, y the roots of $t^2 - st + \frac{uv}{2} = 0$. *Circuit:* Vieta, then discriminant plus root location on an interval. Correct, and only a little worse than the winner. The cost is that root location for a quadratic on a closed interval is a six way case analysis (sign of the leading coefficient, sign at each endpoint, position of the vertex, sign of the discriminant), which you must do three times, once per vertex.

4. **Rotate a line about the incentre.** *Cue:* equal area and equal perimeter together are exactly the two conditions that pin a line to the incentre. *Circuit:* prove that every equalizer passes through the incentre I, then parametrise lines through I by direction. The incentre fact is beautiful and you should know it: with $[T] = rs$, decomposing the corner region into triangles from I gives area $= \frac{r}{2}(x+y) \pm \frac{d}{2}\ell$ where d is the distance from I to the cut, so the two conditions force $d\ell = 0$, that is $d = 0$. It gives existence of an equalizer immediately by a continuity argument as the line rotates. It ranks fourth only because counting them still requires the same analysis as the winning route, so you pay for a lovely lemma you do not strictly need.
5. **Level set of a convex function on a geometric window.** *Cue:* a sum and a product, plus a demand for an exact count. *Circuit:* write $y = \frac{uv}{2x}$, so the condition is $\phi(x) := x + \frac{uv}{2x} = s$ on the window $x \in [u/2, u]$, and use convexity. This is the ideal route, and its punchline is that the two endpoint values of the window are forced by a one line geometric fact rather than by algebra: $\phi(u/2) - s = \frac{1}{2}(v-w)$ and $\phi(u) - s = \frac{1}{2}(u-w)$, because the two endpoints of the window are the two medians that cross the side of length u, and a median is an equalizer exactly when the triangle is isosceles at the vertex it comes from. Three sign comparisons of side lengths then give the count at every vertex with no case analysis at all.

The ideal solution

We show the answer is $\boxed{(a,b,c) = (9,8,7)}$.

Throughout, T is a triangle with vertices A, B, C and side lengths $BC = a$, $CA = b$, $AB = c$, with $a > b > c > 0$; write $p = a+b+c$ and $s = p/2$.

Step 1: every dividing line is a pair of distances from a vertex. Let L be a line dividing T into two regions of positive area. Then L meets the interior of T and does not contain a side, so L meets the boundary ∂T in exactly two points $P \neq Q$. We claim there is a vertex $V \notin \{P, Q\}$ such that P and Q lie on the two closed sides through V. If neither P nor Q is a vertex, they lie in the relative interiors of two distinct sides, and those sides share a vertex V, which is neither P nor Q. If exactly one of them, say P, is a vertex, then Q lies in the relative interior of the side opposite P (otherwise L would be a side), and we may take V to be either endpoint of that opposite side. If both are vertices then L is a side, which does not divide T.

So fix such a V, let u and v be the lengths of the two sides through V and w the length of the side opposite V, and let $x \in (0, u]$ and $y \in (0, v]$ be the distances from V to the two boundary points along those sides.

Step 2: the two conditions are a product and a sum. The corner region is the triangle with vertex V and the two cut points, of area $\frac{1}{2}xy \sin V$, while $[T] = \frac{1}{2}uv \sin V$. Hence

$$\text{equal areas} \iff xy = \tfrac{1}{2}uv.$$

If ℓ denotes the length of the cut segment, the corner region has perimeter $x + y + \ell$ and the other region has perimeter $(u-x) + (v-y) + w + \ell$; equating and cancelling ℓ,

$$\text{equal perimeters} \iff 2(x+y) = u+v+w = p \iff x+y = s.$$

Step 3: eliminate y and read the window. Given x, the area condition forces $y = \frac{uv}{2x}$, and the constraint $y \leq v$ is equivalent to $x \geq u/2$. So the equalizers of T whose two boundary points lie on the sides through V correspond exactly to the solutions of

$$\phi(x) := x + \frac{uv}{2x} = s, \qquad x \in \left[\tfrac{u}{2},\, u\right].$$

Step 4: the endpoints of the window are the two medians. At $x = u/2$ we get $y = v$, so the cut passes through the midpoint of the side of length u and through the far endpoint of the side of

length v: it is a median. Its two regions have perimeters $\frac{u}{2}+v+\ell$ and $\frac{u}{2}+w+\ell$, so it is a perimeter bisector exactly when $v=w$. Consistently,

$$\phi\left(\tfrac{u}{2}\right)-s=\tfrac{u}{2}+v-\tfrac{u+v+w}{2}=\frac{v-w}{2}.$$

At $x=u$ we get $y=v/2$, the other median crossing the side of length u, and

$$\phi(u)-s=u+\tfrac{v}{2}-\tfrac{u+v+w}{2}=\frac{u-w}{2}.$$

So the sign of ϕ minus s at each endpoint is decided by comparing an adjacent side with the opposite side. No computation is needed beyond these two lines.

Step 5: convexity converts the count into sign tests. On $(0,\infty)$ we have $\phi''(x)=\frac{uv}{x^3}>0$, so ϕ is strictly convex, with minimum value $\phi(x_*)=\sqrt{2uv}$ attained at $x_*=\sqrt{uv/2}$ (AM to GM). Consequently $\{x:\phi(x)\le s\}$ is a closed interval, and $\phi(x)=s$ has at most two solutions.

Now take the three vertices in turn, using $a>b>c$.

Vertex A, with $u=c$, $v=b$, $w=a$. By Step 4, $\phi(c/2)-s=\frac{b-a}{2}<0$ and $\phi(c)-s=\frac{c-a}{2}<0$. A convex function on a closed interval attains its maximum at an endpoint, so $\phi<s$ throughout $[c/2,c]$: *no equalizer cuts both AB and AC.*

Vertex B, with $u=c$, $v=a$, $w=b$. Now $\phi(c/2)-s=\frac{a-b}{2}>0$ and $\phi(c)-s=\frac{c-b}{2}<0$. The set $\{\phi\le s\}$ is a closed interval $[\alpha,\beta]$ containing c but not $c/2$, so $\alpha\in(c/2,c)$ and, since $\phi(c)<s$, also $\beta>c$. Hence $\phi=s$ has *exactly one* solution in $[c/2,c]$, and it lies strictly inside: *exactly one equalizer cuts both BA and BC, and it meets the relative interiors of those sides.*

Vertex C, with $u=a$, $v=b$, $w=c$. Here $\phi(a/2)-s=\frac{b-c}{2}>0$ and $\phi(a)-s=\frac{a-c}{2}>0$: both endpoints lie strictly above s. Moreover $x_*=\sqrt{ab/2}$ lies in $(a/2,a)$, because $b<a$ gives $x_*<a$ and $a<b+c<2b$ gives $b>a/2$ and hence $x_*>a/2$. Therefore the number of solutions of $\phi=s$ in $[a/2,a]$ is

$$\begin{cases}2 & \text{if } \sqrt{2ab}<s,\\ 1 & \text{if } \sqrt{2ab}=s,\\ 0 & \text{if } \sqrt{2ab}>s,\end{cases}$$

and in the first two cases the solutions again lie strictly inside $(a/2,a)$.

Step 6: no line is counted twice. The equalizer found at B meets the relative interiors of AB and BC; each equalizer found at C meets the relative interiors of CA and CB. Since a dividing line meets ∂T in exactly two points, two such lines can coincide only if their pairs of boundary points coincide, and one pair contains a point of the relative interior of AB while the other does not. So the counts add.

Hence T has 1, 2 or 3 equalizers, and

$$T\text{ has exactly two equalizers}\iff\sqrt{2ab}=s=\frac{a+b+c}{2}\iff 8ab=(a+b+c)^2.$$

Step 7: the integer search. We need integers $a>b>c\ge 1$ with $b+c>a$ and $8ab=(a+b+c)^2$. Since $8ab$ must be a perfect square and $8ab=4\cdot 2ab$, this says $2ab$ is a perfect square, and then $p=2\sqrt{2ab}$, so

$$c=2\sqrt{2ab}-a-b.$$

The triangle inequality $b+c>a$ becomes $2\sqrt{2ab}>2a$, that is $2b>a$. Conversely, suppose $2ab$ is a perfect square with $\frac{a}{2}<b<a$ and $c:=2\sqrt{2ab}-a-b\ge 1$; then $c<b$ holds automatically, because $c<b$ is equivalent to $2\sqrt{2ab}<a+2b$, that is to $8ab<(a+2b)^2$, that is to $0<(a-2b)^2$, which is true since $a\ne 2b$. So the search is: find the least a for which some integer b with $\frac{a}{2}<b<a$ makes $2ab$ a perfect square and $c\ge 1$.

Run it. For $a = 3, \ldots, 8$ the values of $2ab$ over the admissible b are

$$\begin{aligned} a = 3 &: \ 12 \\ a = 4 &: \ 24 \\ a = 5 &: \ 30,\ 40 \\ a = 6 &: \ 48,\ 60 \\ a = 7 &: \ 56,\ 70,\ 84 \\ a = 8 &: \ 80,\ 96,\ 112 \end{aligned}$$

and none is a perfect square. For $a = 9$ the admissible b are $5, 6, 7, 8$, giving $2ab = 90,\ 108,\ 126,\ 144$, and $144 = 12^2$. So $b = 8$, $p = 2 \cdot 12 = 24$, and $c = 24 - 9 - 8 = 7$.

Check the triple $(9, 8, 7)$ directly: $9 > 8 > 7 > 0$, the triangle inequality holds since $8 + 7 = 15 > 9$, and $8ab = 8 \cdot 9 \cdot 8 = 576 = 24^2 = p^2$. So this triangle has exactly two equalizers, and no smaller a admits one.

The two equalizers, explicitly. For $(a, b, c) = (9, 8, 7)$ we have $s = 12$. At C the tangency gives $x = y = \sqrt{ab/2} = \sqrt{36} = 6$: the cut joins the points at distance 6 from C on CB (length 9) and on CA (length 8), splitting the perimeter as $6 + 6$ against $3 + 7 + 2$ and the area in the ratio $\frac{6 \cdot 6}{9 \cdot 8} = \frac{1}{2}$. At B, $\phi(x) = x + \frac{63}{2x} = 12$ gives $x = 6 \pm \frac{3\sqrt{2}}{2}$, of which only $x = 6 - \frac{3\sqrt{2}}{2} \approx 3.879$ lies in $[3.5, 7]$; the corresponding $y \approx 8.121$ lies in $(4.5, 9)$ as it must.

Layer 1: WHAT

Block 1. A dividing line crosses two sides; parametrise it by the two distances x, y from the shared vertex.

Block 2. Equal area gives the product $xy = uv/2$; equal perimeter gives the sum $x + y = s$. The cut length ℓ cancels on its own.

Block 3. Eliminate y: the condition is $\phi(x) = x + \frac{uv}{2x} = s$ on the window $x \in [u/2, u]$, where the window comes from $x \le u$ and $y \le v$.

Block 4. Identify the window endpoints geometrically: they are the two medians crossing the side of length u. Hence $\phi(u/2) - s = \frac{v - w}{2}$ and $\phi(u) - s = \frac{u - w}{2}$.

Block 5. ϕ is strictly convex. Three sign patterns, one per vertex: below and below at A (zero solutions), above and below at B (exactly one), above and above at C (zero, one or two according to the minimum).

Block 6. "Exactly two" therefore means tangency at C: $\sqrt{2ab} = s$, that is $8ab = (a + b + c)^2$.

Block 7. Reduce to "$2ab$ is a perfect square with $a/2 < b < a$" and search $a = 3, 4, 5, \ldots$ until it succeeds, at $a = 9$.

Juxtaposition. The nominal route agrees with you through Block 2 and then reaches for Vieta: x, y are the roots of $t^2 - st + \frac{uv}{2} = 0$, so compute the discriminant $s^2 - 2uv$, then impose $x \le u$, $y \le v$ by root location conditions. That works, but at each vertex you now need the sign of the quadratic at both endpoints, the position of its vertex relative to the interval, and the sign of the discriminant, and you must repeat all of it three times. Worse, the endpoint conditions come out as opaque quadratic expressions rather than as $\frac{v - w}{2}$ and $\frac{u - w}{2}$, so you lose the geometric reading that makes the three cases obvious.

Bifurcation point. The line where the routes split is the one immediately after $x + y = s$ and $xy = uv/2$ are both on the page. The zombie writes the quadratic in t. You write $y = \frac{uv}{2x}$ and treat the problem as counting intersections of a convex curve with a horizontal line, because the question asked "how many", and counting is what convexity is for.

Layer 2: HOW

Block 1. Cue. A line divides a triangle. The triangle has three sides; the line meets exactly two of them. **Why natural.** The definition of a convex region does the work: a line meeting the interior of a

convex set meets its boundary in exactly two points, and the boundary here is three segments, so the two points lie on two sides which share a vertex. Once you know a vertex is distinguished, the two distances from it are the only natural coordinates: the corner region cut off is a triangle with vertex V and legs x, y along the sides. **Link to the next block.** With V, x, y in place, both constraints are about that corner triangle, so write them.

Block 2. **Cue.** "Equal area" next to "equal perimeter". Two constraints on two unknowns; expect a finite answer set. **Why natural.** Area from two sides and the included angle is the only area formula that does not need the third side, and the corner triangle shares its angle with T, so the sin V cancels and the area condition is pure multiplication. For perimeter, notice before computing that the cut segment ℓ belongs to both regions, so it must cancel; that is why the perimeter condition is pure addition, and it is also why the answer will be independent of the angles. **Link to the next block.** A sum and a product of the same two numbers is one of the strongest structures in elementary mathematics. The only question is which of its two readings, quadratic or convex curve, you take.

Block 3. **Cue.** The question asks for a *count*, not for the equalizers themselves. **Why natural.** When you want the number of solutions, put the problem in a form with one unknown and one level: $\phi(x) = s$. Then the count is the number of times a curve crosses a horizontal line, and there is a standard tool for that (monotonicity or convexity) which needs no case analysis. Deriving the window is equally forced: the two constraints $x \le u$ and $y \le v$ are the statement that the cut points really lie on the sides, and under $y = \frac{uv}{2x}$ the second is $x \ge u/2$. **Link to the next block.** The window has two endpoints, so before invoking convexity you need the values of ϕ there.

Block 4. **Cue.** $x = u/2$ says the cut passes through the midpoint of one side; $y = v$ says it passes through a vertex. **Why natural.** Translate before you compute. A cut through a midpoint and the opposite vertex is a median, and for a median the perimeter condition is trivial: the two regions each contain half of the bisected side plus the cut, so they are equal exactly when the other two sides they contain are equal. Hence the sign of $\phi(u/2) - s$ must be the sign of $v - w$, and the algebra confirms it in one line. Computing first and interpreting later would give you the same two numbers with none of the meaning, and meaning is what makes Block 5 free. **Link to the next block.** Now every endpoint sign is a comparison of two side lengths, and the triangle's ordering $a > b > c$ decides all six of them at once.

Block 5. **Cue.** $\phi(x) = x + \frac{k}{x}$ with $k > 0$. That is the standard convex function. **Why natural.** $\phi'' > 0$, so ϕ is strictly convex and its sublevel sets are intervals; a strictly convex function crosses any horizontal level at most twice, and the AM to GM bound $\phi \ge \sqrt{2uv}$ with equality at $x = \sqrt{uv/2}$ is the exact statement of where the minimum sits. Given the endpoint signs, the count is then immediate and identical in structure at all three vertices. The one detail to check is whether the minimiser lies inside the window, and at C it does because $a < b + c < 2b$. **Link to the next block.** At two of the three vertices the count is forced with no further information, so "exactly two" can only be a statement about the third.

Block 6. **Cue.** The count is $1 + (\text{count at } C)$, and $1 + 1 = 2$. **Why natural.** The vertex opposite the largest side contributes nothing and the vertex opposite the middle side contributes exactly one, no matter what the triangle is; so the entire content of "exactly two" is that the vertex opposite the smallest side contributes exactly one, and for a strictly convex function with both endpoints above the level that means tangency. Equality in AM to GM then gives $\sqrt{2ab} = s$, which squares to $8ab = p^2$. **Link to the next block.** A single Diophantine equation in three positive integers, plus the triangle inequality, is now the whole remaining problem.

Block 7. Cue. "Positive integers, a as small as possible." **Why natural.** Minimality demands an exhaustive check, so first make the condition cheap to test: $8ab = p^2$ forces $2ab$ to be a perfect square and determines c from a and b, so for each a there are fewer than $a/2$ candidate values of b, namely those in $(a/2, a)$, and each is a single perfect square test. Establishing that $c < b$ is automatic (it reduces to $(a-2b)^2 > 0$) is what allows you to drop c from the search entirely. **Link to the next block.** Six values of a to eliminate and one to exhibit, and the write up is a finite table.

Layer 3: WHY

Three truths are doing the work.

The first is that both constraints are *symmetric* in the two cut distances, and that they pick out the two elementary symmetric functions: perimeter gives $x + y$, area gives xy. This is not a coincidence of this problem. Perimeter is a first order (length) quantity and area is a second order quantity, so any pair of conditions of the form "bisect a first order quantity" and "bisect a second order quantity" will give you a sum and a product. Once you see a sum and a product, you are on a hyperbola meeting a line, and the intersection count of a line with a convex branch is 0, 1 or 2, with 1 exactly at tangency. Everything in this problem, including the final equation $8ab = p^2$, is the equality case of AM to GM in disguise.

The second is that the window endpoints are medians, so the endpoint comparisons are side comparisons. This is the discernment mechanism worth extracting. Whenever you reduce a geometric family to a parameter running over an interval, ask what the two extreme parameter values *are* geometrically before you evaluate anything. Degenerate configurations are always simpler than generic ones, so their values are always cheaper to obtain by interpretation than by algebra, and the interpretation carries meaning the algebra does not. Here it turns six algebraic evaluations into six comparisons among a, b, c, which the ordering $a > b > c$ settles instantly.

The third is a structural fact worth remembering in its own right: *every triangle has at least one and at most three equalizers*. For a scalene triangle with $a > b > c$, exactly one cuts the two sides adjacent to the middle side, none cuts the two sides adjacent to the longest side, and zero, one or two cut the two sides adjacent to the shortest side according as $8ab$ exceeds, equals or falls short of p^2. The equilateral triangle sits at the other extreme: there every endpoint value equals s, since $u = v = w$, so at each vertex the two roots are exactly the two medians, and the equalizers are precisely the three medians. A very flat triangle, say $(100, 51, 50)$ with $8ab = 40800 > 40401 = p^2$, has exactly one. The problem is asking you to find the boundary between those regimes, in integers.

To train this: whenever a problem asks for an exact count of solutions and there is a convex or monotone function anywhere in sight, immediately look for the tangency or endpoint case, because "exactly n" problems are always boundary problems. And whenever a problem asks for "the smallest integers such that", separate the structural characterisation from the search completely: characterise first, search second, and never search a condition you have not reduced.

How the examiners nudged. They defined a new word, *equalizer*, which is the standard signal that the two halves of the definition are meant to be combined into a single algebraic relation rather than handled separately. They asked for "exactly two distinct", which forces the tangency reading. And they asked for integers with a minimal, which guarantees the structural condition must be clean enough to search by hand; had the characterisation been messy, the question could not have been posed this way. Reading the shape of the question tells you the shape of the answer before you start.

Revolving concepts

Equalizer, splitter, cleaver, median. A line bisecting the area is an area bisector; one bisecting the perimeter is a perimeter bisector; a *splitter* is a perimeter bisector through a vertex, a *cleaver* is a perimeter bisector through the midpoint of a side, and an equalizer is a line that is both an area

and a perimeter bisector. A median is always an area bisector, and is a perimeter bisector exactly when the triangle is isosceles at the vertex it issues from. See Book 1, field: Geometry, topic: triangle cevians.

Every equalizer passes through the incentre. With I the incentre, r the inradius and s the semiperimeter, $[T] = rs$. If a line cuts the sides through V at distances x, y and d is the distance from I to that line, decomposing the corner region into triangles with apex I gives its area as $\frac{r}{2}(x+y) \pm \frac{d}{2}\ell$. Imposing $x + y = s$ and area $= \frac{rs}{2}$ leaves $d\ell = 0$, so $d = 0$. Conversely a line through I bisects the area if and only if it bisects the perimeter. See Book 1, field: Geometry, topic: incentre and $[T] = rs$.

Convexity of $x + k/x$. For $k > 0$ the function is strictly convex on $(0, \infty)$, with $\phi'' = 2k/x^3$ for $\phi = x + k/x$, minimum $2\sqrt{k}$ at $x = \sqrt{k}$; this is AM to GM for two positive numbers, with the equality case being the tangency case. A strictly convex function meets any horizontal line in at most two points, and its sublevel sets are intervals: that is the counting lemma used three times above. See Book 1, field: Inequalities, topic: AM to GM and convexity.

Symmetric functions and Vieta. If $x + y = \sigma$ and $xy = \pi$ then x, y are the roots of $t^2 - \sigma t + \pi = 0$, real precisely when $\sigma^2 \geq 4\pi$. Here $\sigma^2 \geq 4\pi$ reads $s^2 \geq 2uv$, which is the same tangency condition seen through the discriminant instead of through convexity: $s = \sqrt{2uv}$ is where the discriminant vanishes and the two cut distances coincide. Recognising that two different tools (discriminant, AM to GM) give the same boundary is the sign that you have found the real structure. See Book 1, field: Polynomials, topic: Vieta and the discriminant.

A line meeting a convex region. A line that meets the interior of a compact convex set with nonempty interior meets its boundary in exactly two points, unless it contains a boundary segment. This is what licenses the exhaustive case analysis in Step 1 and the "no double counting" argument in Step 6. See Book 1, field: Geometry, topic: convex sets.

Perfect square conditions. $8ab$ is a perfect square if and only if $2ab$ is, since $8ab = 4 \cdot 2ab$ and 4 is a square. In general, mab is a square exactly when the squarefree part of mab is 1, which for a bounded search is faster to test than to characterise. See Book 1, field: Number theory, topic: squarefree parts.

Recursion note. There is no recursion in this problem, and it is worth saying why rather than leaving the box empty: the family of dividing lines is a continuum parametrised by one real number per vertex, not a discrete family built from earlier members. The tool that replaces induction for a continuum family is the intermediate value theorem together with a convexity or monotonicity statement, which is exactly what Step 5 uses. When you meet a one parameter family and want to count members with a property, the standard substitute for induction is: express the property as $\phi(x) =$ constant, establish convexity or monotonicity of ϕ, and evaluate at the endpoints of the parameter window.

Circuit Bank

- **WHEN** a geometric condition gives you the sum of two lengths and another gives you their product **DO** eliminate one of them and write the condition as a level set $\phi(x) = x + \frac{k}{x} = \sigma$ on an explicit window **BECAUSE** a sum and a product is a hyperbola meeting a line, and convexity turns "how many solutions" into three sign tests instead of a six way root location analysis

- **WHEN** your parameter window has endpoints **DO** identify the endpoint configurations geometrically before evaluating anything **BECAUSE** degenerate configurations (here, medians) have one line proofs, so the endpoint values arrive with meaning attached and the case analysis becomes free

- **WHEN** a question asks for "exactly one" or "exactly two" of something governed by a convex function **DO** look immediately for the tangency case, that is the equality case of the relevant

AM to GM **BECAUSE** an exact count is a boundary condition, and for a convex function the only boundary between two solutions and none is the tangent level

- **WHEN** a question ends with "find the smallest positive integers such that" **DO** reduce to a single clean Diophantine condition first, prove which of the side conditions are automatic, and only then run a finite search you can write out **BECAUSE** minimality claims require exhaustion, and exhaustion is only writable once each candidate costs a single test
- **WHEN** a competition defines a new word out of two familiar conditions **DO** expect the two conditions to combine into one algebraic relation, and look for the object they jointly pin down **BECAUSE** setters coin a term when the conjunction is more rigid than either half, here forcing every equalizer through the incentre

Backtesting

1. First useful cue: a dividing line crosses exactly two sides, so it is described by two distances from the vertex they share; and the cut length cancels in the perimeter condition, so no angle can appear in the answer.
2. Method the expression suggested: equal area gives the product $xy = uv/2$, equal perimeter gives the sum $x + y = s$; eliminate y and count solutions of $x + \frac{uv}{2x} = s$ on $[u/2, u]$ by convexity.
3. Where you would hesitate, and the thought to reinforce: at the window $x \in [u/2, u]$, which looks arbitrary. Reinforce: $x \leq u$ says the cut point is on the side; $y \leq v$ says the other cut point is on its side, and under $y = uv/(2x)$ that is $x \geq u/2$. The endpoints are the two medians, and once you know that, the endpoint values $\frac{v-w}{2}$ and $\frac{u-w}{2}$ are predictable before you compute them.
4. The trap the question sets: two of them. First, forgetting the vertex opposite the largest side, or double counting a line at two vertices, so that the count comes out wrong. Second, and more expensive, jumping to the integer search before proving the characterisation $8ab = p^2$, which makes the minimality claim unprovable.
5. What makes you recognise it faster next time: the phrase "exactly two" beside a convex function, and the pairing of a first order and a second order bisection condition. Also worth storing as a fact: every triangle has one, two or three equalizers, exactly one of which cuts the two sides adjacent to the middle length side.
6. The reusable decision rule: turn "count the members of a one parameter geometric family with a property" into "count the solutions of $\phi =$ constant on a closed window", get the endpoints by geometric interpretation, and get the interior behaviour from convexity.

Mirror drills

1. Show that every equalizer of a triangle passes through its incentre. *Answer:* with $[T] = rs$, split the corner region into triangles with apex I: its area is $\frac{r}{2}(x + y) \pm \frac{d}{2}\ell$ where $d = \text{dist}(I, L)$. Equal perimeter gives $x + y = s$ and equal area gives area $= \frac{rs}{2}$, so $d\ell = 0$ and $d = 0$.
2. Prove that every triangle has at least one equalizer and at most three. *Answer:* apply Step 5 at each vertex. At the vertex opposite the longest side both endpoint values lie below s, giving none; at the vertex opposite the middle side the endpoint values straddle s, giving exactly one; at the vertex opposite the shortest side both lie above s, giving at most two. (For an isosceles or equilateral triangle the same argument runs with weak inequalities.)
3. For which triangles is a median an equalizer? *Answer:* the median from a vertex Q bisects the area automatically, and it bisects the perimeter exactly when the two sides through Q are

equal, so precisely when the triangle is isosceles with apex Q. This is the geometric content of the endpoint identities $\phi(u/2) - s = \frac{v-w}{2}$ and $\phi(u) - s = \frac{u-w}{2}$.

9.12 B6. Distinct tuples under a weighted congruence

Find the number of ordered 64*-tuples* $(x_0, x_1, \ldots, x_{63})$ *such that* $x_0, x_1, \ldots, x_{63}$ *are distinct elements of* $\{1, 2, \ldots, 2017\}$ *and*

$$x_0 + x_1 + 2x_2 + 3x_3 + \cdots + 63x_{63}$$

is divisible by 2017*.*

Read it out loud

This is a counting problem with two constraints of completely different natures. One is algebraic and soft: a single linear congruence modulo 2017. The other is combinatorial and hard: the 64 entries must be pairwise distinct. Soft constraints are easy to count against, because a nonzero linear condition modulo a prime cuts a count down by a factor of exactly p. Hard constraints are what makes counting problems difficult, because "all distinct" is a conjunction of $\binom{64}{2}$ negated conditions and is invisible to Fourier analysis. So the entire question is: how do you get the distinctness constraint and the congruence to cooperate rather than fight?

Before answering that, do the arithmetic the setters planted. 2017 is prime, so $\{1, 2, \ldots, 2017\}$ is a complete residue system modulo 2017 (note $2017 \equiv 0$), and you may as well count tuples of distinct elements of $\mathbb{F}_{2017}$. Now add up the coefficients. Writing $c_0 = c_1 = 1$ and $c_i = i$ for $2 \le i \le 63$,

$$\sum_{i=0}^{63} c_i \;=\; 1 + (1 + 2 + \cdots + 63) \;=\; 1 + \frac{63 \cdot 64}{2} \;=\; 1 + 2016 \;=\; 2017.$$

That is the whole problem, and it is why the coefficient of x_0 and the coefficient of x_1 are both 1 instead of the pattern continuing to $0 \cdot x_0$: the setters needed the total to land exactly on the modulus. Sixty seconds spent adding the coefficients is the highest return per unit of ink on the entire paper.

What does it buy? The linear form $\Lambda(x) = \sum_i c_i x_i$ satisfies $\Lambda(x_0 + t, \ldots, x_{63} + t) = \Lambda(x) + t\sum_i c_i = \Lambda(x)$ for every $t \in \mathbb{F}_{2017}$. So Λ is invariant under simultaneous translation of every coordinate. And distinctness is invariant under simultaneous translation too. Two structures, one shared symmetry group: quotient by it. That is the reaction circuit, and everything after it is bookkeeping.

The fields wired in are finite fields (only lightly: what you need is that $\mathbb{F}_p$ is a field so that nonzero elements are invertible), group actions and orbit counting, and the solution of a first order linear recursion with a binomial inhomogeneity. Knowledge gaps are named honestly in Layer 3; this is a B6 and it is not approachable without them.

Approaches, ranked worst to best

1. **Roots of unity filter, applied directly.** *Cue:* a divisibility condition modulo a prime. *Circuit:* write the indicator of $p \mid \Lambda$ as $\frac{1}{p}\sum_{t \in \mathbb{F}_p} \omega^{t\Lambda(x)}$ and sum over the objects. The count becomes $\frac{1}{p}\sum_t \sum_{x \text{ distinct}} \omega^{t\Lambda(x)}$, and the inner sum over *distinct* tuples is a permanent style object with no product formula. The filter is the right instinct for a congruence and the wrong tool here, because distinctness destroys the factorisation that makes the filter useful. It stalls immediately.

2. **Inclusion and exclusion over the pair conditions** $x_i = x_j$**.** *Cue:* "distinct" is the negation of $\binom{64}{2}$ equalities. *Circuit:* subtract the bad events, add back the intersections. The events $\{x_i = x_j\}$ do not intersect independently: their intersections are indexed by set partitions, not by subsets of pairs, so a naive alternating sum over pairs double counts catastrophically. Ranks second last because it is the first thing most candidates write and it cannot be repaired without the next approach.

3. **Inclusion and exclusion over the partition lattice.** *Cue:* intersections of equality events are indexed by partitions of $\{0,\dots,63\}$. *Circuit:* Mobius inversion on the lattice of set partitions. This is correct and complete, and it is the first official solution. For a partition π with $|\pi|$ blocks, the number of tuples constant on blocks and satisfying the congruence is $p^{|\pi|-1}$, unless every block has coefficient sum divisible by p, which here happens only for the single block partition because $0 < \sum_{i\in S} c_i < p$ for every proper nonempty S. You then need the Mobius value of the full partition lattice, $\mu(\hat{0},\hat{1}) = (-1)^{n-1}(n-1)!$, extracted by comparing degree one coefficients in the falling factorial identity. It ranks third because it needs a piece of algebraic combinatorics most candidates do not have installed, and because in the arena the sign bookkeeping is where you lose the paper.

4. **Fix $x_0 = 0$ by translation, then recurse on the number of variables.** *Cue:* the coefficients sum to the modulus, so the form is translation invariant. *Circuit:* quotient by the shared symmetry, then peel off the special value 0. The ideal route. The translation action of $\mathbb{F}_p$ on the set of distinct tuples is free, and Λ is constant on orbits, so the answer is p times the count with x_0 normalised to 0. What remains is a self similar question in the number of variables, which recurses in one line, and the recursion is solved by Pascal's rule. There is no inclusion and exclusion anywhere, no signs to lose, and every step is forced by the previous one.

The ideal solution

Throughout, $p = 2017$, which is prime. Since $2017 \equiv 0 \pmod{2017}$, reduction modulo p is a bijection from $\{1,2,\dots,2017\}$ onto $\mathbb{F}_p$, so we count ordered 64-tuples of pairwise distinct elements of $\mathbb{F}_p$ satisfying the congruence.

Lemma 9.12.1. *Let p be prime and let $a_1,\dots,a_k$ be positive integers with $a_1+\cdots+a_k < p$. Then the number of solutions of*

$$a_1x_1 + \cdots + a_kx_k = 0 \quad \text{in } \mathbb{F}_p$$

with $x_1,\dots,x_k$ pairwise distinct and all nonzero depends only on k and p. Calling it $f(k)$, we have $f(1) = 0$ and

$$f(k) \;=\; \frac{(p-1)!}{(p-k)!} \;-\; k\,f(k-1) \qquad (k \ge 2).$$

Proof. Induct on k. For $k = 1$ we have $0 < a_1 < p$, so a_1 is invertible and $a_1x_1 = 0$ forces $x_1 = 0$, which is excluded: $f(1) = 0$.

Let $k \ge 2$ and assume the statement for $k-1$. Let S be the set of k-tuples of pairwise distinct elements of $\mathbb{F}_p$, with zero allowed; then $|S| = \frac{p!}{(p-k)!}$, which is nonzero since $k \le \sum a_i < p$. The additive group $\mathbb{F}_p$ acts on S by simultaneous translation $x \mapsto x + t\mathbf{1}$, and this action is free (if $t \neq 0$ then every coordinate moves), so S splits into $\frac{1}{p}\cdot\frac{p!}{(p-k)!} = \frac{(p-1)!}{(p-k)!}$ orbits of size p.

Write $\Lambda(x) = \sum_i a_ix_i$ and $\sigma = \sum_i a_i$. Then $\Lambda(x+t\mathbf{1}) = \Lambda(x) + t\sigma$, and σ is invertible because $0 < \sigma < p$. Hence along each orbit Λ takes every value of $\mathbb{F}_p$ exactly once, so *exactly one* member of each orbit is a solution of $\Lambda = 0$. The number of solutions in S is therefore exactly $\frac{(p-1)!}{(p-k)!}$.

Split those solutions according to whether some coordinate is 0. By distinctness at most one coordinate can be 0. If none is, the solution is counted by $f(k)$. If $x_i = 0$ for exactly one index i, delete that coordinate: the remaining x_j are pairwise distinct and nonzero and satisfy $\sum_{j\neq i} a_jx_j = 0$, where the coefficients $(a_j)_{j\neq i}$ are again positive integers with sum less than p, so by the induction hypothesis there are $f(k-1)$ such solutions, for each of the k choices of i. Adding,

$$\frac{(p-1)!}{(p-k)!} \;=\; f(k) + kf(k-1),$$

which is the claimed recursion; in particular $f(k)$ depends only on k and p. □

Lemma 9.12.2. *With f as above, $f(k) = \dfrac{k!}{p}\left(\binom{p-1}{k} + (-1)^k(p-1)\right)$ for $1 \le k < p$.*

Proof. Put $g(k) = \dfrac{p\,f(k)}{k!}$. Dividing the recursion of Lemma 1 by $k!/p$ gives

$$g(k) \;=\; \frac{p}{k!}\cdot\frac{(p-1)!}{(p-k)!} \;-\; \frac{pf(k-1)}{(k-1)!} \;=\; \binom{p}{k} - g(k-1), \qquad g(1) = 0.$$

Pascal's rule $\binom{p-1}{k} + \binom{p-1}{k-1} = \binom{p}{k}$ says that $G(k) = \binom{p-1}{k}$ is a particular solution of the same relation. Hence $h := g - G$ satisfies the homogeneous relation $h(k) = -h(k-1)$, so $h(k) = (-1)^{k-1}h(1) = (-1)^{k-1}\big(0 - (p-1)\big) = (-1)^k(p-1)$. Therefore $g(k) = \binom{p-1}{k} + (-1)^k(p-1)$, and $f(k) = \frac{k!}{p}g(k)$. □

Applying it. Set $c_0 = c_1 = 1$ and $c_i = i$ for $2 \le i \le 63$, so that the given expression is $\Lambda(x) = \sum_{i=0}^{63} c_i x_i$ and

$$\sum_{i=0}^{63} c_i = 1 + \frac{63\cdot 64}{2} = 2017 = p \equiv 0.$$

Let D be the set of 64-tuples of pairwise distinct elements of $\mathbb{F}_p$ and let $M = \#\{x \in D : \Lambda(x) = 0\}$ be the required count. The group $\mathbb{F}_p$ acts on D by simultaneous translation; the action is free, so every orbit has size p and contains exactly one tuple with $x_0 = 0$. Since $\sum_i c_i \equiv 0$, the form Λ is constant on orbits, so the solutions of $\Lambda = 0$ in D are a union of whole orbits and

$$M \;=\; p \cdot \#\big\{x \in D : x_0 = 0,\ \Lambda(x) = 0\big\}.$$

If $x_0 = 0$ then $\Lambda(x) = x_1 + 2x_2 + \cdots + 63x_{63}$ and $x_1, \ldots, x_{63}$ are pairwise distinct and nonzero. The coefficients here are $1, 2, \ldots, 63$, positive integers with sum $2016 < 2017 = p$, so Lemma 1 applies with $k = 63$ and

$$M \;=\; p\,f(63) \;=\; 63!\left(\binom{2016}{63} + (-1)^{63}\cdot 2016\right) \;=\; 63!\binom{2016}{63} - 2016\cdot 63!.$$

Since $63!\binom{2016}{63} = \frac{2016!}{1953!}$, the answer is

$$\boxed{\frac{2016!}{1953!} \;-\; 2016\cdot 63!}.$$

Two checks before you put the pen down. First, the shape: $\frac{2016!}{1953!} = \frac{1}{2017}\cdot\frac{2017!}{1953!}$ is exactly one 2017th of the total number of 64-tuples of distinct residues, so the answer is the equidistribution prediction minus a correction of $2016\cdot 63!$, which is positive and astronomically smaller. A count that came out larger than the equidistribution prediction, or negative, would be wrong on sight. Second, run the whole argument at a miniature prime. Take $p = 7$, where $1 + 1 + 2 + 3 = 7$, so the analogous question asks for ordered 4-tuples of distinct elements of $\{1, \ldots, 7\}$ with $x_0 + x_1 + 2x_2 + 3x_3 \equiv 0 \pmod 7$; the formula predicts $3!\big(\binom{6}{3} - 6\big) = 6(20 - 6) = 84$, and enumerating the $7\cdot 6\cdot 5\cdot 4 = 840$ tuples confirms it. Building the miniature is five minutes and it catches every sign error.

Layer 1: WHAT

Block 1. 2017 is prime and $\{1, \ldots, 2017\}$ is a complete residue system, so work in $\mathbb{F}_p$ and forget the interval.

Block 2. Add the coefficients: $1 + 1 + 2 + \cdots + 63 = 2017$. Therefore Λ is invariant under simultaneous translation of all coordinates.

Block 3. Distinctness is also translation invariant. Quotient: normalise $x_0 = 0$ and multiply the count by p.

Block 4. The normalised question is "distinct nonzero solutions of a positive integer linear form with coefficient sum less than p". That shape is stable under deleting a variable, so it recurses.

Block 5. Count with zeros allowed, exactly, by the same orbit argument: $\frac{(p-1)!}{(p-k)!}$. Then peel off the solutions using 0 to get $f(k) + kf(k-1) = \frac{(p-1)!}{(p-k)!}$.

Block 6. Normalise the recursion to $g(k) + g(k-1) = \binom{p}{k}$ and read Pascal's rule as a particular solution; the homogeneous part is $(-1)^k$.

Block 7. Substitute $p = 2017$, $k = 63$, and convert $63!\binom{2016}{63}$ to $\frac{2016!}{1953!}$.

Juxtaposition. The nominal route treats distinctness as the enemy: it writes the count as (all tuples satisfying the congruence) minus (those with a repeat), and then spends the rest of the attempt trying to organise the repeats. That is a real solution, but it requires the partition lattice and its Mobius function, and it produces the correction term $-2016 \cdot 63!$ as the value $\mu_{\hat{1}} = (-1)^{63}63!$ of an object most candidates cannot even name.

Bifurcation point. The exact line is the one where you have just written $\sum c_i = 2017$. The zombie writes it down as a curiosity and carries on with inclusion and exclusion. You stop, ask what a coefficient sum divisible by p *means* for the linear form, and answer: it means the all ones vector is in the kernel, that is, Λ descends to the quotient by the diagonal. Everything after that is forced.

Layer 2: HOW

Block 1. **Cue.** A specific four digit modulus, and a ground set $\{1, \ldots, 2017\}$ of exactly that many elements. **Why natural.** 2017 is prime (check: it is not divisible by any prime up to 43), and the ground set has exactly p elements with $2017 \equiv 0$, so it is a complete residue system. A setter who wanted you to work in $\mathbb{Z}$ would have given you $\{1, \ldots, 2000\}$; giving you exactly p consecutive integers is an instruction to move to $\mathbb{F}_p$ and stop thinking about size. **Link to the next block.** In $\mathbb{F}_p$ the natural things to look for are symmetries, because a field has plenty and an interval of integers has none.

Block 2. **Cue.** The coefficients are $1, 1, 2, 3, \ldots, 63$, which is a triangular number plus one, and the modulus is 2017. **Why natural.** $1 + 2 + \cdots + 63 = 2016$ is a number you know on sight, and $2016 + 1 = 2017$. The doubled coefficient on x_0 and x_1 is unnatural unless it is there to make the total exact, so the setter has told you what to compute. And the meaning of $\sum c_i \equiv 0$ is not arithmetic but structural: the vector c is orthogonal to $\mathbf{1}$, so the linear functional Λ kills the diagonal line $\{t\mathbf{1}\}$ and therefore factors through the quotient $\mathbb{F}_p^{64}/\mathbb{F}_p\mathbf{1}$. **Link to the next block.** A symmetry of the algebraic constraint is only useful if the combinatorial constraint shares it, so check that next.

Block 3. **Cue.** "Distinct" is a statement about differences $x_i - x_j$, and translation does not change differences. **Why natural.** This is the crux and it is a definition level observation, not an insight. Distinctness is invariant under any map that preserves differences; translation is exactly such a map. So the diagonal $\mathbb{F}_p$ acts on the solution set, freely (a nonzero translation moves every coordinate) and with Λ constant on orbits, which means the solution set is a union of full orbits of size p. Counting orbits is the same as counting normalised representatives, and the cheapest normalisation is $x_0 = 0$. **Link to the next block.** Setting $x_0 = 0$ removes the coefficient c_0 from the form and forces the remaining variables to be nonzero, which is a new and simpler shape.

Block 4. **Cue.** After normalisation the coefficients are $1, 2, \ldots, 63$ with sum 2016, one less than the modulus. **Why natural.** The condition $0 < \sum a_i < p$ is exactly what the orbit argument needs, and it is inherited when you delete any variable, because all the a_i are positive. That inheritance is the signal to set up a recursion in the number of variables, and it is also the signal to state the lemma for *arbitrary* positive coefficients rather than for $1, 2, \ldots, k$: the induction step deletes a variable and

must appeal to the hypothesis for a different coefficient list, so the hypothesis has to be general enough to cover it. Strengthening the statement is what makes the induction possible. **Link to the next block.** To recurse you need the count with zeros allowed, which is the case the orbit argument handles exactly.

Block 5. **Cue.** The obstruction to recursion is the single value 0, which is distinguished only because it kills its coefficient. **Why natural.** If you allow zeros, the orbit argument gives an exact count with no error term: the translation action is free on tuples of distinct elements, and Λ is injective along each orbit precisely because $\sigma = \sum a_i \not\equiv 0$. So the count is (number of orbits) $= \frac{(p-1)!}{(p-k)!}$, independent of the coefficients. Then distinctness does you a favour: at most one coordinate can equal 0, so the correction is a clean $kf(k-1)$ with no overlaps to subtract. **Link to the next block.** You now have a first order recursion with a factorial style inhomogeneity, so normalise it.

Block 6. **Cue.** $f(k) = \frac{(p-1)!}{(p-k)!} - kf(k-1)$: the multiplier is $-k$, which is the derivative of a factorial. **Why natural.** Whenever the multiplier in $f(k) = \lambda_k f(k-1) + R(k)$ is $-k$, dividing by $k!$ turns it into constant multiplier -1; that is the summation factor method, and $k!$ is the summation factor here. Multiplying additionally by p is cosmetic, chosen so that the inhomogeneity becomes exactly $\binom{p}{k}$. At that point Pascal's rule hands you a particular solution for free, because Pascal's rule is literally the identity "a binomial coefficient is the sum of two consecutive binomial coefficients from the row above". The homogeneous solution of $h(k) = -h(k-1)$ is $C(-1)^k$, pinned by $g(1) = 0$. **Link to the next block.** Substitute the numbers.

Block 7. **Cue.** $63!\binom{2016}{63}$. **Why natural.** $\binom{n}{k}k! = \frac{n!}{(n-k)!}$ is the count of ordered selections, so the leading term is $\frac{2016!}{1953!}$, and writing it that way makes the equidistribution reading visible: it is $\frac{1}{2017}$ of the number of ordered 64-tuples of distinct residues. Presenting the answer as (expected count) minus (bias) is not decoration, it is the sanity check. **Link to the next block.** Verify on a miniature prime, then stop.

Layer 3: WHY

The headline truth is this. The congruence and the distinctness condition share a symmetry group, and when two constraints share a symmetry you should quotient by it rather than count against each one separately. Here the group is the diagonal copy of $\mathbb{F}_p$ acting by simultaneous translation. It preserves distinctness because distinctness only sees differences, and it preserves Λ because $\sum c_i \equiv 0$, that is, because $c \perp \mathbf{1}$. Quotienting costs nothing (the action is free, so you just divide by p) and it converts a symmetric problem into a rigid one in which 0 is now a special value, which is exactly the kind of asymmetry a recursion can eat.

The second truth explains the shape of the answer. Over all $\frac{2017!}{1953!}$ ordered 64-tuples of distinct residues, the value $\Lambda(x)$ is very nearly equidistributed among the 2017 residues: the naive prediction is $\frac{2016!}{1953!}$ per residue and the truth is that prediction minus $2016 \cdot 63!$, a relative error of order $63!$ / $\binom{2016}{63}$, which is minuscule. The bias is not noise: it is exactly $(p-1)$ times the number of orderings of 63 objects, and it is the same $(-1)^k(p-1)$ that fell out of the homogeneous part of the recursion. Through the other route it appears as the Mobius number of the partition lattice, $\mu(\hat{0}, \hat{1}) = (-1)^{n-1}(n-1)!$ with $n = 64$, that is $-63!$. Two derivations, one number: the alternating sign of inclusion and exclusion and the alternating homogeneous solution $(-1)^k$ of the recursion are the same phenomenon wearing different clothes.

The third truth is about why only the one block partition matters in the inclusion and exclusion route, and it is worth internalising even though the ideal route avoids it. For a partition π of the index set, the tuples constant on blocks satisfy a linear congruence whose coefficients are the block sums $\sum_{i \in S} c_i$; the congruence is degenerate exactly when every block sum vanishes modulo p. Since

all c_i are positive and their total is exactly p, every proper nonempty subset has block sum strictly between 0 and p, hence nonzero. So only the one block partition is degenerate. The condition $\sum c_i = p$ with all $c_i > 0$ is therefore doing double duty: it creates the translation symmetry and it simultaneously guarantees that no proper subsum is degenerate. That is a designed problem, and recognising design is part of the discernment.

Knowledge gaps, stated bluntly. You cannot approach this problem without the following installed, and none of it is in Further Mathematics.

(i) *Finite fields.* $\mathbb{F}_p = \mathbb{Z}/p\mathbb{Z}$ for p prime is a field: every nonzero element is invertible. You use this twice, and only twice: $\sigma = \sum a_i$ is invertible, and each individual a_i with $0 < a_i < p$ is nonzero. Without primality you would need $\gcd(\sigma, p) = 1$ instead; the problem does not need any deeper property of $\mathbb{F}_p$.

(ii) *Group actions, orbits, and free actions.* A group G acting on a finite set X partitions it into orbits; if the action is free every orbit has size $|G|$ and $|X| = |G| \cdot$ (number of orbits). A function constant on orbits, such as Λ here, descends to the orbit set, so counting its zeros is counting orbits. This is the single most transferable idea in the solution.

(iii) *Recursions with a strengthened hypothesis.* The lemma is stated for arbitrary positive coefficients with sum below p, not for $1, 2, \ldots, k$, because the induction step deletes a variable and lands on a different coefficient list. Learning to notice, before starting an induction, that the natural statement is too weak to induct on is a skill, not luck.

(iv) *First order linear recursions with a variable multiplier.* For $f(k) = \lambda_k f(k-1) + R(k)$, multiply by a summation factor $\prod \lambda_j^{-1}$ to reduce to constant multiplier, then find any particular solution and add $C\lambda^k$. Here $\lambda_k = -k$ and the summation factor is $k!$.

(v) *Optional but valuable: the partition lattice and its Mobius function.* $\mu(\hat{0}, \hat{1}) = (-1)^{n-1}(n-1)!$ on Π_n, equivalently the degree one coefficient of the falling factorial $x(x-1)\cdots(x-n+1)$ is the Stirling number $s(n,1) = (-1)^{n-1}(n-1)!$. You do not need it for the ideal route, but it is what explains the correction term.

Revolving concepts

Complete residue systems. A set of p consecutive integers is a complete residue system modulo p. Here $\{1, \ldots, 2017\}$ works because $2017 \equiv 0$; had the problem said $\{1, \ldots, 2016\}$ the reduction map would have missed 0 and the whole translation argument would collapse. See Book 1, field: Number theory, topic: residue systems.

Translation invariance of a linear form. $\Lambda(x + t\mathbf{1}) = \Lambda(x) + t\sum c_i$. So Λ is translation invariant if and only if $\sum c_i \equiv 0$, and if $\sum c_i \not\equiv 0$ then Λ is a bijection along every translation orbit. Both halves are used: the first to normalise $x_0 = 0$ in the main count, the second to count solutions inside the lemma. See Book 1, field: Linear algebra, topic: linear functionals and kernels.

Free group actions and orbit counting. If a finite group G acts freely on X, then $|X| = |G| \cdot |X/G|$, and any G-invariant subset is a union of orbits. Compare Burnside's lemma, which is the general tool when the action is not free; here freeness makes it unnecessary. See Book 1, field: Abstract algebra, topic: group actions.

Falling factorials, ordered selections and Pascal. $\frac{n!}{(n-k)!} = n(n-1)\cdots(n-k+1)$ counts ordered k-tuples of distinct elements from an n-set; $\binom{n}{k}k! = \frac{n!}{(n-k)!}$; Pascal's rule $\binom{n}{k} = \binom{n-1}{k} + \binom{n-1}{k-1}$. See Book 1, field: Combinatorics, topic: binomial identities.

The recursion, fully generalised. This is the recursion in the problem, so generalise it properly. The general first order linear recursion is

$$f(k) \;=\; \lambda_k f(k-1) + R(k), \qquad f(k_0) \text{ given.}$$

Set $\Pi_k = \prod_{j=k_0+1}^{k} \lambda_j$ and divide through by Π_k: with $F(k) = f(k)/\Pi_k$ the relation becomes

$F(k) = F(k-1) + R(k)/\Pi_k$, so

$$f(k) \;=\; \Pi_k \left(f(k_0) + \sum_{j=k_0+1}^{k} \frac{R(j)}{\Pi_j} \right).$$

The quantity $1/\Pi_k$ is the *summation factor*. In this problem $\lambda_k = -k$ and $\Pi_k = (-1)^{k-1}k!$, which is why dividing by $k!$ and flipping signs is the right normalisation; the relation becomes $g(k) = -g(k-1) + \binom{p}{k}$, and for a constant multiplier the alternative and usually faster method is (general solution) = (any particular solution) + $C\lambda^k$. Recognising Pascal's rule as a supply of particular solutions for the relation $g(k) + g(k-1) = \binom{p}{k}$ is the specific move worth banking: whenever the inhomogeneity is a binomial coefficient and the multiplier is -1, try a binomial coefficient from the row above. The same trick solves $g(k) + g(k-1) = \binom{n}{k}$ for every n, and, via $\binom{n}{k} = \binom{n-1}{k} + \binom{n-1}{k-1}$ iterated, any inhomogeneity that is a fixed linear combination of binomial coefficients. See Book 1, field: Sequences and recurrences, topic: first order linear recursions and summation factors.

Inclusion and exclusion over set partitions. The intersections of the events $\{x_i = x_j\}$ are indexed by the partition lattice Π_n, and the correct alternating coefficients are the Mobius numbers μ_π, characterised by $\sum_{\pi|\sigma} \mu_\pi = [\sigma = \hat{0}]$. Comparing degree one coefficients in $|A|(|A|-1)\cdots(|A|-n+1) = \sum_\pi \mu_\pi |A|^{|\pi|}$ gives $\mu_{\hat{1}} = (-1)^{n-1}(n-1)!$, which for $n = 64$ is $-63!$: exactly the correction term in the answer. See Book 1, field: Combinatorics, topic: Mobius inversion on posets.

Circuit Bank

- **WHEN** a congruence has explicit numerical coefficients and an explicit prime modulus **DO** add the coefficients before doing anything else, and compare the total with the modulus **BECAUSE** setters hide the entire structure in that one arithmetic fact, and a coefficient sum divisible by p means the form is invariant under simultaneous translation
- **WHEN** a count is over objects with pairwise distinct entries and you are tempted by inclusion and exclusion **DO** first look for a group action preserving both the constraint and the distinctness, and quotient by it **BECAUSE** quotienting by a free action is exact and sign free, whereas inclusion and exclusion over distinctness lands you in the partition lattice
- **WHEN** a normalisation makes one value special (here 0 after setting $x_0 = 0$) **DO** set up a recursion in the number of variables by peeling off the tuples that use the special value **BECAUSE** distinctness guarantees at most one coordinate takes that value, so the correction term is a clean multiple of the previous count with nothing to subtract twice
- **WHEN** you are about to induct and the statement mentions specific constants **DO** restate the claim for arbitrary data of the same shape, choosing the hypotheses so they are inherited when you delete an object **BECAUSE** the induction step almost never lands on the original constants, and a statement you cannot apply to the reduced case is a statement you cannot induct on
- **WHEN** a recursion has the form $f(k) = -kf(k-1) + R(k)$ **DO** divide by $k!$ to get a constant multiplier, then look for a particular solution of the shape of R **BECAUSE** $k!$ is the summation factor for the multiplier $-k$, and for R a binomial coefficient Pascal's rule supplies the particular solution immediately

Backtesting

1. First useful cue: the coefficient list $1, 1, 2, 3, \ldots, 63$, whose sum is $1 + \frac{63\cdot 64}{2} = 2017$, the modulus itself; and the ground set $\{1, \ldots, 2017\}$ being a complete residue system.

2. Method the expression suggested: the linear form is invariant under simultaneous translation, and so is distinctness, so quotient by the diagonal action, normalise $x_0 = 0$, and recurse on the number of variables.
3. Where you would hesitate, and the thought to reinforce: at the decision to state the lemma for arbitrary positive coefficients with sum below p rather than for $1, 2, \ldots, 63$. Reinforce: the induction deletes a variable, so the hypothesis must survive deletion; positivity and "sum below p" are precisely the two properties that do.
4. The trap the question sets: the distinctness condition, which invites inclusion and exclusion and then punishes it. The secondary trap is arithmetic: the coefficients are $1, 1, 2, 3, \ldots$, not $0, 1, 2, 3, \ldots$, and if you misread the first two you get a coefficient sum of 2016 instead of 2017 and the whole method evaporates.
5. What makes you recognise it faster next time: the pairing of a prime modulus with a coefficient sum equal to that prime is a designed signature. Any time a competition gives an explicit numerical linear form modulo a prime, add the coefficients; if they sum to 0 modulo p, the diagonal translation is your first move.
6. The reusable decision rule: when two constraints in a counting problem share a symmetry group, quotient by the group instead of counting against the constraints separately.

Mirror drills

1. Let $p > 3$ be prime. How many ordered pairs (x_1, x_2) of distinct nonzero elements of $\mathbb{F}_p$ satisfy $x_1 + 2x_2 = 0$? *Answer:* $p - 1$. Directly: $x_1 = -2x_2$ with $x_2 \neq 0$ forces $x_1 \neq 0$, and $x_1 \neq x_2$ fails only if $3x_2 = 0$, impossible for $p > 3$. Via the formula, $f(2) = \frac{2}{p}\left(\binom{p-1}{2} + (p-1)\right) = p - 1$.
2. Prove that for positive integers $a_1, \ldots, a_k$ with $a_1 + \cdots + a_k < p$, the number of k-tuples of distinct elements of $\mathbb{F}_p$ (zeros allowed) with $\sum a_i x_i = 0$ is exactly $\frac{(p-1)!}{(p-k)!}$, independent of the a_i. *Answer:* the diagonal translation acts freely with $\frac{(p-1)!}{(p-k)!}$ orbits, and along each orbit $\Lambda(x + t\mathbf{1}) = \Lambda(x) + t\sigma$ runs over all of $\mathbb{F}_p$ bijectively because σ is invertible, so exactly one member of each orbit is a solution.
3. Compute $\mu(\hat{0}, \hat{1})$ for the partition lattice Π_n. *Answer:* $(-1)^{n-1}(n-1)!$, by comparing the coefficient of x^1 on both sides of $x(x-1)\cdots(x-n+1) = \sum_\pi \mu_\pi x^{|\pi|}$: only $\pi = \hat{1}$ has one block, and the left side has x^1 coefficient $s(n, 1) = (-1)^{n-1}(n-1)!$. For $n = 64$ this is $-63!$, the bias in the answer to B6.

Chapter 10

Putnam 2016

10.1 A1. derivative order forcing divisibility by 2016

Find the smallest positive integer j such that for every polynomial $p(x)$ with integer coefficients and for every integer k, the integer

$$p^{(j)}(k) = \frac{d^j}{dx^j} p(x)\Big|_{x=k}$$

(the j-th derivative of $p(x)$ at k) is divisible by 2016.

Read it out loud

Two universal quantifiers sit inside this question before you ever reach the number 2016: "for every polynomial with integer coefficients" and "for every integer k". Whenever a divisibility claim is dressed up with "for every" over a structured family like this, the claim cannot secretly depend on which member of the family you picked, so your first fifteen seconds should be spent asking what structure the whole family shares. Every integer-coefficient polynomial is built from the monomials x^m by integer linear combinations, and differentiation is linear, so whatever the j-th derivative does to 2016-divisibility, it does uniformly across that whole basis. That is the field this problem lives in: calculus supplies the mechanism, the power rule iterated j times, and number theory supplies the target, divisibility by a fixed composite integer.

The second thing worth writing down inside that first half minute is the prime factorisation of 2016, because a fixed integer appearing as a divisibility target is never meant to be used as 2016; it is meant to be used as $2^5 \cdot 3^2 \cdot 7$. Any claim "N divides something, for every choice of parameters" reduces, by unique factorisation, to a set of independent prime power claims, and those are always the real content.

The final cue is the shape of the question itself: "find the smallest j" is an extremal claim, and an extremal claim always splits into two separate jobs, a proof that some j always works (an upper bound, true for every p and k) and a proof that no smaller j always works (a lower bound, witnessed by one specific failing case). Reading the question out loud, you should already suspect, before writing a single equation, that the eventual argument finds a formula for $p^{(j)}(k)$ that visibly contains a factorial, then turns the whole problem into finding the least j with $2016 \mid j!$.

Approaches, ranked worst to best

1. **numerical trial on sample polynomials.** *Cue:* "find the smallest j" invites experimenting with $p(x) = x^2, x^3, \ldots$ at a handful of integers k. *Circuit:* guess and check. (this closes neither half of a minimality argument: no finite experiment proves a property for every integer-coefficient polynomial and every integer k, and no finite experiment reliably finds the true worst case, since a badly chosen sample polynomial can look fine by accident. It costs unlimited ink and delivers no proof.)

2. **route the derivative through finite differences.** *Cue:* integer-valued sequences and divisibility patterns often go through the finite difference operator Δ, whose iterates $\Delta^j p(k)$ are always integer combinations of values of p. *Circuit:* Polya-Mahler style integer-valued polynomial reasoning. (a genuine technique elsewhere, but D^j and Δ^j are different operators that only agree in the limit as a step size shrinks to zero, so this route needs a translation lemma between the two operators before it can say anything about $p^{(j)}(k)$. That lemma costs more ink than differentiating x^m directly, and lands on the same term regardless.)

3. **expand in the monomial basis and differentiate term by term.** *Cue:* "for every polynomial with integer coefficients" is precisely the hypothesis that licenses working with the general term $a_m x^m$ and invoking linearity. *Circuit:* linearity reduction to the generating basis, closed by

one extremal test polynomial. (this reaches the factor $j!\binom{m}{j}$ in one line, hands you sufficiency for every p and k at once, and needs only $p(x) = x^j$ for the converse. No detour, no unproven translation lemma, and the remaining work is arithmetic on $2016 = 2^5 \cdot 3^2 \cdot 7$.)

The ideal solution

Write $p(x) = \sum_{m=0}^{n} a_m x^m$ with every $a_m \in \mathbb{Z}$. For $m \geq j$, the power rule applied j times gives

$$\frac{d^j}{dx^j} x^m = m(m-1)(m-2)\cdots(m-j+1)\, x^{m-j} = j!\binom{m}{j} x^{m-j},$$

and for $m < j$ this derivative is 0. Summing over m and using linearity of differentiation,

$$p^{(j)}(x) = j! \sum_{m=j}^{n} \binom{m}{j} a_m x^{m-j},$$

so for every integer k,

$$p^{(j)}(k) = j! \sum_{m=j}^{n} \binom{m}{j} a_m k^{m-j}.$$

Every factor inside that sum is an integer: $\binom{m}{j}$ is an integer because it counts subsets, a_m is an integer by hypothesis, and k^{m-j} is an integer power of an integer. So $p^{(j)}(k)$ is $j!$ times an integer, for every integer-coefficient p and every integer k, with no further hypothesis on j at all. This proves that whenever $2016 \mid j!$, the required divisibility holds universally.

For the converse, apply the hypothesis to the single polynomial $p(x) = x^j$, whose j-th derivative is the constant $j!$ for every x, so $p^{(j)}(k) = j!$ for every integer k. If j is to satisfy the problem's condition, this constant must in particular be divisible by 2016. So the condition "$p^{(j)}(k)$ is divisible by 2016 for every integer-coefficient p and every integer k" holds if and only if $2016 \mid j!$: the paragraph above gave sufficiency, this paragraph gives necessity, and together they say the answer is exactly the smallest j with $2016 \mid j!$.

Factorise $2016 = 2^5 \cdot 3^2 \cdot 7$ (since $2016 = 32 \cdot 63 = 2^5 \cdot 9 \cdot 7$). The prime 7 divides none of $1, 2, \ldots, 6$, so $v_7(j!) = 0$ for every $j \leq 6$, and already $j \geq 7$ is forced. At $j = 7$: $7! = 5040$, and $5040/2016 = 2.5$, not an integer, so $2016 \nmid 7!$; equivalently $v_2(7!) = \lfloor 7/2 \rfloor + \lfloor 7/4 \rfloor = 3 + 1 = 4$, one short of the required 5. At $j = 8$: $8! = 40320 = 20 \cdot 2016$ exactly, so $2016 \mid 8!$; checking each prime confirms this is not an accident: $v_2(8!) = 4 + 2 + 1 = 7 \geq 5$, $v_3(8!) = 2 + 0 = 2 \geq 2$, $v_7(8!) = 1 \geq 1$. Since $j = 7$ fails and $j = 8$ succeeds,

$$j = \boxed{8}.$$

Layer 1: WHAT

Block 1: expand p in the monomial basis and push the derivative through the sum by linearity, reducing to the single computation $D^j x^m$. Block 2: recognise the falling factorial $m(m-1)\cdots(m-j+1)$ as $j!\binom{m}{j}$, which strips p and k out of the argument and leaves a bare statement about $j!$. Block 3: realise the converse needs only one polynomial, the one whose j-th derivative collapses to a constant with nothing left over, $p(x) = x^j$. Block 4: convert to pure number theory, factorise 2016, and hunt the rarest prime first.

The nominal route tries to reason about $p^{(j)}(k)$ mod 2016 directly, case by case on small numerical polynomials, without ever writing the general monomial expansion; it never produces a clean sufficient condition and can never rule out smaller j with certainty. The bifurcation point is the decision, at the very first line, to write $p(x) = \sum a_m x^m$ symbolically and differentiate the generic term x^m, rather than picking numbers to differentiate. That one choice, a generic monomial instead of a numerical example, turns an open-ended search into a two-line identity.

Layer 2: HOW

Block 1. **Cue.** The hypothesis quantifies over every integer-coefficient polynomial, and every such polynomial is an integer linear combination of monomials. **Why natural.** Differentiation is linear, so once you know what D^j does to every monomial x^m, superposition tells you what it does to every polynomial at once; there is never a need to reason about an unspecified p again. **Link to the next block.** Applying the power rule j times to x^m produces the falling factorial $m(m-1)\cdots(m-j+1)$, a raw product of j consecutive integers that begs to be simplified.

Block 2. **Cue.** A product of j consecutive integers, $m(m-1)\cdots(m-j+1)$. **Why natural.** This product equals $j!\binom{m}{j}$, and $\binom{m}{j}$ is an integer for every integer m because it counts subsets, so the product is automatically $j!$ times an integer with no extra argument required. **Link to the next block.** With p and k both absorbed into "some integer", the remaining problem is a statement about $j!$ alone, so the next move is to stop thinking about polynomials and start thinking about which j make 2016 divide $j!$.

Block 3. **Cue.** The problem is a minimality claim, so sufficiency alone is not enough; some specific p and k must force the bound to be tight. **Why natural.** The cleanest test case is the one where $p^{(j)}$ collapses to a bare constant with nothing left over: $p(x) = x^j$ gives $p^{(j)}(x) = j!$ identically, independent of k, so there is no residual freedom for the divisibility to slip through on a technicality. **Link to the next block.** Plugging this single polynomial in shows $2016 \mid j!$ is not merely sufficient but forced, so the problem is now, precisely and only, "find the smallest j with $2016 \mid j!$".

Block 4. **Cue.** A fixed composite integer, 2016, must divide a quantity that grows with a parameter j. **Why natural.** Unique factorisation says $2016 \mid j!$ exactly when every prime power in $2016 = 2^5 \cdot 3^2 \cdot 7$ divides $j!$, so one hard question splits into three easy ones, and the rarest prime, here 7, which does not appear at all until $j = 7$, is always worth checking first, since it can never be satisfied early. **Link to the next block.** Checking $j = 7$ shows the count of 2s is one short; checking $j = 8$, the very next candidate, shows all three prime powers are now present, closing the problem.

Layer 3: WHY

The fact beneath the whole solution is that a product of j consecutive integers is always divisible by $j!$, because that product is, by definition, $j!$ times a binomial coefficient, and binomial coefficients count things; every other feature of the statement, which polynomial, which integer k, only disguises that the true content is one arithmetic fact about factorials. The discernment mechanism is to treat "for every polynomial with integer coefficients" as a claim about a $\mathbb{Z}$-module with a known generating set, so that any linear operator on it, derivative, finite difference, or evaluation, is fixed entirely by its action on the monomials. You train this by asking, on first reading such a phrase, whether the final claim could possibly depend on which polynomial was chosen; here it plainly cannot, since the target is the fixed number 2016, and that tells you the reduction to generators is forced before you write a further line. The examiners nudge you the same way by naming a specific composite, 2016, rather than an abstract N: naming it is an invitation to factorise it and treat its three primes as three small separate puzzles, the strategy that finishes the problem in four lines of arithmetic.

Revolving concepts

Falling factorials and binomial coefficients. For integers $m \geq j \geq 0$, $m(m-1)\cdots(m-j+1) = j!\binom{m}{j}$, and $\binom{m}{j}$ extends to every integer m, including negative m, via $\binom{-n}{j} = (-1)^j\binom{n+j-1}{j}$, remaining an integer throughout. This identity underlies the binomial theorem, Vandermonde's identity, and

every argument that a product of consecutive integers is divisible by a factorial. See Book 1, field: Polynomials, topic: falling factorial and binomial coefficient identities.

Legendre's formula. The exponent of a prime p in $n!$ is $v_p(n!) = \sum_{i \geq 1} \lfloor n/p^i \rfloor$, equivalently $\frac{n - s_p(n)}{p-1}$, where $s_p(n)$ is the base p digit sum of n. This is the standard tool for any question asking for the smallest factorial divisible by a given number, and it generalises to Kummer's theorem, which counts the carries produced when adding two numbers in base p and relates that count to the prime valuation of a binomial coefficient. See Book 1, field: Number theory, topic: prime valuations of factorials.

Integer-valued polynomials and Polya's basis theorem. A polynomial with rational coefficients that takes an integer value at every integer, such as $\binom{x}{2} = \frac{x(x-1)}{2}$, need not have integer coefficients itself; Polya's theorem says every such polynomial is a $\mathbb{Z}$-linear combination of the binomial polynomials $\binom{x}{n}$, with coefficients equal to the finite differences of p at 0. Bhargava extended this from $\mathbb{Z}$ to arbitrary subsets of Dedekind domains using a recursively built sequence called a P-ordering, which replaces the ordinary factorial $n!$ by a generalised factorial $k!_P$: at each step you adjoin the element minimising a certain valuation against the elements already chosen, and ordinary Legendre's formula is recovered when the domain is $\mathbb{Z}$ with its usual valuation. This is genuinely beyond the syllabus, and is the honest answer to why the official remark mentions Dedekind domains: it is not a trick, it is a named research-level generalisation.

Circuit Bank

- **WHEN** a hypothesis quantifies over every integer-coefficient polynomial **DO** expand in the monomial basis and use linearity of whichever operator is in play, derivative, finite difference, or evaluation **BECAUSE** a linear operator on a module is determined entirely by its action on a generating set, so testing every monomial once replaces testing every polynomial forever
- **WHEN** a product of consecutive integers appears, in a derivative, a permutation count, or a combinatorial identity **DO** rewrite it immediately as $j!$ times a binomial coefficient **BECAUSE** binomial coefficients are always integers, so this rewriting produces a factorial divisor for free, with no case analysis
- **WHEN** a fixed composite number N must divide a quantity that grows with a parameter **DO** factorise N into prime powers, find the least parameter value meeting each prime power's threshold separately using Legendre's formula, then take the maximum of those thresholds **BECAUSE** divisibility by N splits, by unique factorisation, into independent divisibility by each prime power in N, and each of those is a short, fully determined calculation
- **WHEN** a problem asks for the smallest parameter value that works for every case in some family **DO** budget two separate arguments immediately, a general proof valid for every case, and one explicit failing case at the next value down **BECAUSE** a minimality claim is an equality between a proven bound and an achieved value, and only an explicit example can prove that a smaller value genuinely fails

Backtesting

1. First useful cue: "for every polynomial with integer coefficients", a universally quantified claim over a family with a known generating basis.
2. Method the expression suggested: expand in the monomial basis, differentiate term by term, and watch a factorial fall out of the falling factorial by linearity.
3. Where you would hesitate, and the thought to reinforce: after seeing $j! \mid p^{(j)}(k)$ always, it is tempting to stop, forgetting that minimality demands an explicit failing polynomial one value down, not merely the absence of a proof for it.

4. The trap the question sets: assuming the largest prime power in 2016's factorisation, 2^5, must be the bottleneck, when the prime that appears latest, here 7, absent from $j!$ until $j = 7$, is what actually forces the lower bound, with the power of 2 only barely failing at that same value.
5. What makes you recognise it faster next time: seeing a specific four digit constant like 2016 inside a divisibility claim and reflexively factorising it before doing anything else, since such a constant is chosen for its factorisation, never left arbitrary.
6. The reusable decision rule: WHEN a fixed integer N must divide a quantity that only grows with a parameter j, such as $j!$, DO factorise N and test candidate values of j against every prime power in turn, starting with the prime that first appears latest inside $j!$, BECAUSE that prime, not the one with highest exponent, usually sets the true threshold.

Mirror drills

1. Find the smallest positive integer j such that $p^{(j)}(k)$ is divisible by 720 for every integer-coefficient p and every integer k. *Answer:* $720 = 2^4 \cdot 3^2 \cdot 5$; $j = 5$ fails since $v_2(5!) = 3 < 4$; $j = 6$ gives $6! = 720$ exactly, so $j = 6$.
2. Redo the original problem with 2016 replaced by $4032 = 2^6 \cdot 3^2 \cdot 7$. *Answer:* still $j = 8$, since $v_2(8!) = 7 \geq 6$, $v_3(8!) = 2$ and $v_7(8!) = 1$ already hold, while $j = 7$ still fails on the power of 2 alone.
3. Prove, without quoting Legendre's formula, that $j!$ divides any product of j consecutive integers, even when some of them are negative. *Answer:* if the product includes 0 it is trivially divisible; otherwise the product equals $j!\binom{m}{j}$ for the largest integer m in the range, and $\binom{m}{j}$ remains an integer for negative m by $\binom{-n}{j} = (-1)^j\binom{n+j-1}{j}$.

10.2 A2. limiting growth rate of a binomial threshold

Given a positive integer n, let $M(n)$ be the largest integer m such that

$$\binom{m}{n-1} > \binom{m-1}{n}.$$

Evaluate

$$\lim_{n\to\infty} \frac{M(n)}{n}.$$

Read it out loud

The two objects being compared are binomial coefficients whose indices are each offset from one another by a small fixed amount: the top index moves from m to $m-1$, and the bottom index moves from $n-1$ to n. Whenever two binomial coefficients sit this close to one another, the correct reflex is to form their ratio rather than to expand each one and subtract. A ratio is cheap here because the factorial numerators and denominators of $\binom{m}{n-1}$ and $\binom{m-1}{n}$ overlap almost completely; a difference has no such overlap to exploit and generally produces an expression with no simplification at all. That is the first field this problem lives in: combinatorics supplying the object, algebra supplying the simplification.

The second cue sits in the closing instruction: you are asked to evaluate $\lim_{n\to\infty} M(n)/n$, not to find a closed form for $M(n)$ itself. That single word, limit, tells you before any algebra that $M(n)$ grows linearly in n and that only the proportionality constant is wanted. This licenses a strategy that would be unacceptably lossy if an exact formula for $M(n)$ were required: bounding $M(n)$ between two quantities that share the same behaviour as $n \to \infty$, without ever pinning $M(n)$ down to the nearest integer. Recognising this early saves you from the much harder task of computing a floor function exactly.

The third cue is what happens after the ratio simplifies: a comparison of two combinatorial quantities becomes, in one line, a polynomial inequality in the single variable m. Once a discrete combinatorial condition has been converted into an algebraic inequality with no residual number theoretic content (no coprimality, no parity, nothing but a quadratic), the rest of the problem is pure single variable algebra: find the roots, read off the sign, and pass to a limit. The moment you see the ratio become a rational function of m and n, you should already expect the final constant to be a root of some quadratic, and quadratics with a 3 and a 5 in them on the Putnam are worth being alert to, since $x^2 - 3x + 1 = 0$ is the characteristic equation you get from squaring the roots of the Fibonacci equation $x^2 - x - 1 = 0$, and its larger root is $(3+\sqrt{5})/2$.

Approaches, ranked worst to best

1. **numerical search and pattern spotting.** *Cue:* compute $M(n)$ directly for $n = 1, 2, 3, \ldots$ by testing integers m one at a time. *Circuit:* small case exploration. (this never produces a proof, and it converges slowly: because the limiting constant $(3+\sqrt{5})/2$ is irrational, decimal approximations to $M(n)/n$ from small n settle only gradually, and nothing about the numerical data alone tells you the constant is a root of a quadratic rather than, say, a rational approximation or a different surd entirely.)

2. **Stirling asymptotics on the binomial coefficients directly.** *Cue:* "evaluate the limit" invites approximating both binomial coefficients for $m = cn$ and large n using a Stirling type expansion, then solving for the crossing value of c. *Circuit:* continuous approximation of a discrete extremal problem. (this can locate the constant $c = (3+\sqrt{5})/2$ reasonably quickly as a heuristic, but turning "the approximate crossing point of two Stirling expansions" into a genuine proof that $M(n)/n$ converges to exactly that value requires controlling the error

terms in the approximation to the same precision that the exact algebraic route gives for free. You end up redoing the rigorous part of the argument anyway, after having spent ink on an approximation that was never going to be the final proof.)

3. **exact ratio, then quadratic, then sandwich.** *Cue:* the offset between the two binomial coefficients is small and fixed, which is precisely the situation where the ratio collapses by factorial cancellation to a low degree rational function. *Circuit:* ratio reduction followed by exact root extraction and a squeeze. (this is exact at every step: no approximation is introduced anywhere, the quadratic's roots are found in closed form via the quadratic formula, and the final limit is read off the roots directly. The only extra care needed, confirming that the region where the ratio identity is valid actually contains the relevant root, costs a single short paragraph and closes a gap the fastest write ups sometimes leave open.)

The ideal solution

Fix a positive integer n and restrict attention first to integers $m > n+1$, so that $m-1 \geq n$ and both $\binom{m}{n-1}$ and $\binom{m-1}{n}$ are genuine positive binomial coefficients. For such m,

$$\frac{\binom{m}{n-1}}{\binom{m-1}{n}} = \frac{\dfrac{m!}{(n-1)!\,(m-n+1)!}}{\dfrac{(m-1)!}{n!\,(m-n-1)!}} = \frac{m!}{(m-1)!}\cdot\frac{n!}{(n-1)!}\cdot\frac{(m-n-1)!}{(m-n+1)!} = m\cdot n\cdot\frac{1}{(m-n+1)(m-n)} = \frac{mn}{(m-n+1)}$$

Every factorial term cancelled except the single outermost factor at each of the four ends, because the two binomial coefficients differ by exactly one in each index; that is what makes this ratio worth computing in the first place.

Since $m > n+1$ makes $m-n+1$ and $m-n$ both positive, the ratio above is a ratio of two positive quantities, so $\binom{m}{n-1} > \binom{m-1}{n}$ holds exactly when this ratio exceeds 1, that is when $mn > (m-n+1)(m-n)$. Expanding the right side, $(m-n+1)(m-n) = (m-n)^2 + (m-n) = m^2 - 2mn + n^2 + m - n$, so the condition rearranges to the single quadratic inequality

$$m^2 - (3n-1)m + (n^2 - n) < 0.$$

The coefficient of m^2 is positive, so this holds exactly on the open interval strictly between the two real roots of $m^2 - (3n-1)m + (n^2-n) = 0$, provided those roots are real. By the quadratic formula, the roots are

$$\alpha(n) = \frac{(3n-1) + \sqrt{5n^2 - 2n + 1}}{2}, \qquad \beta(n) = \frac{(3n-1) - \sqrt{5n^2 - 2n + 1}}{2},$$

where the discriminant simplifies as $(3n-1)^2 - 4(n^2-n) = 9n^2 - 6n + 1 - 4n^2 + 4n = 5n^2 - 2n + 1$. This discriminant is positive for every real n, since as a quadratic in n its own discriminant is $4 - 20 < 0$, so $\alpha(n)$ and $\beta(n)$ are always real and distinct, and for $m > n+1$,

$$\binom{m}{n-1} > \binom{m-1}{n} \iff \beta(n) < m < \alpha(n).$$

Two facts confirm this description genuinely captures $M(n)$. First, $\alpha(n) - \beta(n) = \sqrt{5n^2 - 2n + 1}$, and $5n^2 - 2n + 1 - n^2 = 4n^2 - 2n + 1 > 0$ for every $n \geq 1$, so $\alpha(n) - \beta(n) > n \geq 1$: the open interval always contains at least one integer, so the set of valid m is never empty and $M(n)$ is genuinely well defined. Second, the region $m > n+1$ used to derive the ratio identity must actually contain the top of that interval, or the argument would only be describing part of the picture. Since $5n^2 - 2n + 1 > (2n-1)^2 = 4n^2 - 4n + 1$ whenever $n^2 + 2n > 0$, true for every $n \geq 1$, we get $\sqrt{5n^2 - 2n + 1} > 2n - 1$ and hence $\alpha(n) > \frac{(3n-1)+(2n-1)}{2} = \frac{5n-2}{2}$, which exceeds $n+1$ once $n \geq 2$.

So for every $n \geq 2$, $\alpha(n)$ sits well inside the region $m > n+1$ where the ratio identity is exact, and because a single real quadratic's sign pattern (negative strictly between its roots, positive elsewhere) is a global statement about every real m, not merely those in one sub-range, the largest integer anywhere satisfying the original inequality is exactly the largest integer strictly below $\alpha(n)$, with nothing missed by having derived the identity only for $m > n+1$.

Consequently $M(n)$ is the greatest integer strictly less than $\alpha(n)$, so

$$\alpha(n) - 1 \leq M(n) < \alpha(n).$$

To find $\lim \alpha(n)/n$, pull n out from under the square root: for $n > 0$,

$$\frac{\alpha(n)}{n} = \frac{3 - \frac{1}{n} + \sqrt{5 - \frac{2}{n} + \frac{1}{n^2}}}{2} \longrightarrow \frac{3+\sqrt{5}}{2} \qquad (n \to \infty).$$

Dividing the sandwich $\alpha(n) - 1 \leq M(n) < \alpha(n)$ through by n, both outer bounds converge to $\frac{3+\sqrt{5}}{2}$ as $n \to \infty$, so by the sandwich theorem,

$$\lim_{n\to\infty} \frac{M(n)}{n} = \boxed{\frac{3+\sqrt{5}}{2}}.$$

Layer 1: WHAT

Block 1: recognise the two binomial coefficients differ by a fixed small shift in both indices, and choose the ratio over the difference. Block 2: cancel the ratio by factorials down to the rational function $mn/[(m-n+1)(m-n)]$. Block 3: convert "ratio exceeds 1" into a single quadratic inequality in m, and extract its two real roots via the quadratic formula. Block 4: confirm the region of validity actually contains the controlling root, then sandwich $M(n)$ between the larger root and that root minus one, divide by n, and take the limit.

The nominal route tries to manipulate the difference $\binom{m}{n-1} - \binom{m-1}{n}$ directly, perhaps via Pascal's rule or a combinatorial bijection, hunting for a sign without ever forming a ratio; this produces a higher degree, less transparent expression that does not obviously reduce to a quadratic at all. The bifurcation point is the decision, at the very first line, to divide the two binomial coefficients rather than subtract them: that single choice is what turns a combinatorial identity search into a two line factorial cancellation.

Layer 2: HOW

Block 1. **Cue.** The two binomial coefficients have upper indices $m, m-1$ and lower indices $n-1, n$, each pair differing by exactly one. **Why natural.** Nearby binomial coefficients share almost all of their factorial content, so their ratio, unlike their difference, collapses to a low degree rational function; a comparison phrased with a strict inequality between two positive quantities is always more cheaply attacked through a ratio to 1 than through a difference to 0. **Link to the next block.** Writing out the ratio and cancelling the shared factorial terms leaves only the outermost factors, m, n, and the two linear terms $m-n+1$, $m-n$.

Block 2. **Cue.** The simplified ratio $\dfrac{mn}{(m-n+1)(m-n)}$, compared against the threshold 1. **Why natural.** Since $m > n+1$ makes both $m-n+1$ and $m-n$ positive, comparing the ratio to 1 is safe to cross multiply without flipping any inequality, and the resulting condition $mn > (m-n+1)(m-n)$ is a single polynomial inequality with no combinatorics left in it at all. **Link to the next block.** Expanding the right hand side collects everything into one quadratic in m, whose sign is fully governed by its two real roots.

Block 3. **Cue.** A quadratic inequality $m^2 - (3n-1)m + (n^2 - n) < 0$ with a positive leading coefficient. **Why natural.** An upward opening quadratic is negative exactly between its two real roots and positive outside, so the entire solution set for m, for every fixed n, is the open interval between $\beta(n)$ and $\alpha(n)$ found from the quadratic formula, with no further case analysis needed. **Link to the next block.** Since the problem only wants a limiting ratio, the next step is not to solve for $M(n)$ but to bound it tightly enough between quantities whose ratio to n has a known limit.

Block 4. **Cue.** The closing instruction asks for $\lim_{n\to\infty} M(n)/n$, a normalised limit, not an exact value of $M(n)$. **Why natural.** $M(n)$ is the greatest integer below $\alpha(n)$, so it is trapped between $\alpha(n) - 1$ and $\alpha(n)$ regardless of how $\alpha(n)$'s fractional part behaves; dividing by n and pulling n out from under the square root inside $\alpha(n)$ makes both bounds converge to the same value. **Link to the next block.** The sandwich theorem then hands over the limit directly, with no need ever to know $M(n)$ itself.

Layer 3: WHY

The truth beneath the whole solution is that a ratio of two binomial coefficients whose indices are offset by a bounded amount is always a low degree rational function, because the bulk of each factorial is shared and cancels; this is the same cancellation that drives Pascal's rule and the ratio test used to find the largest term of a binomial expansion. The discernment mechanism is to notice, on first reading, whether a comparison of combinatorial quantities is phrased through nearby indices (ratio territory) or through unrelated indices (where no such cancellation exists and a direct combinatorial argument is genuinely needed); training this means asking, before any algebra, "how many index steps separate these two binomial coefficients", since a small answer is the signal that a ratio will collapse cleanly.

A second, independent discernment is needed for the closing instruction: recognising that "evaluate the limit of $X(n)/n$" is a standing licence to bound $X(n)$ rather than compute it, since any two bounds sharing the same leading order behaviour already prove the limit by the sandwich theorem, however badly they might disagree about $X(n)$'s exact value or its fractional part. The examiners nudge you toward the whole route by giving you a problem where the exact value of $M(n)$ genuinely has no clean closed form (it depends on the floor of an irrational number), while the limiting ratio does; asking for the limit rather than the exact value is itself the hint that a closed form for $M(n)$ was never the intended target.

Revolving concepts

Ratios of nearby binomial coefficients. When the upper and lower indices of two binomial coefficients each differ from one another by a bounded fixed amount, their ratio reduces after factorial cancellation to a rational function of bounded degree; here $\binom{m}{n-1}/\binom{m-1}{n} = mn/[(m - n + 1)(m - n)]$ for $m > n + 1$. The same cancellation is what proves the ratio test for the largest binomial coefficient in a row of Pascal's triangle, and what justifies the standard recursive definition $\binom{m}{k} = \binom{m-1}{k-1} \cdot \frac{m}{k}$. See Book 1, field: Combinatorics, topic: consecutive binomial coefficient ratios.

Sign of an upward opening quadratic. For $a > 0$, $am^2 + bm + c$ is negative exactly on the open interval strictly between its two real roots when the discriminant is positive, and nonnegative everywhere else; this is the entire content needed to pass from a quadratic inequality to a description of the solution set, with no further case work. See Book 1, field: Polynomials, topic: quadratic sign charts.

The sandwich theorem for a normalised extremal quantity. If $a_n \le X(n) < b_n$ for all large n and a_n/n, b_n/n both converge to the same limit L, then $X(n)/n \to L$ as well, even when $X(n)$ itself, here an integer defined by a largest-satisfying condition, has no closed form and its distance to a_n or

b_n does not itself converge to anything in particular. See Book 1, field: Real analysis, topic: squeeze arguments for discrete extrema.

The golden ratio's square and the general root squaring transform. The limiting constant $(3+\sqrt{5})/2$ is a root of $x^2-3x+1=0$, and this is exactly ϕ^2, the square of the golden ratio $\phi=(1+\sqrt{5})/2$, itself a root of the Fibonacci characteristic equation $x^2-x-1=0$. This is not a coincidence but an instance of a general transform: if r_1, r_2 are the roots of $x^2-px+q=0$, Vieta's formulas give $r_1+r_2=p$ and $r_1r_2=q$, so $r_1^2+r_2^2=(r_1+r_2)^2-2r_1r_2=p^2-2q$ and $(r_1r_2)^2=q^2$, meaning r_1^2, r_2^2 are the roots of $x^2-(p^2-2q)x+q^2=0$. With $p=1, q=-1$ this gives exactly $x^2-3x+1=0$. The recursion this generalises: a linear recursion $a_{n+1}=pa_n-qa_{n-1}$ has characteristic roots r_1, r_2, and the subsequence obtained by taking every second term satisfies the recursion with characteristic roots r_1^2, r_2^2; concretely the even indexed Fibonacci numbers satisfy $F_{2n+2}=3F_{2n}-F_{2n-2}$ (check: $F_6=8$ and $3F_4-F_2=3\cdot 3-1=8$), and the even indexed Lucas numbers obey the same recursion. The same idea extends to any power t via Newton's identities on the power sums of r_1, r_2, giving, for instance, r_1^3, r_2^3 as the roots of $x^2-(p^3-3pq)x+q^3=0$, which governs every third term of the original sequence. See Book 1, field: Sequences and recurrences, topic: characteristic root transforms under taking subsequences.

Circuit Bank

- **WHEN** two binomial coefficients are compared whose upper and lower indices are each shifted from one another by a small fixed amount **DO** form the ratio rather than the difference **BECAUSE** the factorial terms overlap almost entirely and cancel to a low degree rational function, while a difference of two such terms generally has no simplification at all
- **WHEN** a strict inequality is given between two quantities known to be positive **DO** convert it to a ratio compared against 1 and cross multiply, after explicitly confirming positivity **BECAUSE** cross multiplying an inequality is only valid once both sides are known to be positive, and stating that positivity range explicitly is what turns a heuristic step into a rigorous one
- **WHEN** the final request is a limit of $X(n)/n$ rather than an exact formula for $X(n)$ **DO** bound $X(n)$ between two quantities sharing the same leading asymptotic behaviour and invoke the sandwich theorem **BECAUSE** any tighter computation of $X(n)$ itself, such as pinning down a floor function exactly, is strictly more work than a normalised limit ever requires
- **WHEN** a limiting constant emerges as a root of a quadratic x^2-px+q **DO** check whether p, q relate to a familiar recursion's characteristic equation, in particular whether the quadratic is the "square the roots" transform of a smaller, more recognisable equation such as $x^2-x-1=0$ **BECAUSE** such constants recur across the Putnam, and recognising the family lets you cite a known closed form and known integer sequence identities instead of re-deriving decimal approximations from scratch

Backtesting

1. First useful cue: two binomial coefficients with indices offset from one another by exactly one on top and one on the bottom, compared by a strict inequality.
2. Method the expression suggested: form the ratio of the two binomial coefficients and simplify by factorial cancellation, rather than expanding a difference or a generating function.
3. Where you would hesitate, and the thought to reinforce: after reducing to a quadratic and finding its larger root $\alpha(n)$, it is tempting to declare $M(n)$ equal to the floor of $\alpha(n)$ without checking that this root actually lies inside the region $m>n+1$ where the ratio identity was derived; that check is one short paragraph and closes a real logical gap.

4. The trap the question sets: the phrase "evaluate the limit" invites solving for $M(n)$ exactly via floor functions and case work on whether $\alpha(n)$ is ever an integer, far more work than a normalised limit requires, when a two sided sandwich of $\alpha(n)$ is already exact and sufficient.
5. What makes you recognise it faster next time: seeing binomial coefficients whose indices differ by one step on each side as an immediate ratio cue, and seeing "evaluate $\lim X(n)/n$" as a signal that bounding, not solving exactly, is the intended route.
6. The reusable decision rule: WHEN two binomial coefficients with nearby indices are compared and only an asymptotic constant is required, DO reduce to a ratio, then a quadratic, then sandwich the extremal integer between the quadratic's larger root and that root minus one, BECAUSE this produces the exact limiting constant without ever computing the discrete extremal value itself.

Mirror drills

1. Let $N(n)$ be the largest integer m with $\binom{m}{n} > \binom{m-1}{n+1}$. Find $\lim N(n)/n$. *Answer:* the same cancellation gives $\binom{m}{n}/\binom{m-1}{n+1} = m(n+1)/[(m-n)(m-n-1)]$, leading to $m^2 - (3n+2)m + (n^2+n) < 0$; dividing by n^2 and letting $n \to \infty$, the lower order shifts vanish and the limit is again $(3+\sqrt{5})/2$.
2. Explain why the sandwich argument for $\lim M(n)/n$ succeeds even though the gap $\alpha(n) - M(n)$ need not converge to any particular value as n varies. *Answer:* a bounded (indeed $O(1)$) discrepancy divided by n tends to 0 regardless of whether the discrepancy itself converges, oscillates, or merely stays bounded, so boundedness alone is all the sandwich theorem for a normalised limit ever needs.
3. A quadratic $x^2 - px + q = 0$ has roots r_1, r_2. Find, in terms of p, q, the quadratic satisfied by r_1^3, r_2^3. *Answer:* using $r_1^3 + r_2^3 = (r_1+r_2)^3 - 3r_1r_2(r_1+r_2) = p^3 - 3pq$ and $(r_1r_2)^3 = q^3$, the equation is $x^2 - (p^3 - 3pq)x + q^3 = 0$.

10.3 A3. cyclic functional equation and its arctan integral

Suppose that f is a function from $\mathbb{R}$ to $\mathbb{R}$ such that

$$f(x) + f\left(1 - \frac{1}{x}\right) = \arctan x$$

for all real $x \neq 0$. (As usual, $y = \arctan x$ means $-\pi/2 < y < \pi/2$ and $\tan y = x$.) Find

$$\int_0^1 f(x)\,dx.$$

Read it out loud

There is exactly one structural device in this equation, the substitution $x \mapsto 1 - 1/x$, and it is reused, not varied, so the first thing to do with it is compose it with itself and see where it goes. A functional equation built from a single repeated substitution is secretly a linear system in the values of f at the points of that substitution's orbit, and you cannot know how to solve the system until you know how large the orbit is. Writing $\sigma(x) = 1 - 1/x$ and computing $\sigma(\sigma(x))$ and $\sigma(\sigma(\sigma(x)))$ by hand, within the first thirty seconds, is the single most useful thing you can do with this problem.

The second cue sits on the right hand side: $\arctan x$. Inverse tangent has a standard reflection property linking $\arctan t$ and $\arctan(1/t)$, and whenever a problem's functional equation pairs a variable with a reciprocal-flavoured transform of itself and the right hand side is arctan, that reflection identity is very likely the mechanism that turns several transcendental terms into a single constant. Fields in play: functional equations and the group structure of the substitution (algebra), inverse trigonometry (a short calculus lemma), and a definite integral at the end (calculus again).

The third cue is the target itself: not "find f", but $\int_0^1 f(x)\,dx$, over an interval that is symmetric under $x \mapsto 1 - x$. Whenever an integral is requested over an interval invariant under some involution, and the integrand is only known through a functional equation, the fast route is almost never to solve for f pointwise first; it is to compute $f(x) + f(1-x)$, since the substitution $u = 1 - x$ shows $\int_0^1 f(x)\,dx = \int_0^1 f(1-x)\,dx$ automatically, so only that sum, not f itself, is ever required.

Approaches, ranked worst to best

1. **solve for f explicitly everywhere, then integrate.** *Cue:* the three term system below determines $2f(x)$ completely, so it is tempting to push through to a genuine closed form for $f(x)$ for every real x. *Circuit:* full inversion of the functional equation before specialising. (this works, since the official remark notes it can be done "with some effort", but it forces you to track the sign of x, the sign of $(x-1)/x$, and the sign of $1/(1-x)$ as three separate case splits inside the reflection identity, merge them into one piecewise formula for f alone, and only then integrate termwise. It reaches the same number after considerably more ink and considerably more room for a sign error.)

2. **substitute the integral representation of arctan and change variables in the resulting double integral.** *Cue:* $\arctan x$ has the integral representation $\int_0^x \frac{dt}{1+t^2}$, and integrating both sides of the functional equation over $[0,1]$ turns the right hand side into a double integral. *Circuit:* representation plus a two dimensional substitution. (a genuine alternate route, credited to an AoPS contributor in the official solutions, but it trades the finite linear system you already have for a new piece of machinery, a change of variables inside a double integral, that has to be set up and justified from scratch. It is not obviously less ink, only differently shaped ink.)

3. **use the substitution's finite order to build a three term linear system, then pair with the interval's own symmetry.** *Cue:* the substitution has order 3, and the target interval $[0,1]$ is itself symmetric under $x \mapsto 1 - x$. *Circuit:* cyclic elimination followed by a reflection identity

and a symmetric pairing. (this needs only linear algebra on three equations, one short calculus lemma proved by differentiating a sum of two arctans, and one substitution to exploit the interval's symmetry. Every step is forced by the structure already present in the statement, and the final integral is the integral of a constant.)

The ideal solution

Write $\sigma(x) = 1 - \frac{1}{x} = \frac{x-1}{x}$. Composing,

$$\sigma(\sigma(x)) = 1 - \frac{1}{\sigma(x)} = 1 - \frac{x}{x-1} = \frac{(x-1)-x}{x-1} = \frac{-1}{x-1} = \frac{1}{1-x}, \qquad \sigma(\sigma(\sigma(x))) = 1-(1-x) = x,$$

so σ has order exactly 3: the three points x, $\sigma(x) = \frac{x-1}{x}$, $\sigma^2(x) = \frac{1}{1-x}$ cycle back to x. For $x \neq 0, 1$ (which keeps x, $\sigma(x)$, $\sigma^2(x)$ all defined and all nonzero, so the given equation may be applied at each), writing the hypothesis at x, at $\sigma(x)$, and at $\sigma^2(x)$ gives

$$\begin{aligned} f(x) + f(\sigma(x)) &= \arctan x, \\ f(\sigma(x)) + f(\sigma^2(x)) &= \arctan\left(\frac{x-1}{x}\right), \\ f(\sigma^2(x)) + f(x) &= \arctan\left(\frac{1}{1-x}\right). \end{aligned}$$

Adding the first and third equations and subtracting the second cancels $f(\sigma(x))$ and $f(\sigma^2(x))$ completely, since each appears once with a plus sign and once with a minus sign, while $f(x)$ appears twice with a plus sign, leaving

$$2f(x) = \arctan x - \arctan\left(\frac{x-1}{x}\right) + \arctan\left(\frac{1}{1-x}\right), \qquad x \neq 0, 1.$$

Before combining terms, record the following short lemma, since it is the only fact doing any real work in what follows. For $t \neq 0$, let $g(t) = \arctan t + \arctan(1/t)$. On $(0, \infty)$, $g'(t) = \frac{1}{1+t^2} + \frac{-1/t^2}{1+1/t^2} = \frac{1}{1+t^2} - \frac{1}{t^2+1} = 0$, so g is constant there, and $g(1) = \arctan 1 + \arctan 1 = \pi/2$; the identical computation on $(-\infty, 0)$ shows g is constant there too, and $g(-1) = -\pi/4 - \pi/4 = -\pi/2$. So

$$\arctan t + \arctan \frac{1}{t} = \begin{cases} \pi/2 & t > 0 \\ -\pi/2 & t < 0 \end{cases} \qquad (t \neq 0).$$

Now substitute $x \to 1 - x$ in the boxed formula for $2f(x)$ (valid since $1 - x \neq 0, 1$ exactly when $x \neq 1, 0$, the same domain):

$$2f(1-x) = \arctan(1-x) - \arctan\left(\frac{-x}{1-x}\right) + \arctan\left(\frac{1}{x}\right).$$

Add this to the formula for $2f(x)$ and regroup into three reciprocal pairs, using $\frac{-x}{1-x} = \frac{x}{x-1}$, the reciprocal of $\frac{x-1}{x}$:

$$2\big[f(x)+f(1-x)\big] = \left[\arctan x + \arctan\frac{1}{x}\right] + \left[\arctan(1-x) + \arctan\frac{1}{1-x}\right] - \left[\arctan\left(\frac{x-1}{x}\right) + \arctan\left(\frac{x}{x-1}\right)\right]$$

For $x \in (0, 1)$: the first bracket has $t = x > 0$, giving $\pi/2$; the second has $t = 1 - x > 0$, giving $\pi/2$; the third has $t = \frac{x-1}{x} < 0$ (numerator negative, denominator positive), giving $-\pi/2$. So

$$2\big[f(x)+f(1-x)\big] = \frac{\pi}{2} + \frac{\pi}{2} - \left(-\frac{\pi}{2}\right) = \frac{3\pi}{2}, \qquad \text{that is,} \qquad f(x)+f(1-x) = \frac{3\pi}{4} \quad \text{for } x \in (0,1).$$

Finally, the substitution $u = 1 - x$ gives $\int_0^1 f(x)\,dx = \int_0^1 f(1-x)\,dx$, so

$$2\int_0^1 f(x)\,dx = \int_0^1 \big[f(x) + f(1-x)\big]\,dx = \int_0^1 \frac{3\pi}{4}\,dx = \frac{3\pi}{4},$$

and therefore

$$\int_0^1 f(x)\,dx = \boxed{\frac{3\pi}{8}}.$$

(The problem's hypothesis presumes such an f exists; nothing above needs that presumption verified, since the question only asks for the value the integral is forced to take given the constraint, not for a construction of f itself.)

Layer 1: WHAT

Block 1: identify $\sigma(x) = 1 - 1/x$ as the only structural device and compose it with itself to discover it has order 3. Block 2: write the hypothesis at x, $\sigma(x)$, $\sigma^2(x)$ and take the alternating sum that cancels the two unwanted values, isolating $2f(x)$ as a sum of three arctan terms. Block 3: prove the short reflection lemma $\arctan t + \arctan(1/t) = \pm\pi/2$. Block 4: instead of simplifying $2f(x)$ alone, form $2f(1-x)$ by the same formula and add the two, so the six arctan terms regroup into three reciprocal pairs. Block 5: use the symmetry of $[0,1]$ under $x \mapsto 1-x$ to convert the target integral into the integral of the now-constant sum $f(x) + f(1-x)$.

The nominal route stops after Block 2 and tries to resolve the three individual arctan terms in $2f(x)$ into an explicit closed form for f alone, tracking the sign of x, of $(x-1)/x$, and of $1/(1-x)$ as three separate, only loosely related case splits, then integrating that explicit piecewise formula term by term. The bifurcation point is the decision, immediately after obtaining the formula for $2f(x)$, not to simplify it in isolation but to write down $2f(1-x)$ and add: that one choice regroups the six arctan terms into exactly the three reciprocal pairs the lemma was built for, and it is the reason the whole computation ends at a constant rather than at a genuine piecewise function.

Layer 2: HOW

Block 1. **Cue.** The equation reuses a single substitution, $x \mapsto 1 - 1/x$, rather than a family of different ones. **Why natural.** A repeatedly applied substitution generates an orbit under composition, and a functional equation is only as easy to solve as that orbit is small; composing the substitution with itself is the cheapest possible way to discover the orbit's size before committing to any algebra. **Link to the next block.** Composing twice gives $1/(1-x)$ and composing three times returns x, so the orbit has exactly three points, and the equation can be written down at all three.

Block 2. **Cue.** Three points in a cycle, each related to the next by the same substitution. **Why natural.** Writing the hypothesis at each of the three points produces three linear equations in the three unknowns $f(x)$, $f(\sigma x)$, $f(\sigma^2 x)$; because the cycle length is odd, each of the two unwanted unknowns appears in exactly two of the three equations, so giving those equations alternating signs cancels both unwanted unknowns while the target unknown, appearing in two equations with the same sign, survives doubled. **Link to the next block.** The result is a formula for $2f(x)$ as a sum of three arctan terms with arguments x, $(x-1)/x$, and $1/(1-x)$, none of which is obviously simple on its own.

Block 3. **Cue.** Two arctan terms with reciprocal arguments would collapse instantly if such an identity existed; here it does. **Why natural.** Differentiating $\arctan t + \arctan(1/t)$ gives 0 away from $t = 0$, so the sum is constant on each half-line, and evaluating at $t = \pm 1$ pins the two constants at $\pm\pi/2$; this is exactly the shape needed to simplify a sum of arctans with reciprocal arguments, but

the three arguments in the formula for $2f(x)$ do not pair up with each other as reciprocals. **Link to the next block.** Since the terms will not pair up within $2f(x)$ alone, the next move is to bring in a second copy of the same formula, evaluated at a related point, so that cross pairing becomes possible.

Block 4. Cue. The eventual target is $\int_0^1 f(x)\,dx$, an integral over an interval symmetric under $x \mapsto 1-x$. **Why natural.** Substituting $x \to 1-x$ into the formula for $2f(x)$ produces $2f(1-x)$, and adding the two formulas together regroups the six arctan terms into exactly three reciprocal pairs, $(x, 1/x)$, $(1-x, 1/(1-x))$, and $((x-1)/x,\ x/(x-1))$, each ready for the lemma from Block 3. **Link to the next block.** Applying the lemma to each pair, with the sign of each argument checked for $x \in (0,1)$, collapses the whole right hand side to the single constant $3\pi/2$.

Block 5. Cue. $f(x) + f(1-x)$ is now a known constant, and the requested integral runs exactly over $[0,1]$. **Why natural.** The substitution $u = 1-x$ shows $\int_0^1 f(x)\,dx = \int_0^1 f(1-x)\,dx$, so their sum integrates to twice the target integral, and since the sum is the constant $3\pi/4$, the target integral is immediate. **Link to the next block.** No further work is needed; the answer follows by dividing by two.

Layer 3: WHY

The truth underneath the whole solution is that a functional equation built from one substitution repeated is a statement about the orbit of that substitution, and an orbit of odd length is always solvable for a single value by an alternating sum, because each unwanted term necessarily appears an even number of times (here twice) across the equations written around the cycle, letting a plus and minus assignment cancel it exactly. The second truth is that $\arctan t + \arctan(1/t)$ is piecewise constant, a fact special to inverse tangent among the inverse trigonometric functions in this clean a form, and it is this bounded, sign-dependent constancy, not anything about the substitution, that turns a sum of transcendental terms into a rational multiple of π. The discernment mechanism is to separate these two truths in your head: the algebra of the substitution's orbit tells you how many equations you need and how to combine them, while the specific right hand side (arctan here) tells you what identity will finish the job once the combination is found, and conflating the two, trying to find the identity before finding the orbit, or trying to guess the orbit's size from the right hand side, wastes time on both.

Training this discernment means practising the reflex of composing a functional equation's substitution with itself before reading the right hand side at all, since the orbit size is a purely algebraic fact about σ, independent of what the equation equals. The examiners nudge you toward the paired-integral shortcut specifically by asking for $\int_0^1 f(x)\,dx$ rather than a general antiderivative or a value at a single point: an interval matching a natural symmetry of the substitution's territory ($[0,1]$ is exactly the fixed set of the induced involution $x \mapsto 1-x$, itself expressible via σ since σ^2 fixes the same reflection structure) is the standing invitation to pair rather than solve pointwise.

Revolving concepts

Cyclic substitutions and alternating elimination. If a substitution σ satisfies $\sigma^k = \mathrm{id}$, writing $f(x) + f(\sigma x) = c(x)$ at $x, \sigma(x), \ldots, \sigma^{k-1}(x)$ gives k linear equations in k unknowns. When k is odd, the alternating sum around the whole cycle isolates $2f(x)$ exactly as it did here, because every other unknown occurs an even number of times with cancelling signs. When k is even, the same alternating sum instead telescopes to zero, giving only a consistency condition rather than a value, so individual values of f generally cannot be recovered this way without extra information; this is why the odd order of σ in this problem is not incidental but load bearing. See Book 1, field: Functional equations, topic: solving cyclic functional equations by elimination.

The order of a Mobius substitution. A map $x \mapsto \frac{ax+b}{cx+d}$ with $ad - bc \neq 0$ composes according to 2×2 matrix multiplication up to an overall scalar, so its order as a function equals the order of the associated matrix in the projective general linear group. Here $\sigma(x) = \frac{x-1}{x}$ corresponds to a matrix of trace 1 and determinant 1, whose characteristic equation $\lambda^2 - \lambda + 1 = 0$ has roots that are primitive sixth roots of unity, which is the structural reason σ has order 3 rather than some other value; the six functions x, $1/x$, $1 - x$, $1/(1 - x)$, $(x - 1)/x$, $x/(x - 1)$ together form the full order six group generated by $x \mapsto 1/x$ and $x \mapsto 1 - x$ (the group permuting a cross ratio under its six standard values), and the three used in this problem are its unique subgroup of order three. See Book 1, field: Geometry, topic: Mobius transformations and cross ratio symmetry.

The arctan reflection identity. For $t \neq 0$, $\arctan t + \arctan(1/t)$ equals $\pi/2$ for $t > 0$ and $-\pi/2$ for $t < 0$, proved by showing the derivative vanishes on each half line and evaluating at $t = \pm 1$. It is the $s = -1/t$ special case of the general subtraction formula $\arctan t - \arctan s = \arctan \frac{t-s}{1+ts}$ read modulo π, and it is the standard mechanism whenever a problem pairs a variable with its negative reciprocal inside two arctan terms. See Book 1, field: Real analysis, topic: inverse trigonometric identities via differentiation.

Pairing $f(x)$ with $f(a - x)$ on a symmetric interval. For any integral $\int_0^a f(x)\,dx$, the substitution $u = a - x$ shows it equals $\int_0^a f(a - x)\,dx$, so twice the integral equals $\int_0^a [f(x) + f(a - x)]\,dx$; whenever that sum simplifies, the original integral is found without ever isolating f pointwise. See Book 1, field: Calculus and integrals, topic: symmetry substitutions in definite integrals.

Circuit Bank

- **WHEN** a functional equation reuses a single substitution rather than a family of different ones **DO** compose the substitution with itself to find its order before doing any further algebra **BECAUSE** the order tells you exactly how many equations and unknowns the problem reduces to, and whether a clean alternating sum exists, which happens precisely when the order is odd
- **WHEN** two arctan (or other inverse trigonometric) terms appear with reciprocal or negative reciprocal arguments **DO** apply the reflection identity $\arctan t + \arctan(1/t) = \pm\pi/2$, fixing the sign from the sign of t **BECAUSE** this is the standard mechanism collapsing a sum of two inverse trig terms to a constant, and the sign of t is the only case work it requires
- **WHEN** a definite integral of an unknown function defined by a functional equation is requested over an interval symmetric under some involution **DO** pair $f(x)$ with f of the involution's image of x and integrate their sum, rather than solving for f pointwise first **BECAUSE** the substitution defining the involution shows both orderings of the integral are equal, so only the sum needs to be known, and that sum is often forced to a constant even when f itself is not
- **WHEN** a problem only asks for a definite integral of a function pinned down by a functional equation **DO** resist finding a full closed form for f before integrating **BECAUSE** the target combination, an orbit sum or an involution pair sum, is frequently far simpler than f itself, and finding f completely solves a harder problem than the one asked

Backtesting

1. First useful cue: a single substitution, $1 - 1/x$, reused inside the equation, feeding a function whose right hand side is arctan.
2. Method the expression suggested: compose the substitution with itself to find its order, then write the given equation at every point of the resulting orbit.

3. Where you would hesitate, and the thought to reinforce: after finding the order is three and writing three equations, the right sign pattern for the alternating sum is not automatic; the reinforcing thought is that each unwanted unknown occurs in exactly two of the three equations, so opposite signs on those two equations cancel it while the target unknown, occurring in two equations with the same natural sign, survives doubled.
4. The trap the question sets: it looks as though f must be found explicitly, sign case by sign case, before the integral can be evaluated, when pairing $f(x)$ with $f(1-x)$ using the interval's own symmetry bypasses ever finding f pointwise.
5. What makes you recognise it faster next time: seeing a request for $\int_0^1 f(x)\,dx$ specifically, an interval symmetric under $x \mapsto 1-x$, as an immediate invitation to compute $f(x)+f(1-x)$ rather than $f(x)$ alone.
6. The reusable decision rule: WHEN a functional equation's substitution has finite odd order k, DO write the equation around the whole cycle and take the alternating sum to isolate $2f(x)$, and WHEN the actual target is a symmetric definite integral, DO additionally pair that result with its image under the interval's own symmetry before integrating, BECAUSE the pairing frequently collapses transcendental terms to a constant via a standard reflection identity that the isolated formula alone does not display.

Mirror drills

1. Verify directly that composing $\sigma(x) = 1 - 1/x$ with itself three times returns x, and write the two other nontrivial maps in the cycle in simplest form. *Answer:* $\sigma^2(x) = \dfrac{1}{1-x}$ and $\sigma^3(x) = x$; the cycle is x, $\dfrac{x-1}{x}$, $\dfrac{1}{1-x}$.
2. Suppose $g(x) + g\left(\dfrac{1}{1-x}\right) = x$ for all $x \neq 0, 1$. Using the same cyclic elimination (note $\tau(x) = 1/(1-x)$ is σ^2 from the main solution, so it also has order 3), find the analogous formula for $2g(x)$. *Answer:* $2g(x) = x - \dfrac{1}{1-x} + \left(1 - \dfrac{1}{x}\right)$, obtained by adding the equations at x and at $\tau^2(x) = \sigma(x)$ and subtracting the equation at $\tau(x)$.
3. If the right hand side of the original equation were an even function $E(x) = E(-x)$ instead of $\arctan x$, would $f(x) + f(1-x)$ still be forced to a constant on $(0,1)$ by the same method. *Answer:* not in general; the collapse relied specifically on $\arctan t + \arctan(1/t)$ being piecewise constant, a special reflection property of arctan, and a generic even function satisfies no such reciprocal-sum identity, so the paired sum would typically remain a genuine, non-constant function of x.

10.4 A4. Minimum tile count for an odd rectangle

Consider a $(2m-1) \times (2n-1)$ rectangular region, where m and n are integers such that $m, n \geq 4$. This region is to be tiled using tiles of the two types shown:

(the dotted lines of the printed figure divide the tiles into 1×1 squares: the first tile is a 2×2 square with one unit cell deleted, the second is a 2×3 rectangle with two opposite corner cells deleted). The tiles may be rotated and reflected, as long as their sides are parallel to the sides of the rectangular region. They must all fit within the region, and they must cover it completely without overlapping.

What is the minimum number of tiles required to tile the region?

Read it out loud

This is a tiling question with two polyominoes: an L tromino of area 3 and an S tetromino of area 4, on a board whose two side lengths are both odd, written for you as $2m-1$ and $2n-1$. It asks for a minimum, so it is an extremal question, which means two separate jobs: a lower bound that no tiling can beat, and one explicit tiling that meets it. Neither half alone scores.

The fields wired into it are combinatorial tiling, colouring and weighting invariants, and constructive induction on a board. There is no algebra here and no geometry beyond incidence of unit cells. What is really being tested is whether you know that the minimum tile count of a tiling is bounded below by a sparse witness set, and whether you can then run a routine strip decomposition to build the matching construction. It is a two-sided extremal problem dressed up as a puzzle.

The first cue is the parametrisation itself. The examiners did not write "an odd by odd rectangle"; they wrote $(2m-1) \times (2n-1)$, and they did not write the answer in terms of side lengths. They have handed you m and n and are waiting for an answer in m and n. The set of cells with both coordinates odd has exactly m choices of column and n choices of row, so it has exactly mn points. Within thirty seconds you should have written down "odd cells: mn of them" and the guess "answer mn", because that is the only clean function of m and n anywhere near the area count.

The second cue is the total area, $(2m-1)(2n-1) = 4mn - 2m - 2n + 1$. Divide by the largest tile: you get $mn - \frac{2m+2n-1}{4}$, strictly less than mn. So if the answer really is mn, the area bound is not the obstruction and you must find a combinatorial one. That single comparison is what tells you to go hunting for a colouring instead of grinding on constructions.

Approaches, ranked worst to best

1. **Area accounting only.** *Cue:* the words "minimum number of tiles" with tiles of areas 3 and 4. *Circuit:* divide the area by the largest tile and round up. This gives at least $\lceil (4mn - 2m - 2n + 1)/4 \rceil = mn - \lfloor (2m + 2n - 1)/4 \rfloor$ tiles, which for $m = n = 4$ reads 13. It is true and useless: you would then burn the rest of the session trying to build a 13 tile or 14 tile covering of the 7×7 square that does not exist. Worse than useless, in fact, because it makes you confident in a wrong target.

2. **Checkerboard colouring.** *Cue:* it is a tiling problem, so colour it. *Circuit:* count the imbalance between the two colours. The tromino covers two of one colour and one of the other, the tetromino covers two of each. The board has one more black cell than white. You get an inequality with no bite, because both tiles are nearly balanced. This is the reflex answer and it fails; knowing why it fails is what points you at the right colouring.

3. **Strip induction for a construction, with the bound assumed.** *Cue:* the side lengths $2m-1$ and $2n-1$ peel naturally into strips of width 2. *Circuit:* reduce a large board to a fixed base block plus strips. This half is genuinely necessary and you will use it, but on its own it proves only that mn tiles suffice. A Putnam grader gives you at most half the marks for one side of an extremal problem.

4. **Sparse witness colouring plus strip construction.** *Cue:* the tromino fits inside a 2×2 box, and the board is given as $2m-1$ by $2n-1$. *Circuit:* find the largest set of cells that no single tile can cover twice, then match it with a construction. Best. The lower bound is three lines, the construction is a decomposition into a 7×7 base case and strips of width 2, and the two meet exactly at mn. Every step is finite and checkable in the arena.

The ideal solution

The answer is $\boxed{mn}$.

Index the cells of the region by (i, j) with $1 \le i \le 2m-1$ the column and $1 \le j \le 2n-1$ the row. Call the two tiles the *tromino* (a 2×2 block of cells with one cell deleted) and the *tetromino* (a 2×3 block of cells with two opposite corner cells deleted). Call a cell *red* if i and j are both odd.

Lemma 10.4.1. *There are exactly mn red cells, and every legal placement of either tile covers at most one red cell. Consequently every tiling of the region uses at least mn tiles.*

Proof. The odd values of i in $\{1, \dots, 2m-1\}$ are $1, 3, \dots, 2m-1$, so there are m of them, and likewise n odd values of j; hence mn red cells.

A tromino occupies three of the four cells of some 2×2 block, with columns $\{i, i+1\}$ and rows $\{j, j+1\}$. Exactly one of $i, i+1$ is odd and exactly one of $j, j+1$ is odd, so that block contains exactly one red cell, and the tromino covers at most one.

A tetromino in horizontal orientation occupies columns $\{i, i+1, i+2\}$ and rows $\{j, j+1\}$, taking two horizontally adjacent cells in one row and the two horizontally adjacent cells shifted by one column in the other row. Exactly one of the rows $j, j+1$ is odd, so every red cell it covers lies in that one row; in that row it occupies exactly two consecutive columns, exactly one of which is odd. So it covers exactly one red cell. The vertical orientation is the same statement with rows and columns interchanged.

Since each tile covers at most one red cell and all mn red cells must be covered, a tiling has at least mn tiles. □

Lemma 10.4.2. *For every integer $k \ge 2$, a $2 \times (2k-1)$ rectangle can be tiled by exactly k tiles.*

Proof. Take the two rows to be a top row and a bottom row, and number the columns $1, \dots, 2k-1$.

For $k = 2$ the rectangle is 2×3 and two trominoes tile it: one covering the whole of column 1 together with the bottom cell of column 2, the other covering the top cell of column 2 together with the whole of column 3.

For $k \ge 3$, place a tromino on the whole of column 1 together with the bottom cell of column 2. Then for $t = 1, 2, \dots, k-2$ place a tetromino on the top cells of columns $2t$ and $2t+1$ together with the bottom cells of columns $2t+1$ and $2t+2$; this is a legal placement since $2t+2 \le 2k-2 < 2k-1$. An immediate induction on t shows that after the tth tetromino, columns 1 through $2t+1$ are completely covered and exactly the bottom cell of column $2t+2$ is covered beyond them. Taking $t = k-2$: columns 1 through $2k-3$ are full and the bottom cell of column $2k-2$ is covered. The three cells that remain are the top cell of column $2k-2$ and both cells of column $2k-1$, which form a tromino. The count is $1 + (k-2) + 1 = k$. □

Lemma 10.4.3. *The 7×7 square can be tiled by 16 tiles.*

Proof. Here is such a tiling, written as a 7×7 array in which the cells carrying the same label form one tile (rows listed from top to bottom, columns from left to right):

1	1	3	3	5	6	6
2	1	4	3	5	5	6
2	2	4	4	7	8	8
13	14	14	4	7	7	8
13	13	14	9	9	11	11
15	16	16	10	9	12	11
15	15	16	10	10	12	12

Tile 4 occupies the cells in rows 2,3,3,4 and columns 3,3,4,4, that is, a 3×2 block with two opposite corners removed, so it is a tetromino in vertical orientation. Each of the other fifteen labels occupies three cells of a 2×2 block, so each is a tromino. The labels exhaust all 49 cells with no repetition, and $15 \cdot 3 + 4 = 49$ confirms the areas. □

To see where that array comes from rather than merely that it works: delete the centre cell of the 7×7 square and the remaining 48 cells split into four 3×4 rectangles arranged as a pinwheel, namely rows 1 to 3 with columns 1 to 4, rows 1 to 4 with columns 5 to 7, rows 5 to 7 with columns 4 to 7, and rows 4 to 7 with columns 1 to 3. Each 3×4 rectangle splits into two 2×3 rectangles and each 2×3 rectangle is two trominoes, which would give 16 trominoes and area 48. The one cell left over is the centre, so exactly one of those 2×3 rectangles must be enlarged by the centre cell into a 7 cell region, and 7 cells is one tromino plus one tetromino. The array above does this with the 2×3 block in rows 1 to 3, columns 3 to 4.

Now assemble. Let $m, n \geq 4$ and take the region to have $2m - 1$ columns and $2n - 1$ rows. Split it into

1. the 7×7 square formed by columns 1 to 7 and rows 1 to 7;
2. for each $s = 1, \ldots, m - 4$, the block of columns $\{6 + 2s, 7 + 2s\}$ and rows 1 to 7, a 2×7 rectangle;
3. for each $t = 1, \ldots, n - 4$, the block of all $2m - 1$ columns and rows $\{6 + 2t, 7 + 2t\}$, a $(2m - 1) \times 2$ rectangle.

These pieces are pairwise disjoint and their union is the whole region, because $7 + 2(m - 4) = 2m - 1$ and $7 + 2(n - 4) = 2n - 1$. By Lemma 2 with $k = 4$, each 2×7 rectangle takes 4 tiles; by Lemma 2 with $k = m$, each $(2m - 1) \times 2$ rectangle takes m tiles; by Lemma 3 the square takes 16. The total is

$$16 + 4(m - 4) + m(n - 4) = 16 + 4m - 16 + mn - 4m = mn.$$

So mn tiles suffice, and by Lemma 1 no tiling uses fewer. The minimum is mn.

Remark 10.4.4. The count of each tile type in a minimum tiling is forced. If a tiling uses a trominoes and b tetrominoes then $3a + 4b = 4mn - 2m - 2n + 1$, and $a + b = mn$ gives $b = mn - 2m - 2n + 1 = (m - 2)(n - 2) - 3$. For $m, n \geq 4$ this is at least 1, so every minimum tiling must contain at least one tetromino; at $m = n = 4$ it equals 1, which is why the 7×7 base case uses exactly one.

Layer 1: WHAT

Block 1. Name the tiles: L tromino, area 3, bounding box 2×2; S tetromino, area 4, bounding box 2×3.

Block 2. Compute the area $4mn - 2m - 2n + 1$ and the area bound $mn - \frac{2m+2n-1}{4}$. Note that the natural guess mn exceeds it, so the binding constraint is not area.

Block 3. Ask the only question that produces a better bound: what is the largest set of cells that no single tile can cover twice? Because the tromino lives in a 2×2 box, such a set may not contain

two cells of one 2×2 box, so its cells must differ by at least 2 in one coordinate. The densest such set is the cells with both coordinates odd.

Block 4. Verify the tetromino also covers at most one of them. Count them: mn. Lower bound complete.

Block 5. Build. Strips of width 2 are the natural unit because $2m - 1 = 7 + 2(m - 4)$ and $2n - 1 = 7 + 2(n - 4)$: peel strips until only a 7×7 square is left.

Block 6. Tile a $2 \times (2k - 1)$ strip with k tiles (tromino, then tetrominoes climbing the staircase, then tromino), and tile the 7×7 with 16 by pinwheeling four 3×4 rectangles around the centre cell and paying for the centre cell with the single tetromino.

Block 7. Add: $16 + 4(m - 4) + m(n - 4) = mn$. Bound and construction meet, so the minimum is mn.

The nominal route goes: compute the area, divide by 4, start drawing tilings of the 7×7 square on squared paper, discover after twenty minutes that 15 tiles seems to be the floor, fail to prove it, and hand in a construction with a hand wave. The ideal route never draws a single tiling until the lower bound is in hand.

The bifurcation point is the line immediately after the area computation. Zombie: "the bound is about $mn - 2$, so let me try to hit it". Ideal: "the bound is not an integer of the right shape, so area is the wrong invariant; which cells can a single tile not hit twice?" Everything downstream follows from that one question.

Layer 2: HOW

Block 1. Cue. Two tiles are drawn with dotted subdivision lines, and the question asks only for a count. **Why natural.** Before anything else you convert a picture into two numbers and two boxes: area 3 in a 2×2 box, area 4 in a 2×3 box. The bounding box is not decoration; for tiling bounds the bounding box is the whole content of the tile, because any invariant that is constant on 2×2 boxes automatically controls the tile. **Link to the next block.** Once you have the areas you can price the board, and pricing the board is the only cheap thing available.

Block 2. Cue. "Minimum number of tiles" with tiles of different areas. **Why natural.** The area bound is free and takes one line, so you always take it, but you always then ask whether it is tight. Here the total area $4mn - 2m - 2n + 1$ is odd while the tiles have areas 3 and 4, and the bound $mn - \frac{2m+2n-1}{4}$ has a denominator that does not belong in an answer expressed in m and n. The examiners gave you m and n; they expect an answer built from them. **Link to the next block.** A bound you do not believe is a bound you must replace, and the standard replacement in tiling is a colouring.

Block 3. Cue. The tromino fits inside a 2×2 block of cells. **Why natural.** This is the definition-level step. A tile covers at most one cell of a set R precisely when R is sparse relative to the tile's footprint. For a tile confined to a 2×2 box, "no two cells of R inside one 2×2 box" is exactly "any two cells of R differ by at least 2 in the row index or by at least 2 in the column index". The densest set with that property is the sublattice of cells whose row and column indices are both odd, and it is the densest because every 2×2 box must contain at most one point of R while the odd sublattice contains exactly one. So the colouring is derived, not guessed. **Link to the next block.** You now have a candidate witness set; before using it you must confirm the second tile obeys the same rule, since one bad tile destroys the bound.

Block 4. Cue. The tetromino has a 2×3 box, which contains two red cells, so the check is not automatic. **Why natural.** You look at where the tetromino's cells sit inside its box. Only one of its two rows is odd, and in that row it holds exactly two consecutive columns, of which exactly one

is odd. So it covers exactly one red cell, not two. That "exactly", stronger than what you need, is the sign that this colouring is the right one: the tetromino cannot even waste a red cell. **Link to the next block.** With the invariant verified, the count of red cells on a $(2m-1)\times(2n-1)$ board is immediate and gives the lower bound mn.

Block 5. **Cue.** The side lengths are $2m-1$ and $2n-1$ with $m,n\geq 4$, and $2m-1-7=2(m-4)$. **Why natural.** The hypothesis $m,n\geq 4$ is the examiner telling you the base case is 7×7 and the increment is 2. When a construction must work for all large parameters, you never build the general board directly; you build one fixed block and one repeating unit, and check that the repeating unit is cheap enough. Here the repeating unit is a strip of width 2. **Link to the next block.** Strips of width 2 and odd length are small enough to tile by hand, so the whole construction reduces to two finite checks.

Block 6. **Cue.** A $2\times(2k-1)$ strip has odd length, so it cannot be cut into 2×2 blocks; something must absorb the odd cell. **Why natural.** The tetromino is exactly a staircase step: it advances the boundary between covered and uncovered by two columns while flipping which row is ahead. So a chain of tetrominoes moves along the strip, and the two ends, where the staircase must start and stop flush, are exactly where the trominoes go. That is why the pattern is tromino, then tetrominoes, then tromino, and why the count is $1+(k-2)+1=k$, which matches the red cell count k of the strip. The strip is itself extremal. **Link to the next block.** The same accounting applied to the 7×7 base case says you need 16 tiles there, and area forces 15 trominoes and 1 tetromino.

Block 7. **Cue.** $49=15\cdot 3+4$, and $48=8\cdot 6$. **Why natural.** Since fifteen of the sixteen tiles are trominoes and two trominoes tile a 2×3 rectangle, aim to cover the board by 2×3 rectangles and see what is left over. Deleting the centre cell of an odd square leaves a region that pinwheels into four congruent rectangles, which is the standard way to handle a square with a distinguished centre. Then one 2×3 rectangle adopts the centre cell to make a 7 cell region, and $7=3+4$ tells you that region is one tromino plus one tetromino. **Link to the next block.** Adding the base case to the strips gives $16+4(m-4)+m(n-4)=mn$, which meets the lower bound, so both halves are done and the problem is closed.

Layer 3: WHY

The mathematical truth underneath the lower bound is this. Let R be any set of cells such that every legal placement of every tile covers at most one cell of R. Then in any tiling, the map sending each cell of R to the tile covering it is injective, so the number of tiles is at least $|R|$. That is the whole of the colouring method, and it is a special case of linear programming duality: the minimum number of tiles is the value of a covering programme, and any assignment of weights to cells whose sum over each legal tile placement is at most 1 gives a lower bound equal to the total weight. Colourings are the 0 and 1 weightings. When 0 and 1 weightings are too crude, fractional weightings sometimes do better; here they do not need to, because the 0 and 1 witness already meets a construction.

The discernment mechanism, the thing you must actually train, is the choice of R. You do not guess colourings. You compute the bounding boxes of the tiles, take the smallest one, and ask for the maximum set of cells meeting every translate of that box at most once. For a 2×2 box the answer is forced: the four cosets of the sublattice $2\mathbb{Z}\times 2\mathbb{Z}$ are the only candidates of maximum density, and on a board with both side lengths odd the coset "odd, odd" is strictly the largest, with mn points against $m(n-1)$, $(m-1)n$ and $(m-1)(n-1)$ for the other three. That is the entire reason the problem says $2m-1$ by $2n-1$ instead of giving numbers: odd side lengths maximise the witness set, and the answer mn is just its size. Read the parametrisation as a hint about what to count and you have solved the problem before you have started it.

The second truth is that in an extremal tiling problem the area bound and the colouring bound measure different kinds of waste. The area bound measures how much space the tiles occupy; the colouring bound measures how much of a scarce resource they consume. Whenever the tile set contains pieces of unequal area, the area bound is achieved only if the largest tile is used almost everywhere, and you can test that instantly: here $b = (m-2)(n-2) - 3$ tetrominoes in a minimum tiling against $a = mn - b$ trominoes, so the tetromino is rare and the area bound is hopeless. Do that arithmetic before choosing which bound to chase.

The examiners nudged in three places. They wrote the sides as $2m-1$ and $2n-1$ rather than as odd numbers, which is a direct instruction to count an odd sublattice. They imposed $m, n \geq 4$, which is exactly the condition making at least one tetromino necessary and making the 7×7 plus strips decomposition legal, so it names the base case for you. And they drew a tromino whose bounding box is 2×2, which is the smallest useful footprint and therefore the one that dictates the colouring. Three cues, one route.

To train this: for every tiling problem you meet, before attempting anything, write the bounding box of each tile, list the sublattices that meet each box at most once, and count them on the given board. If the largest count exceeds the area bound, you have your answer and you only need a construction. That takes ninety seconds and it decides the problem.

Revolving concepts

Polyomino and tiling. A polyomino is a finite edge connected union of unit cells; a tiling of a region is a partition of its cells into congruent copies (here under rotation and reflection) of the allowed pieces. Packing is the same with "cover at most once" instead of "exactly once"; every lower bound proved by a witness set is really a packing bound and therefore survives if you weaken tiling to packing. See Book 1, field: Combinatorics, topic: polyomino tilings.

Colouring and weighting invariants. The general statement is the one proved above: a weight function w on cells with $\sum_{c \in T} w(c) \leq 1$ for every legal placement T gives #tiles $\geq \sum_c w(c)$. The classical instances you must have installed are the mutilated chessboard (dominoes and a two colouring), the 8×8 board and the T tetromino (a four colouring), and de Bruijn's theorem that an $a \times b$ brick tiles a box only if the box is "harmonic" in the same sense. The deep generalisation, which is beyond A level and worth naming as a gap, is the Conway and Lagarias tiling group, where you replace colourings with a boundary word in a finitely presented group and get obstructions no colouring can see. See Book 1, field: Combinatorics, topic: colouring invariants for tilings.

Maximum sparse set. The witness set is the maximum independent set of the graph whose vertices are cells and whose edges join two cells lying in a common bounding box of some tile. For a 2×2 box this graph is the king graph, and its independent sets are exactly the sets with no two cells within Chebyshev distance 1, so the maximum on a $(2m-1) \times (2n-1)$ board has mn elements, realised uniquely by the odd sublattice. See Book 1, field: Discrete structures and graphs, topic: independent sets.

The recursions, generalised. Two recursions appear and both are of the "add a fixed slab, pay a fixed cost" type. The strip recursion is $T(k) = T(k-1) + 1$ with $T(2) = 2$, whose solution is $T(k) = k$: adding two columns to a strip of height 2 costs one more tile. The board recursion is $N(m,n) = N(m-1,n) + n$ and $N(m,n) = N(m,n-1) + m$ with base $N(4,4) = 16$, whose solution is $N(m,n) = mn$. The general form is $N(m,n) = N(m-1,n) + f(n)$ with f independent of m, solved by $N(m,n) = N(m_0,n) + (m-m_0)f(n)$; whenever a construction is built by appending congruent slabs, write this recursion down explicitly rather than describing the picture, because the closed form is what you compare to the lower bound. The same pattern governs every "tile a large board by peeling strips" argument. See Book 1, field: Sequences and recurrences, topic: linear recursions with constant increment.

Extremal two sidedness. Any answer to "find the minimum" is a pair (bound, example). The write-up convention is to state the answer first, prove the bound, then exhibit the example and

verify it explicitly. See Book 1, field: Combinatorics, topic: extremal arguments.

Circuit Bank

- **WHEN** a tiling question asks for the minimum number of tiles **DO** look for the largest set of cells that no single tile can cover twice, and count it **BECAUSE** each tile then consumes at most one witness cell, so the tile count is at least the witness count, and this beats the area bound whenever the tiles have unequal areas
- **WHEN** a tile family contains a piece whose bounding box is 2×2 **DO** test the four sublattices given by the parity of the two coordinates **BECAUSE** every 2×2 box contains exactly one cell of each parity class, so each class is automatically a valid witness set, and on an odd by odd board the "odd, odd" class is the biggest
- **WHEN** a board is described as $(2m-1) \times (2n-1)$ rather than by explicit numbers **DO** read it as an instruction to count something of size mn **BECAUSE** the examiner chose the parametrisation so that the answer is a clean function of m and n, and the odd sublattice is the only natural object of size mn
- **WHEN** you must construct a tiling for all large m and n **DO** fix one base block and one repeating slab of width 2, and write the slab recursion **BECAUSE** the construction then reduces to two finite checks and one arithmetic identity, instead of an unbounded family of pictures
- **WHEN** your lower bound and your construction agree **DO** stop, and state the answer **BECAUSE** extremal problems are two sided, and further optimisation of either half is wasted ink

Backtesting

1. First useful cue: the side lengths are written as $2m-1$ and $2n-1$, and the tromino's bounding box is 2×2. Together these say "count the cells with both coordinates odd", and there are exactly mn of them.
2. Method the expression suggested: a witness colouring for the lower bound, then a decomposition of the board into one 7×7 base square and strips of width 2 for the construction.
3. Where you would hesitate, and the thought to reinforce: at the tetromino check, because its 2×3 bounding box does contain two red cells and for a moment the whole colouring looks dead. The thought to reinforce is that a tile is not its bounding box; you must look at which cells of the box the tile actually occupies. Here the tetromino uses only one of the two rows that could be odd, and only two consecutive columns of that row, so it covers exactly one red cell.
4. The trap the question sets: the area bound. It is easy, it is wrong as a target, and it points you at 13 or 14 tiles for the 7×7 square, which sends you hunting for a tiling that does not exist. The second trap is stopping after the construction, which is worth about half the marks.
5. What makes you recognise it faster next time: the reflex "unequal tile areas plus a request for a minimum equals colouring, not area". Also the reflex that a hypothesis like $m, n \geq 4$ is naming your base case.
6. The reusable decision rule: for any tiling minimum, compute the tile bounding boxes first, take the maximum set of cells meeting every translate of the smallest box at most once, count it on the given board, and compare with the area bound before writing anything else.

Mirror drills

1. Show that in any tiling of the $(2m-1)\times(2n-1)$ board that uses exactly mn tiles, the number of tetrominoes is exactly $(m-2)(n-2)-3$, and deduce that at least one tetromino is used when $m,n\geq 4$. *Answer:* with a trominoes and b tetrominoes, $3a+4b=4mn-2m-2n+1$ and $a+b=mn$; subtract three times the second from the first to get $b=mn-2m-2n+1=(m-2)(n-2)-3\geq 4-3=1$.
2. Prove that no $(2m-1)\times(2n-1)$ board can be tiled by tetrominoes alone, for any $m,n\geq 1$. *Answer:* the area $(2m-1)(2n-1)$ is odd and every tetromino has area 4, so the area is not divisible by 4; in fact it is not even.
3. A $2\times(2k-1)$ strip: prove that k tiles are needed as well as sufficient. *Answer:* the strip has k cells with both coordinates odd (one row is odd, and k of the $2k-1$ columns are odd), each tile covers at most one of them, and Lemma 2 achieves k.

10.5 A5. Bounded alternating words in two generators

Suppose that G is a finite group generated by the two elements g and h, where the order of g is odd. Show that every element of G can be written in the form

$$g^{m_1}h^{n_1}g^{m_2}h^{n_2}\cdots g^{m_r}h^{n_r}$$

with $1 \leq r \leq |G|$ and $m_1, n_1, m_2, n_2, \ldots, m_r, n_r \in \{-1, 1\}$. (Here $|G|$ is the number of elements of G.)

Read it out loud

This is a finite group theory question with two separate demands hidden inside one sentence. The first demand is qualitative: every element must be reachable at all by words of this restricted shape. The second is quantitative: reachable in at most $|G|$ blocks. Read the word out loud and you hear the structure immediately, because $g^{m_1}h^{n_1}g^{m_2}h^{n_2}\cdots$ is not a word in g and h at all. It is a word in the four products

$$gh, \quad gh^{-1}, \quad g^{-1}h, \quad g^{-1}h^{-1},$$

and r is its length. That single re-reading is the whole problem: you were handed two generators with unrestricted exponents and you must work instead with an alphabet of four fixed letters and no inverses allowed.

The fields wired in are elementary finite group theory (generated subgroups, order of an element, Lagrange and index 2 subgroups) and a counting principle that is really graph reachability: how many steps does it take for a growing set to fill a finite set. There is nothing analytic and nothing about the specific structure of G; every step must work for an arbitrary finite group.

Within thirty seconds you should have written down $T = \{g^{\pm 1}h^{\pm 1}\}$ and the two questions "does T generate G?" and "why $|G|$?". You should also have noticed where the odd order hypothesis must live. It cannot be about the bound, because the bound $|G|$ is a counting statement that has nothing to do with parity. So it must be about reachability, that is, about whether T generates. And it takes one line to see how: the four letters let you form

$$(gh)(g^{-1}h)^{-1} = ghh^{-1}g = g^2,$$

so the subgroup generated by T contains g^2, and g^2 is a generator of $\langle g \rangle$ precisely when the order of g is odd. The hypothesis is not decoration; it is the hinge.

Approaches, ranked worst to best

1. **Direct word rewriting.** *Cue:* every element is some word in $g^{\pm 1}, h^{\pm 1}$, so massage that word into the required shape. *Circuit:* normal form manipulation, inserting hh^{-1} and gg^{-1} to force alternation. You can indeed pad a general word into alternating shape, but g^k for k large needs k blocks, and nothing in the process bounds r by $|G|$. It also never uses the odd order hypothesis, which is proof that it is the wrong route: a proof that does not consume the hypothesis is a proof of something false.

2. **Cayley digraph and shortest paths.** *Cue:* the phrase "with $1 \leq r \leq |G|$" is a diameter bound. *Circuit:* build the digraph on G with an edge $s \to st$ for each $t \in T$, then take a shortest path. Correct and intuitive: a shortest path cannot repeat a vertex, so it has at most $|G|$ edges. But you still have to prove the digraph is strongly connected, which is exactly the reachability half of the problem, so the graph language buys you only the bound, and it buys it at the cost of a paragraph setting up vocabulary.

3. **Shortest representation plus pigeonhole.** *Cue:* a minimum exists because lengths are positive integers. *Circuit:* take a shortest word, look at its partial products, and delete a repeated one. Clean and short. You prove reachability separately (a nonempty subset of a finite group closed under multiplication is a subgroup), then bound the length by pigeonhole on the partial products. Two arguments, both standard.
4. **Grow or stabilise.** *Cue:* the reachable sets $S_1 \subseteq S_2 \subseteq \cdots$ live inside a finite set. *Circuit:* a monotone chain in a finite set either strictly grows or is stable, and stability upgrades to invariance under the whole group. Best, because it does both jobs at once. You never need a separate reachability argument and never need minimality: each step either adds an element or ends the proof, so after $|G|$ steps you are done. It is also the argument that generalises without change to any finite state reachability problem.

The ideal solution

Write e for the identity of G and set

$$T = \{\, gh,\ gh^{-1},\ g^{-1}h,\ g^{-1}h^{-1} \,\} \subseteq G.$$

An expression $g^{m_1}h^{n_1}\cdots g^{m_r}h^{n_r}$ with all $m_i, n_i \in \{-1, 1\}$ is precisely a product of r elements of T, so the assertion to be proved is: every element of G is a product of at most $|G|$ elements of T, using at least one factor. For $r \geq 1$ let

$$S_r = \{\, t_1 t_2 \cdots t_k \ :\ 1 \leq k \leq r,\ t_1, \ldots, t_k \in T \,\},$$

so that $S_1 \subseteq S_2 \subseteq \cdots \subseteq G$ and $S_r \neq \varnothing$. The goal is $S_{|G|} = G$.

Lemma 10.5.1. *The subgroup $\langle T \rangle$ generated by T is the whole of G.*

Proof. Since $\langle T \rangle$ is a subgroup containing gh and $g^{-1}h$, it contains

$$(gh)(g^{-1}h)^{-1} = (gh)(h^{-1}g) = g^2.$$

Let d be the order of g; by hypothesis d is odd, say $d = 2e + 1$. Then

$$(g^2)^{e+1} = g^{2e+2} = g^{d+1} = g,$$

so $g \in \langle T \rangle$. Hence $h = g^{-1}(gh) \in \langle T \rangle$ as well, and therefore $\langle T \rangle \supseteq \langle g, h \rangle = G$. □

Lemma 10.5.2. *If $S_r = S_{r+1}$ for some $r \geq 1$, then $S_r = G$.*

Proof. Let $t \in T$. Appending the letter t to a product of at most r letters gives a product of at most $r + 1$ letters, so $S_r t \subseteq S_{r+1} = S_r$. Right multiplication by t is a bijection of G, so $|S_r t| = |S_r|$, and a subset of S_r of the same finite size as S_r equals S_r; thus $S_r t = S_r$, and applying t^{-1} on the right of both sides gives $S_r t^{-1} = S_r$ too.

Therefore the set $H = \{x \in G : S_r x = S_r\}$ contains T, and it is a subgroup of G because $S_r(xy) = (S_r x)y$ and $S_r x^{-1} = S_r$ whenever $S_r x = S_r$. By Lemma 1, $H \supseteq \langle T \rangle = G$, so $S_r x = S_r$ for every $x \in G$. Pick any $u \in S_r$ (possible since $gh \in S_1 \subseteq S_r$). Then $ux \in S_r$ for every $x \in G$, and $\{ux : x \in G\} = G$, so $S_r = G$. □

Proof of the required statement. We show by induction on $r \geq 1$ that $|S_r| \geq \min\{r, |G|\}$.

For $r = 1$ this says $|S_1| \geq 1$, which holds since $gh \in S_1$. Suppose it holds for some $r \geq 1$. If $S_r = G$ then $S_{r+1} = G$ and the claim for $r + 1$ is immediate. If $S_r \neq G$ then Lemma 2 forces $S_r \neq S_{r+1}$, so $S_{r+1} \supsetneq S_r$ and $|S_{r+1}| \geq |S_r| + 1 \geq \min\{r, |G|\} + 1 \geq \min\{r + 1, |G|\}$, where the last inequality uses that $|S_r| \geq |G|$ would give $S_r = G$. This completes the induction.

Taking $r = |G|$ gives $|S_{|G|}| \geq |G|$, hence $S_{|G|} = G$. So every $s \in G$ is a product of r elements of T for some r with $1 \leq r \leq |G|$, that is,

$$s = g^{m_1} h^{n_1} \cdots g^{m_r} h^{n_r}$$

for some $m_1, n_1, \ldots, m_r, n_r \in \{-1, 1\}$, as required. □

Remark 10.5.3. The hypothesis on the order of g cannot be dropped. Take $G = \mathbb{Z}/2\mathbb{Z}$ written additively and $g = h = 1$. Every allowed word is a sum of $2r$ terms each equal to ± 1, hence even, hence 0 in G; the element 1 has no representation of the required form. Here g has order 2.

Layer 1: WHAT

Block 1. Re-read the target word: it is a product of r letters drawn from the four element set $T = \{g^{\pm 1} h^{\pm 1}\}$, with no inverses of letters permitted.

Block 2. Split the task in two: reachability (is every element such a product at all?) and the length bound $r \leq |G|$.

Block 3. For reachability, compute inside $\langle T \rangle$: $(gh)(g^{-1}h)^{-1} = g^2$. So $g^2 \in \langle T \rangle$.

Block 4. Odd order upgrades g^2 to g, because $g = (g^2)^{(d+1)/2}$ when $d = \mathrm{ord}(g)$ is odd. Then $h = g^{-1}(gh)$ and so $\langle T \rangle = G$.

Block 5. For the bound, define the reachable sets S_r (products of at most r letters) and observe that the chain $S_1 \subseteq S_2 \subseteq \cdots$ lives in a finite set, so it either strictly grows or repeats.

Block 6. If it repeats at step r, then S_r is stable under right multiplication by every letter, hence by every inverse letter, hence by all of $\langle T \rangle = G$, which forces $S_r = G$.

Block 7. So each step before termination adds at least one element: $|S_r| \geq \min\{r, |G|\}$, giving $S_{|G|} = G$. Done.

The nominal route reads the word as "a word in g and h with restricted exponents" and tries to rewrite an arbitrary product $g^{a_1} h^{b_1} \cdots$ into that shape by inserting cancelling pairs. It produces pages of algebra, never controls r, and never uses the odd order hypothesis.

The bifurcation point is the very first line of work. Zombie: treat g and h as the letters and the exponents as the problem. Ideal: treat $gh, gh^{-1}, g^{-1}h, g^{-1}h^{-1}$ as the letters and ask what semigroup they generate. Everything else in the solution is forced once you make that substitution.

Layer 2: HOW

Block 1. Cue. The exponents are confined to $\{-1, 1\}$ and the pattern alternates g then h rigidly. **Why natural.** A restriction on exponents is never about exponents. It means the problem has secretly changed alphabet: the atoms are no longer g and h but the four syllables that the pattern permits. You always perform this substitution explicitly, because the restriction that looked awkward ("only ± 1") becomes the natural statement "a word of length r in a four letter alphabet". **Link to the next block.** With the alphabet named, the target statement splits cleanly into reachability and length.

Block 2. Cue. The problem asks for existence of a representation and a bound on its length in one sentence. **Why natural.** Two quantifiers, two proofs. Separating them tells you where each hypothesis lives: a bound of $|G|$ smells of counting the elements of G, while the parity condition on $\mathrm{ord}(g)$ cannot possibly affect a counting bound. So the odd order must be spent on reachability. Locating a hypothesis before using it is the fastest way to find the intended route. **Link to the next block.** Reachability means asking what the four letters generate.

Block 3. **Cue.** You have four products of $g^{\pm 1}$ and $h^{\pm 1}$ and you want to eliminate h. **Why natural.** To isolate g you must cancel the h on the right, and the only cancellation available is to multiply by the inverse of another letter with the same h exponent. There are exactly two letters ending in h, namely gh and $g^{-1}h$, so $(gh)(g^{-1}h)^{-1}$ is the only nontrivial product of that shape, and it collapses to g^2. There is no search here: the computation is the unique one available. **Link to the next block.** You have g^2 but you want g, and that is exactly where a hypothesis about the order of g is needed.

Block 4. **Cue.** "the order of g is odd". **Why natural.** The cyclic group $\langle g \rangle$ has order d, and $\langle g^k \rangle = \langle g \rangle$ exactly when $\gcd(k, d) = 1$. With $k = 2$ this is exactly the condition that d is odd. Explicitly $g = (g^2)^{(d+1)/2}$, since $g^d = e$. So the hypothesis is precisely the statement "g^2 is as good a generator as g", which is what the previous block needs. **Link to the next block.** Once $g \in \langle T \rangle$, then $h = g^{-1}(gh) \in \langle T \rangle$, and generation of G by g and h finishes reachability.

Block 5. **Cue.** The requested bound is $|G|$, the size of the group, not a power or a factorial. **Why natural.** A bound equal to the number of states is the signature of a reachability argument: you are filling a finite set one layer at a time and each layer that fails to grow ends the process. So you define S_r, the set reachable in at most r letters, and study the chain. This is the same object as the ball of radius r in the Cayley digraph of T. **Link to the next block.** A monotone chain in a finite set has only two behaviours, so you now analyse the stable case.

Block 6. **Cue.** $S_r = S_{r+1}$ means appending a letter never escapes S_r. **Why natural.** Right multiplication by a fixed element is a bijection of G, so $S_r t \subseteq S_r$ upgrades from an inclusion to an equality by counting, and equality is what lets you invert: $S_r t^{-1} = S_r$. That is the crucial move, and it is the reason finiteness is doing real work. Once S_r is right invariant under T and under T^{-1}, it is right invariant under the group they generate, which Lemma 1 says is all of G; a nonempty right G invariant set is G. **Link to the next block.** So stability implies completion, and hence growth is compulsory until completion.

Block 7. **Cue.** Each step adds at least one element until the process ends. **Why natural.** This converts the dichotomy into an inequality: $|S_r| \geq \min\{r, |G|\}$, proved by a two line induction. The bound $r \leq |G|$ falls out with no further work, and note that the hypothesis $r \geq 1$ in the problem is automatically respected because S_r was defined with $k \geq 1$, so no empty product ever appears. **Link to the next block.** Nothing remains: reachability and the bound are both proved, and the odd order hypothesis has been used exactly once, in Lemma 1.

Layer 3: WHY

Three mathematical truths carry this problem.

The first is that in a finite group, closure under multiplication is already closure under inverses. If $\varnothing \neq S \subseteq G$ satisfies $SS \subseteq S$, then for $a \in S$ the map $x \mapsto ax$ is injective on S, hence surjective on S since S is finite, so a has a left inverse inside S and $e \in S$, and repeating gives $a^{-1} \in S$. The same finiteness is what upgrades $S_r t \subseteq S_r$ to $S_r t = S_r$ in Lemma 2. Every time you see a semigroup condition inside a finite group, this upgrade is available and you should take it without comment.

The second is the grow or stabilise dichotomy. A chain $S_1 \subseteq S_2 \subseteq \cdots$ of subsets of an N element set, in which stability at any step implies completion, must be complete by step N. This is the abstract skeleton shared by breadth first search, by transitive closure algorithms, by the proof that a connected Cayley graph has diameter less than $|G|$, and by the proof that a finite state machine's reachable set is found in at most (number of states) rounds. When a problem asks for a bound equal to the size of the ambient finite set, this is almost always the intended engine.

The third is the obstruction theory that explains the odd order hypothesis, and this is the part that turns the problem from a puzzle into a piece of structure. Let $N = \langle T \rangle$. As computed, $g^2 \in N$, and also $h^2 = (gh^{-1})^{-1}(gh) \in N$. A short check shows N is normal: for $t = g^{\varepsilon}h^{\delta} \in T$ one has $gtg^{-1} = g^2(gh^{-\delta})^{-1}$ if $\varepsilon = 1$ and $gtg^{-1} = (gh^{-\delta})^{-1}$ if $\varepsilon = -1$, while $hth^{-1} = (g^{-\varepsilon}h^{-1})^{-1}h^{\delta-1}$ with $h^{\delta-1} \in \{e, h^{-2}\}$; all of these lie in N. In the quotient G/N the images satisfy $\overline{g}\,\overline{h} = \overline{e}$ and $\overline{g}^2 = \overline{e}$, so G/N is generated by $\overline{g}$ with $\overline{g}^2 = \overline{e}$ and therefore has order 1 or 2. In other words, the only possible obstruction to T generating G is a homomorphism $\varphi\colon G \to \mathbb{Z}/2\mathbb{Z}$ with $\varphi(g) = \varphi(h) = 1$, which sends every letter of T to 0. The order of $\varphi(g)$ divides the order of g; if that order is odd then $\varphi(g) = 0$ and the obstruction cannot exist. So the hypothesis is exactly, and only, the death of the mod 2 obstruction, and the counterexample $G = \mathbb{Z}/2\mathbb{Z}$ with $g = h = 1$ is the obstruction in its smallest form.

The discernment mechanism is therefore: when a hypothesis looks arbitrary, construct the counterexample it forbids, and you will have found both the place it is used and the shape of the argument. Here "odd order" forbids a parity, parity comes from index 2 subgroups, index 2 subgroups are kernels of maps to $\mathbb{Z}/2\mathbb{Z}$, and maps to $\mathbb{Z}/2\mathbb{Z}$ kill the alternating word because every letter has an even total exponent. That chain of thought takes fifteen seconds once trained and it hands you the entire solution plan.

Train it by making the substitution reflex automatic: whenever exponents in a word are constrained to a finite set, rename the permitted syllables as an alphabet and ask two questions, does the alphabet generate, and how fast does the reachable set grow. The examiners nudged you toward both: they wrote the exponent set $\{-1, 1\}$ explicitly rather than saying "nonzero", and they wrote the bound as $|G|$ rather than as some function of the order of g.

Revolving concepts

Generated subgroup and word length. For $T \subseteq G$, $\langle T \rangle$ is the smallest subgroup containing T, equivalently the set of finite products of elements of T and their inverses. If G is finite, then the set of finite products of elements of T alone (no inverses) is already a subgroup, so the two notions coincide. See Book 1, field: Abstract algebra, topic: generators and relations.

Order of an element and powers that still generate. If $\operatorname{ord}(g) = d$ then $\langle g^k \rangle = \langle g^{\gcd(k,d)} \rangle$, so $\langle g^k \rangle = \langle g \rangle$ if and only if $\gcd(k, d) = 1$. The case used here is $k = 2$: squaring loses nothing exactly when d is odd. The same fact powers many problems about squares in groups, for instance that in a group of odd order every element is a square, uniquely. See Book 1, field: Abstract algebra, topic: cyclic groups.

Cayley digraph and diameter. Given $T \subseteq G$, the Cayley digraph has vertex set G and an edge $s \to st$ for each $t \in T$. Reachability in this digraph is exactly representability by words in T, and the sets S_r are the balls of radius r about e. If the digraph is strongly connected then its diameter is at most $|G| - 1$, since a shortest path repeats no vertex. See Book 1, field: Discrete structures and graphs, topic: Cayley graphs.

Index 2 subgroups and the mod 2 obstruction. A subgroup of index 2 is normal, and quotients of order 2 correspond to surjections $G \to \mathbb{Z}/2\mathbb{Z}$, which factor through $G/[G, G]$ tensored with $\mathbb{Z}/2\mathbb{Z}$. Any expression in which every generator appears an even number of times in total lands in the kernel of every such map, which is precisely why alternating ± 1 words are trapped. See Book 1, field: Abstract algebra, topic: normal subgroups and quotients.

The recursion, generalised. The reachable sets satisfy the recursion

$$S_1 = T, \qquad S_{r+1} = S_r \cup S_r T,$$

a monotone recursion in the finite lattice of subsets of G. The general theory: any monotone map F on the subsets of an N element set, applied repeatedly from a starting set, gives an increasing chain that becomes constant after at most N steps, and the limit is the least fixed point containing the start. In this problem the extra structural input is that the only fixed points here are $\varnothing$ and G,

which turns "becomes constant" into "equals G". The same generalised recursion governs transitive closure, reachable states of an automaton, the set of positions in a combinatorial game reachable from the start, and closure under a set of moves in an invariants problem: write $S_{r+1} = S_r \cup F(S_r)$, prove that a fixed point must be everything, and read off a bound equal to the size of the ambient set. See Book 1, field: Discrete structures and graphs, topic: reachability and closure.

Circuit Bank

- **WHEN** a word has its exponents restricted to a finite set, or a rigid alternating pattern **DO** rename the permitted syllables as a new alphabet T and restate the problem as "words in T" **BECAUSE** the restriction is a change of generating set in disguise, and once renamed the question becomes the standard pair "does T generate?" and "how long are the words?"
- **WHEN** a bound equal to the size of a finite set is requested **DO** run the chain $S_{r+1} = S_r \cup S_r T$ and prove that stability forces completion **BECAUSE** each round before termination adds at least one new element, so the process finishes within the size of the set, which is exactly the requested bound
- **WHEN** a nonempty subset of a finite group is closed under multiplication **DO** call it a subgroup immediately, and if it also satisfies $St \subseteq S$ then upgrade to $St = S$ **BECAUSE** right multiplication is a bijection of the group, so an inclusion between finite sets of equal size is an equality
- **WHEN** a hypothesis in the problem looks arbitrary, for instance a parity or coprimality condition **DO** build the counterexample it forbids before you start proving anything **BECAUSE** the counterexample names the obstruction, and the obstruction names the single line of the proof where the hypothesis must be spent
- **WHEN** you need g but only have g^2 inside a subgroup **DO** use $g = (g^2)^{(d+1)/2}$ where $d = \operatorname{ord}(g)$ is odd **BECAUSE** $\langle g^k \rangle = \langle g \rangle$ exactly when $\gcd(k, \operatorname{ord}(g)) = 1$, so odd order makes squaring lossless

Backtesting

1. First useful cue: the exponent set $\{-1, 1\}$ with the rigid g then h alternation, which says the real alphabet is $T = \{gh, gh^{-1}, g^{-1}h, g^{-1}h^{-1}\}$ and r is a word length in that alphabet.
2. Method the expression suggested: prove $\langle T \rangle = G$ using the odd order, then bound the word length by the grow or stabilise argument on the reachable sets S_r.
3. Where you would hesitate, and the thought to reinforce: at the moment when you have $g^2 \in \langle T \rangle$ but want g. Reinforce that $\langle g^k \rangle = \langle g \rangle$ whenever $\gcd(k, \operatorname{ord} g) = 1$, and that the explicit exponent is $(d+1)/2$. Also hesitate at the step $S_r t \subseteq S_r \Rightarrow S_r t = S_r$; reinforce that finiteness plus injectivity is what makes this legal.
4. The trap the question sets: never using the odd order hypothesis. Any argument that "clearly you can write everything as such a word" is false, as $G = \mathbb{Z}/2\mathbb{Z}$ with $g = h = 1$ shows. The second trap is producing a representation of length 0 for the identity, which the condition $r \geq 1$ forbids; define your sets with at least one letter from the start.
5. What makes you recognise it faster next time: the pairing of a bound equal to $|G|$ with a generation question is the fingerprint of a reachability or Cayley graph argument, and a parity hypothesis on the order of a generator is the fingerprint of an index 2 obstruction.
6. The reusable decision rule: when constrained words are involved, change alphabet first, then ask generation and growth separately, and locate every hypothesis before writing a line.

Mirror drills

1. Show that the statement fails without the odd order hypothesis. *Answer:* take $G = \mathbb{Z}/2\mathbb{Z}$ additively with $g = h = 1$; each block $g^m h^n$ contributes $m + n \in \{-2, 0, 2\}$, which is 0 modulo 2, so only the identity is representable.

2. Prove the length bound instead by taking a shortest representation $s = t_1 \cdots t_r$ and applying pigeonhole to the partial products, and explain why you must use $s_0 = e, s_1, \ldots, s_{r-1}$ rather than $s_1, \ldots, s_r$. *Answer:* if $r > |G|$ two of the r partial products $s_0, \ldots, s_{r-1}$ coincide, say $s_i = s_j$ with $i < j$, and deleting $t_{i+1} \cdots t_j$ gives a representation of length $i + (r - j) \geq 1$ and less than r; using $s_1, \ldots, s_r$ instead could delete every letter and produce the forbidden empty word when $s = e$.

3. Prove that if a finite group G is generated by a set T that is closed under inverses, every element is a product of at most $|G| - 1$ elements of T. *Answer:* let B_r be the ball of radius r about e; if $B_r = B_{r+1}$ then $B_r T = B_r$ so B_r is right invariant under $\langle T \rangle = G$ and equals G; otherwise $|B_r| \geq r + 1$, so $B_{|G|-1} = G$.

10.6 A6. Sharp integral bound for cubics with a root

Find the smallest constant C such that for every real polynomial $P(x)$ of degree 3 that has a root in the interval $[0,1]$,

$$\int_0^1 |P(x)|\, dx \le C \max_{x\in[0,1]} |P(x)|\,.$$

Read it out loud

This compares two norms of the same function on the same interval: the L^1 norm $\int_0^1 |P|$ and the sup norm $\max_{[0,1]} |P|$, over the class of real cubics with a root in $[0,1]$. Both sides are homogeneous of degree 1 in P, so the class being a cone (closed under multiplication by scalars) means you may normalise: set $\max_{[0,1]} |P| = 1$ and the question becomes "how large can $\int_0^1 |P|$ be?".

The fields wired in are approximation theory (extremal problems for polynomials under a sup norm constraint), quadrature (exact integration formulas for low degree polynomials), and finite dimensional convexity (a linear functional on a compact convex set attains its maximum at an extreme point). What is really being tested is whether you know that integration against a fixed interval is a linear functional on a four dimensional space, and that such a functional can be written exactly in terms of finitely many point values.

Before touching the cubic, ask what the root is for. Without it the answer is 1: take P with $\max|P| = 1$ and almost constant on $[0,1]$, say $P(x) = 1 - \varepsilon x^3$, and the ratio tends to 1. So the root is the entire source of the inequality: it forces $|P|$ to touch zero somewhere in $[0,1]$, which wastes integral, and the question is exactly how much waste is forced. That reframing tells you the extremal P will hug the value ± 1 everywhere except near its root.

Within thirty seconds you should have written three things. First, normalise $\max|P| = 1$. Second, "the absolute value must go", which means splitting $[0,1]$ at the roots of P so that $|P|$ is a genuine polynomial on each piece. Third, and this is the cue that decides the problem, "$\int_0^1$ is a linear functional on a four dimensional space, so it equals a fixed weighted sum of a few point values": Simpson's rule with weights $\frac{1}{6}, \frac{4}{6}, \frac{1}{6}$ at $0, \frac{1}{2}, 1$ is exact on cubics, and if the root sits at the node 0 then that whole node contributes nothing, leaving at most $\frac{4}{6} + \frac{1}{6} = \frac{5}{6}$. The answer is visible before any algebra.

Approaches, ranked worst to best

1. **Coefficient bashing with multipliers.** *Cue:* "find the smallest constant" over a family of polynomials. *Circuit:* parametrise $P = ax^3 + bx^2 + cx + d$ and optimise. You must maximise $\int_0^1 |P|$, a piecewise defined function of four parameters, subject to a root condition and to a sup norm constraint that is an infinite family of inequalities. Lagrange multipliers do not apply cleanly to max constraints, the absolute value breaks differentiability, and you will not finish. Worst by a distance.

2. **Guess the extremal polynomial and verify.** *Cue:* extremal polynomials under a sup norm constraint touch the constraint repeatedly, as with Chebyshev. *Circuit:* equioscillation. This produces $4x^3 - 8x^2 + 5x$ and the value $5/6$, so you get the lower bound $C \ge 5/6$ and the correct answer to write in a box. It proves nothing about the upper bound, and the upper bound is where the marks are.

3. **Convexity and extreme points.** *Cue:* the constraint set is convex and compact and the objective is linear. *Circuit:* maximise a linear functional at an extreme point, or exhibit a supporting hyperplane. Genuinely the discovery route: the set of cubics with $P(0) = 0$ and $0 \le P \le 1$ on $[0,1]$ is a compact convex body in a three dimensional space, and $\int_0^1$ is linear on it, so the

maximum is at an extreme point, and extreme points are pinned by three active constraints. Correct and illuminating, but classifying extreme points rigorously in a write up costs a page.

4. **Localise at the roots, then integrate exactly by quadrature.** *Cue:* a root in $[0,1]$, an integral of $|P|$, and degree 3. *Circuit:* split at the roots so $|P|$ is a polynomial on each piece, rescale each piece to $[0,1]$ so its root sits at an endpoint, then use a quadrature rule that is exact on cubics and has that endpoint as a node. Best. The upper bound becomes five lines, everything is elementary, and the equality analysis hands you the extremal polynomial without guessing.

The ideal solution

The answer is $C = \boxed{\dfrac{5}{6}}$.

Lemma 10.6.1 (Simpson's rule is exact on cubics)**.** *For every real polynomial Q of degree at most 3,*

$$\int_0^1 Q(t)\,dt = \frac{1}{6}\Big(Q(0) + 4Q\big(\tfrac{1}{2}\big) + Q(1)\Big).$$

Proof. Both sides are linear in Q, so it suffices to check them on the basis $1, t, t^2, t^3$ of the space of polynomials of degree at most 3. The left sides are $1, \frac{1}{2}, \frac{1}{3}, \frac{1}{4}$; the right sides are $\frac{1}{6}(1+4+1) = 1$, $\frac{1}{6}(0+2+1) = \frac{1}{2}$, $\frac{1}{6}(0+1+1) = \frac{1}{3}$ and $\frac{1}{6}(0+\frac{1}{2}+1) = \frac{1}{4}$. □

Lemma 10.6.2 (the normalised case)**.** *Let Q be a real polynomial of degree at most 3 with $Q(0) = 0$ and $Q(x) \geq 0$ for all $x \in [0,1]$, and put $\mu = \max_{x\in[0,1]} Q(x)$. Then $\int_0^1 Q(x)\,dx \leq \frac{5}{6}\mu$.*

Proof. By Lemma 1 and $Q(0) = 0$,

$$\int_0^1 Q(x)\,dx = \frac{1}{6}\Big(4Q\big(\tfrac{1}{2}\big) + Q(1)\Big) \leq \frac{1}{6}(4\mu + \mu) = \frac{5}{6}\mu.$$ □

Proposition 10.6.3. *If P is a real polynomial of degree 3 with a root in $[0,1]$, then $\int_0^1 |P(x)|\,dx \leq \frac{5}{6}M$ where $M = \max_{x\in[0,1]} |P(x)|$.*

Proof. List the distinct roots of P lying in $[0,1]$ as $r_1 < r_2 < \cdots < r_j$ with $j \geq 1$, and set $r_0 = 0$, $r_{j+1} = 1$. The intervals $[r_0, r_1], [r_1, r_2], \ldots, [r_j, r_{j+1}]$ cover $[0,1]$, overlap only at endpoints, and their lengths sum to 1; discard any of length 0. Fix one of them, $I = [\alpha, \beta]$ with $\alpha < \beta$. At least one endpoint of I is a root of P: for $[r_0, r_1]$ it is β, for $[r_j, r_{j+1}]$ it is α, and for the others both. Also P has no root in the open interval (α, β), so by the intermediate value theorem P has constant sign there; choose $\varepsilon \in \{-1, 1\}$ with $\varepsilon P \geq 0$ on I.

Let $\phi\colon [0,1] \to I$ be the affine bijection with $\phi(0)$ equal to a root endpoint of I and $\phi(1)$ the other endpoint, and set $Q = \varepsilon\,(P \circ \phi)$. Then Q is a polynomial of degree at most 3, $Q(0) = \varepsilon P(\phi(0)) = 0$, and $Q \geq 0$ on $[0,1]$ with $\max_{[0,1]} Q = \max_I |P| \leq M$. Substituting $x = \phi(t)$, so that $dx = \pm(\beta - \alpha)\,dt$, gives

$$\int_I |P(x)|\,dx = (\beta - \alpha)\int_0^1 Q(t)\,dt \leq (\beta - \alpha)\cdot\frac{5}{6}\max_I |P| \leq \frac{5}{6}M(\beta - \alpha),$$

using Lemma 2. Summing over all the intervals and using that their lengths sum to 1,

$$\int_0^1 |P(x)|\,dx \leq \frac{5}{6}M\sum(\beta - \alpha) = \frac{5}{6}M.$$ □

It remains to prove that no smaller constant works, that is, to exhibit a cubic attaining equality. The equality analysis tells you what it must be rather than leaving you to guess. Equality in Lemma 2 forces $Q(\frac{1}{2}) = Q(1) = \mu$; normalise $\mu = 1$. Since $\frac{1}{2}$ lies in the interior of $[0,1]$ and $Q \leq 1$ there,

$x = \frac{1}{2}$ is an interior maximum, so $1 - Q$ vanishes to order at least 2 at $\frac{1}{2}$, and it also vanishes at 1. As $1 - Q$ has degree at most 3 and is not identically 0 (because $Q(0) = 0$), it must be exactly

$$1 - Q(x) = k\big(x - \tfrac{1}{2}\big)^2(x - 1)$$

for some constant $k \neq 0$, and $Q(0) = 0$ gives $1 = k \cdot \frac{1}{4} \cdot (-1)$, so $k = -4$ and

$$Q(x) = 1 + 4\big(x - \tfrac{1}{2}\big)^2(x - 1) = 1 + (2x - 1)^2(x - 1) = 4x^3 - 8x^2 + 5x.$$

Now verify that this Q really is admissible. It has degree 3 and $Q(0) = 0$, so it has a root in $[0, 1]$. Its derivative is

$$Q'(x) = 12x^2 - 16x + 5 = (2x - 1)(6x - 5),$$

so on $[0, 1]$ the polynomial increases on $[0, \frac{1}{2}]$, decreases on $[\frac{1}{2}, \frac{5}{6}]$ and increases on $[\frac{5}{6}, 1]$, with

$$Q(0) = 0, \qquad Q\big(\tfrac{1}{2}\big) = 1, \qquad Q\big(\tfrac{5}{6}\big) = \tfrac{25}{27}, \qquad Q(1) = 1.$$

Hence $0 \leq Q \leq 1$ on $[0, 1]$ and $\max_{[0,1]} |Q| = 1$. Finally

$$\int_0^1 Q(x)\,dx = 1 - \frac{8}{3} + \frac{5}{2} = \frac{12 - 32 + 30}{12} = \frac{5}{6},$$

so $\int_0^1 |Q| = \frac{5}{6} \max_{[0,1]} |Q|$ and no constant smaller than $\frac{5}{6}$ can work. Combined with the Proposition, the smallest constant is $C = \frac{5}{6}$.

Remark 10.6.4. The choice of quadrature rule is not free, and the comparison is instructive. Any rule $\int_0^1 Q = \sum_i w_i Q(x_i)$ with nodes $x_i \in [0, 1]$, nonnegative weights and exactness on cubics satisfies $\sum_i w_i = 1$, so for Q with $0 \leq Q \leq \mu$ and $Q(x_{i_0}) = 0$ at a node x_{i_0} it gives $\int_0^1 Q \leq (1 - w_{i_0})\mu$. You therefore want the rule, with the root as a node, whose weight at that node is as large as possible. The two point Gauss rule is exact on cubics but its nodes are $\frac{1}{2} \pm \frac{1}{2\sqrt{3}}$ and neither is a root, so it gives nothing. The closed four node rule $\frac{1}{8}(Q(0) + 3Q(\frac{1}{3}) + 3Q(\frac{2}{3}) + Q(1))$ has $w_0 = \frac{1}{8}$ and gives only $\frac{7}{8}$. Simpson has $w_0 = \frac{1}{6}$ and gives $\frac{5}{6}$, which the example above shows is optimal.

Layer 1: WHAT

Block 1. Both sides are homogeneous of degree 1, so normalise $\max_{[0,1]} |P| = 1$ and maximise $\int_0^1 |P|$.

Block 2. The modulus sign is the obstruction. Split $[0, 1]$ at the roots of P; on each piece P has constant sign, so $|P| = \pm P$ is a polynomial there.

Block 3. Every piece has a root of P at one of its endpoints. Rescale each piece affinely onto $[0, 1]$ with that root sent to 0: the maximum is unchanged, the integral scales by the length, and the lengths sum to 1. So it is enough to prove the inequality once, for a nonnegative cubic on $[0, 1]$ vanishing at 0.

Block 4. Now you need $\int_0^1 Q$ in terms of a few values of Q, one of which is the known zero. Integration is a linear functional on the four dimensional space of cubics; Simpson's rule reproduces it exactly from the three values at $0, \frac{1}{2}, 1$ with weights $\frac{1}{6}, \frac{4}{6}, \frac{1}{6}$.

Block 5. Since $Q(0) = 0$, the node at 0 contributes nothing and $\int_0^1 Q = \frac{1}{6}(4Q(\frac{1}{2}) + Q(1)) \leq \frac{5}{6}\mu$. The upper bound is done.

Block 6. Equality forces $Q(\frac{1}{2}) = Q(1) = \mu$ with $\frac{1}{2}$ an interior maximum, so $\mu - Q$ has a double root at $\frac{1}{2}$ and a root at 1; together with $Q(0) = 0$ this pins Q uniquely as $4x^3 - 8x^2 + 5x$ after normalising $\mu = 1$.

Block 7. Verify that this Q actually satisfies $0 \leq Q \leq 1$ on $[0, 1]$, which the equality conditions do not guarantee, and compute $\int_0^1 Q = \frac{5}{6}$.

The nominal route writes $P = ax^3 + bx^2 + cx + d$, imposes $P(r) = 0$, and tries to optimise a four parameter family against an infinite family of sup norm constraints. It never terminates.

The bifurcation point is the line after the normalisation. Zombie: introduce coefficients. Ideal: ask what kind of object $\int_0^1$ is on the space of cubics, and answer "a linear functional, hence a fixed weighted sum of point values". Everything after that is forced.

Layer 2: HOW

Block 1. **Cue.** The inequality has P on both sides, once inside an integral and once inside a maximum, and both are homogeneous of degree 1. **Why natural.** Scaling P by λ scales both sides by $|\lambda|$, and the hypothesis (degree 3, a root in $[0,1]$) is preserved, so the ratio is what matters and you may normalise the maximum to 1. Always strip the homogeneity of an extremal problem first: it removes one dimension for free and turns "find the smallest C" into "maximise one quantity over a bounded set". **Link to the next block.** With the maximum fixed at 1, the only remaining enemy is the modulus sign.

Block 2. **Cue.** $\int_0^1 |P|$, with P a polynomial whose roots you are told something about. **Why natural.** A modulus of a polynomial is not a polynomial, but it is one on each interval between consecutive roots, and the problem has handed you a root to split at. This is the standard move: when an absolute value sits inside an integral, cut the domain at the sign changes of the integrand. Here it is doubly natural because the hypothesis is about roots, so the splitting points are exactly the objects the problem gives you. **Link to the next block.** After splitting, each piece carries a root at one of its endpoints, which is a much more rigid situation than "a root somewhere in the interval".

Block 3. **Cue.** Each piece is an interval with a root at an endpoint, and the desired inequality is invariant under affine changes of variable. **Why natural.** Under $x = \phi(t)$ with ϕ affine from $[0,1]$ onto $[\alpha,\beta]$, the maximum of $|P|$ over the piece is unchanged and the integral picks up the factor $\beta - \alpha$. So the inequality $\int_I |P| \le C\,\ell(I) \max_I |P|$ says the same thing on every interval, and proving it once on $[0,1]$ with the root at 0 proves it everywhere. Then summing over the pieces works only because the lengths add to 1, which is why the factor $\ell(I)$ had to be there. **Link to the next block.** The problem is now the single clean question: how large can $\int_0^1 Q$ be for a nonnegative cubic with $Q(0) = 0$ and $Q \le 1$?

Block 4. **Cue.** Degree at most 3 means a four dimensional vector space; $Q \mapsto \int_0^1 Q$ is linear. **Why natural.** Any linear functional on a finite dimensional space of polynomials is a finite weighted sum of point evaluations, and for integration those are exactly the quadrature rules. Since you know one value already ($Q(0) = 0$), you want a rule with 0 as a node, so that the unknown part of the estimate involves as little weight as possible. Simpson's rule is the standard rule with node set $\{0, \frac{1}{2}, 1\}$, and it is exact on cubics, not merely on quadratics, because the node set is symmetric about $\frac{1}{2}$ and both sides annihilate the odd function $(x - \frac{1}{2})^3$. **Link to the next block.** Substituting the known zero into the rule immediately produces a numerical bound.

Block 5. **Cue.** $Q(0) = 0$ sits precisely on a node of the rule. **Why natural.** The weights of a quadrature rule exact on constants sum to 1, so knocking out one node removes its weight from the estimate: $\int_0^1 Q \le (1 - w_0)\mu$. For Simpson $w_0 = \frac{1}{6}$ and the bound is $\frac{5}{6}\mu$. The whole content of the answer $5/6$ is "one minus the Simpson endpoint weight", and that is why the constant looks the way it does. **Link to the next block.** An inequality proved by a weighted sum of values has an obvious equality condition, so you get the extremal polynomial for free.

Block 6. **Cue.** Equality needs every term that was bounded by μ to equal μ. **Why natural.** That means $Q(\frac{1}{2}) = Q(1) = \mu$. Since $\frac{1}{2}$ is interior and $Q \le \mu$ throughout, $\mu - Q$ has a minimum of 0 at an interior point, hence a double root there, plus a root at 1. A cubic with a prescribed double root and

a prescribed simple root is determined up to a scalar, and the remaining condition $Q(0) = 0$ fixes the scalar. No guessing, no equioscillation folklore: three linear conditions on a three dimensional space. **Link to the next block.** The candidate is forced, but forced candidates still have to be checked.

Block 7. Cue. The equality conditions used only $Q(\frac{1}{2})$ and $Q(1)$, never the constraint $0 \le Q \le \mu$ on the whole interval. **Why natural.** A necessary condition can produce a polynomial that violates the constraints it was derived under, so you must verify admissibility. Factor $Q' = (2x-1)(6x-5)$, read the shape (up, down, up), and evaluate at the four relevant points $0, \frac{1}{2}, \frac{5}{6}, 1$. The local minimum value $\frac{25}{27} > 0$ and the maxima both equal 1, so $0 \le Q \le 1$ and the example is legitimate. **Link to the next block.** Upper bound plus attained example gives the smallest constant, so the problem is closed.

Layer 3: WHY

The first truth is that integration over a fixed interval, restricted to polynomials of degree at most n, is a linear functional on an $(n+1)$ dimensional space, and every such functional is a weighted sum of at most $n+1$ point evaluations. Quadrature rules are not numerical analysis trivia here; they are the coordinates in which the problem is linear. Once you accept that, the entire difficulty of the problem collapses to choosing the right nodes.

The second truth is the exactness statement itself, and it deserves its honest reason rather than a citation. Write $u = x - \frac{1}{2}$. A rule with nodes symmetric about $\frac{1}{2}$ and weights symmetric to match sends the odd function u^3 to 0, and $\int_0^1 u^3\,dx = 0$ as well. So a symmetric rule that is exact on degree 2 is automatically exact on degree 3: the extra degree is a gift of symmetry, not an accident. That is why Simpson, a three node rule, integrates cubics exactly, and it is the reason a solver who knows only "Simpson is a numerical approximation" will not see the route.

The third truth is the localisation principle. An inequality of the form $\int_I |P| \le C\,\ell(I)\max_I |P|$ is invariant under affine reparametrisation of I, so its truth on one interval implies its truth on all, and a quantity that is additive over a partition (the integral) can then be bounded by summing the local bounds, provided the local bound carries the length factor. Whenever both sides of an inequality scale the same way under $x \mapsto \alpha + (\beta - \alpha)x$, the correct move is always the same: localise to the worst configuration, prove the normalised statement, and sum. Here the localisation also upgrades the hypothesis "a root somewhere in $[0,1]$" into the far stronger "a root at an endpoint", which is what makes the bound sharp.

The discernment mechanism is the choice of node set, and it is a genuinely finite search. The bound produced by a rule with nonnegative weights and nodes in $[0,1]$, exact on cubics, and with the root at a node, is $1 - w_0$. So you want the largest possible weight at the root node. The two point Gauss rule is exact on cubics but has no node at 0, so it is worthless here. The closed four node rule has $w_0 = \frac{1}{8}$ and gives $\frac{7}{8}$. Simpson has $w_0 = \frac{1}{6}$ and gives $\frac{5}{6}$. Since $\frac{5}{6}$ is attained, the search stops. This same reasoning solves the analogous problem for other degrees: for degree at most 1 the trapezium rule $\int_0^1 Q = \frac{1}{2}(Q(0) + Q(1))$ gives the sharp constant $\frac{1}{2}$, attained by $Q(x) = x$; for degree at most 2 the correct rule is the two node Radau rule $\int_0^1 Q = \frac{1}{4}Q(0) + \frac{3}{4}Q(\frac{2}{3})$, which is exact on quadratics and gives the sharp constant $\frac{3}{4}$, attained by $Q(x) = 3x - \frac{9}{4}x^2$. Notice that for degree 2 the Newton to Cotes rule is not the right one; the rule must be chosen for the problem, not from memory.

How to train this: whenever you meet an inequality between $\int |P|$ and $\max |P|$ on a finite dimensional space of functions, write the objective as a linear functional, write the constraint set, and check whether the functional can be expressed through point values at the constrained points. If yes, the problem is a weighing exercise and it is over in five lines.

Now the knowledge gaps, stated plainly, because this problem is not approachable without them. First, quadrature: you must know what "a rule exact on polynomials of degree at most n" means, that the weights of such a rule sum to 1 on $[0,1]$, that Simpson's rule has weights $\frac{1}{6}, \frac{4}{6}, \frac{1}{6}$ and

degree of exactness 3, and the symmetry argument for that extra degree. A level numerical methods teaches the trapezium rule as an approximation and stops; exactness is the whole point here and it is a gap. Second, extremal theory of polynomials: the fact that a linear functional on a compact convex set attains its maximum at an extreme point, and the Chebyshev style heuristic that extremal polynomials touch their constraints at as many points as the dimension allows. You do not need this to write the final proof, but without it you will not believe that an extremal polynomial exists or know how many contact conditions to impose. Third, and mildest, the localisation principle for affine invariant inequalities, which is standard practice but rarely stated as a principle.

Revolving concepts

Norms on a space of polynomials. On $[0,1]$ the quantities $\|P\|_1 = \int_0^1 |P|$ and $\|P\|_\infty = \max_{[0,1]} |P|$ are both norms on the four dimensional space of cubics, and all norms on a finite dimensional space are equivalent, so constants like the one asked for necessarily exist. Always $\|P\|_1 \le \|P\|_\infty$; the reverse comparison $\|P\|_\infty \le c_n \|P\|_1$ also holds with a constant depending only on the degree, and inequalities of that shape are called Nikolskii inequalities. This problem asks for the exact constant in the easy direction after the class has been cut down by a root condition. See Book 1, field: Real analysis, topic: norms on finite dimensional spaces.

Quadrature and degree of exactness. A rule $\int_0^1 Q \approx \sum_{i=0}^{k} w_i Q(x_i)$ is exact on degree n when it holds with equality for $Q = 1, x, \dots, x^n$, that is, when the moment equations $\sum_i w_i x_i^m = \frac{1}{m+1}$ hold for $m = 0, 1, \dots, n$. With $k+1$ prescribed nodes you can always achieve $n = k$ by solving a Vandermonde system; symmetry of the node set buys one extra degree when k is even, which gives Simpson its exactness on cubics; and choosing the nodes optimally (Gauss to Legendre) buys $k+1$ extra degrees. Radau rules are the intermediate case where one node is fixed at an endpoint and the rest are optimised, which is exactly the family this problem wants. See Book 1, field: Calculus and integrals, topic: quadrature rules.

Extreme points and linear objectives. If K is a compact convex subset of $\mathbb{R}^d$ and f is linear, then $\max_K f$ is attained at an extreme point of K. Here K is the set of cubics with $Q(0) = 0$ and $0 \le Q \le 1$ on $[0,1]$, sitting inside $\mathbb{R}^3$, and its extreme points are pinned by three active constraints; the extremal polynomial found above has exactly three, namely $Q(\frac{1}{2}) = 1$, $Q'(\frac{1}{2}) = 0$ and $Q(1) = 1$. Counting active constraints against the dimension is the reliable way to predict the shape of an extremiser before computing it. See Book 1, field: Inequalities, topic: convexity and extreme points.

Chebyshev polynomials and equioscillation. The classical extremal problems for polynomials under a sup norm constraint are solved by Chebyshev polynomials, whose defining feature is that they attain their extreme value at the maximum possible number of points with alternating signs. The polynomial $4x^3 - 8x^2 + 5x = 1 + (2x-1)^2(x-1)$ is the analogue for this constrained problem: it hits its maximum twice and its minimum once inside $[0,1]$. See Book 1, field: Polynomials, topic: Chebyshev extremal problems.

Structure of the argument, generalised. The scheme is: normalise by homogeneity, localise by affine invariance, linearise by quadrature, and close by equality analysis. The generalised statement it proves is this. Let $n \ge 1$ and let C_n be the smallest constant with $\int_0^1 |P| \le C_n \max_{[0,1]} |P|$ for all real P of degree at most n with a root in $[0,1]$. If there is a quadrature rule with nodes in $[0,1]$, nonnegative weights, exactness on degree n, and node 0 carrying weight w_0, then $C_n \le 1 - w_0$; and if some admissible P attains that value, the bound is sharp. This gives $C_1 = \frac{1}{2}$, $C_2 = \frac{3}{4}$ and $C_3 = \frac{5}{6}$. There is no recursion in n here; each degree needs its own optimal rule, which is why you must know the Radau construction rather than one memorised formula. See Book 1, field: Calculus and integrals, topic: quadrature rules.

Circuit Bank

- **WHEN** an inequality is homogeneous of the same degree in the unknown function on both sides **DO** normalise one side to 1 and maximise the other over the resulting bounded set **BECAUSE** the class is a cone, so the ratio is the only content, and normalising removes a dimension for free
- **WHEN** an absolute value sits inside an integral of a polynomial **DO** split the domain at the roots, where the sign changes, so the integrand is a polynomial on each piece **BECAUSE** a modulus is only piecewise smooth, and the pieces are exactly the intervals between roots, which the hypothesis is usually about
- **WHEN** both sides of an inequality scale identically under an affine change of variable **DO** prove the normalised version on $[0, 1]$ with the length factor included, then sum over a partition **BECAUSE** affine invariance means one proof covers every interval, and the length factor is what makes the sum telescope to the whole domain
- **WHEN** you need the integral of a polynomial of degree at most n and you know its value at some specific point **DO** write the integral as a quadrature rule exact on degree n whose nodes include that point **BECAUSE** integration is a linear functional on an $(n + 1)$ dimensional space, so it is a fixed weighted sum of point values, and a known zero deletes a whole weight
- **WHEN** you have proved an upper bound by bounding several terms by the same quantity **DO** read off the equality conditions and use them to construct the extremal example **BECAUSE** the equality conditions are linear conditions on a finite dimensional space and usually determine the extremiser uniquely, which converts guessing into solving

Backtesting

1. First useful cue: degree 3 with an integral and a maximum over the same interval, plus a prescribed root. That says linear functional on a four dimensional space, and a known value at a point, so quadrature.
2. Method the expression suggested: normalise, split at the roots, rescale each piece so the root sits at an endpoint, apply Simpson's rule, and read off $1 - \frac{1}{6}$.
3. Where you would hesitate, and the thought to reinforce: at the reduction. It feels like a lot of bookkeeping for what looks like a special case. Reinforce that the reduction is not bookkeeping but the step that upgrades "a root somewhere" into "a root at an endpoint", which is what makes the constant sharp; and that it is legitimate only because the local inequality carries the factor $\ell(I)$ and the lengths sum to 1.
4. The trap the question sets: producing only the example. It is the more enjoyable half, it gives the right numerical answer, and it is worth about half the credit. The second trap is verifying the example incompletely: the equality conditions do not imply $0 \leq Q \leq 1$, so the sign analysis via $Q' = (2x - 1)(6x - 5)$ is compulsory.
5. What makes you recognise it faster next time: the pairing of $\int$ and max over one interval on a finite dimensional function space is the fingerprint of a quadrature or extreme point argument, and a constraint of the form "vanishes at a point" is telling you to put that point at a node.
6. The reusable decision rule: to bound a linear functional on polynomials of bounded degree subject to sup norm and interpolation constraints, express the functional exactly as a nonnegative weighted sum of values at points where you have information, and the bound is the total weight at the points where the value is unconstrained.

Mirror drills

1. Find the smallest C such that $\int_0^1 |P| \le C \max_{[0,1]} |P|$ for every real polynomial of degree 1 with a root in $[0,1]$. *Answer:* $\frac{1}{2}$; the trapezium rule $\int_0^1 Q = \frac{1}{2}(Q(0)+Q(1))$ is exact on degree 1, and $Q(x) = x$ attains it.
2. Do the same for degree 2. *Answer:* $\frac{3}{4}$; use the two node rule $\int_0^1 Q = \frac{1}{4}Q(0) + \frac{3}{4}Q(\frac{2}{3})$, which is exact on quadratics (check on $1, x, x^2$), and note $Q(x) = 3x - \frac{9}{4}x^2$ has maximum 1 at $x = \frac{2}{3}$ and integral $\frac{3}{4}$.
3. Prove that Simpson's rule is exact on cubics using symmetry rather than by checking four basis elements, and explain why the closed four node rule with weights $\frac{1}{8}, \frac{3}{8}, \frac{3}{8}, \frac{1}{8}$ gives only the weaker constant $\frac{7}{8}$. *Answer:* write $u = x - \frac{1}{2}$; the rule is symmetric so it annihilates u^3, as does $\int_0^1$, and exactness on degree 2 is a direct check, so exactness on degree 3 follows. The four node rule has endpoint weight $\frac{1}{8}$, and the bound produced is $1 - w_0 = \frac{7}{8}$: more nodes means less weight sitting on the known zero.

10.7 B1. exponentiate the log to expose telescoping

Let $x_0, x_1, x_2, \ldots$ be the sequence such that $x_0 = 1$ and, for $n \geq 0$,

$$x_{n+1} = \ln\left(e^{x_n} - x_n\right)$$

(as usual, $\ln$ denotes the natural logarithm). Show that the infinite series $x_0 + x_1 + x_2 + \cdots$ converges and find its sum.

Read it out loud

This is a sequences and series question wearing a transcendental disguise. Strip the disguise and what is actually being tested is completely standard: a recursively defined sequence, a request to prove convergence, and a request for the exact sum. The only unusual feature is that the recursion is defined through a composition of ln and exp, and that composition is itself the first command term. Whenever the rule for x_{n+1} places e^{x_n} inside a ln, the two functions are begging to be cancelled, because they are inverses of each other and cancelling them is the one manipulation guaranteed to make progress.

The second thing to read out loud is the phrase find its sum, not merely does it converge. The general term x_n has no elementary closed form: check this within thirty seconds by noting $x_1 = \ln(e-1)$ is already not a nice number. So an exact sum can only exist if the partial sums collapse, not the individual terms. That is the second cue: it tells you, before you write a line of proof, that you are hunting for a telescoping identity, not a formula for x_n.

The field embedded here is real analysis dressed as calculus: monotone bounded sequences, continuity of exp, and the inequality $e^x \geq x + 1$. None of this needs anything beyond what you already carry from Further Maths calculus; what is new is the discipline of reading the composition $\ln(e^{(\cdot)} - \cdot)$ as an instruction to exponentiate, rather than as an expression to simplify by brute force.

Approaches, ranked worst to best

1. **hunt for a closed form of x_n.** *Cue:* a recursively defined sequence always tempts a pattern search. *Circuit:* small case pattern matching. (worst: $x_1 = \ln(e-1)$ and $x_2 = \ln(e^{x_1} - x_1)$ are not recognisable numbers, so this stalls before it starts and costs ink for nothing).
2. **numerical iteration to guess the target value.** *Cue:* you want a number to aim at before committing to a proof. *Circuit:* decimal iteration as a sanity check. (a fine backtest, but it is not a proof and earns nothing on its own; keep it in your head, not on the page).
3. **exponentiate the recursion to expose a telescoping identity.** *Cue:* ln applied to an expression built from e^{x_n}. *Circuit:* cancel inverse functions on sight. (best: converts an opaque transcendental recursion into the algebraic identity $x_n = e^{x_n} - e^{x_{n+1}}$, which is exactly the shape of a telescoping summand).

The ideal solution

First certify that the recursion is always well defined. For real x let $\varphi(x) = e^x - x$; then $\varphi'(x) = e^x - 1$, negative for $x < 0$, zero at $x = 0$, positive for $x > 0$, so φ has a strict global minimum at $x = 0$ with $\varphi(0) = 1$. Hence

$$e^x - x \geq 1 \quad \text{for every real } x, \text{ with equality only at } x = 0.$$

So $e^{x_n} - x_n$ is always at least 1, meaning $\ln(e^{x_n} - x_n)$ is always defined, and moreover $x_{n+1} = \ln(e^{x_n} - x_n) \geq \ln 1 = 0$, with equality only if $x_n = 0$.

Since $x_0 = 1 \neq 0$, induction gives $x_n > 0$ for every n: the base case is immediate, and if $x_n > 0$ then $x_n \neq 0$, so the inequality above is strict and $x_{n+1} > 0$.

Now exponentiate the defining relation. Since $x_{n+1} = \ln(e^{x_n} - x_n)$,

$$e^{x_{n+1}} = e^{x_n} - x_n, \qquad \text{that is,} \qquad x_n = e^{x_n} - e^{x_{n+1}}.$$

This single identity carries the whole problem. Because $x_n > 0$, it gives $e^{x_{n+1}} < e^{x_n}$, and since exp is strictly increasing, $x_{n+1} < x_n$. So (x_n) is strictly decreasing and bounded below by 0, and by the Monotone Convergence Theorem it converges to some limit $L \geq 0$. Taking $n \to \infty$ in $x_n = e^{x_n} - e^{x_{n+1}}$, using continuity of exp on both sides, gives $L = e^L - e^L = 0$. So $x_n \to 0$.

Finally, sum the identity for $n = 0, \ldots, N$:

$$\sum_{n=0}^{N} x_n = \sum_{n=0}^{N} \left(e^{x_n} - e^{x_{n+1}}\right) = e^{x_0} - e^{x_{N+1}} = e - e^{x_{N+1}},$$

the middle terms cancelling in pairs. Since $x_{N+1} \to 0$ as $N \to \infty$ and exp is continuous, $e^{x_{N+1}} \to e^0 = 1$. Hence the partial sums converge, and

$$\sum_{n=0}^{\infty} x_n = \boxed{e - 1}.$$

Layer 1: WHAT

Block 1: certify positivity of the argument of every ln in the recursion via $e^x \geq x + 1$, and deduce $x_n > 0$ for all n by induction. Block 2: exponentiate the recursion to trade the opaque log identity for the algebraic identity $x_n = e^{x_n} - e^{x_{n+1}}$. Block 3: read monotonicity straight off that same identity. Block 4: invoke the Monotone Convergence Theorem, then find the limit by substituting it back into the identity. Block 5: sum the identity from $n = 0$ to N, watch it telescope, and let $N \to \infty$.

The nominal route computes $x_1, x_2, x_3, \ldots$ directly and searches for a pattern in the numbers themselves; it dies at $x_1 = \ln(e - 1)$, a number with no visible structure. The ideal route never looks at x_n as a number at all; it manipulates the relation between consecutive terms. The bifurcation point sits at the very first line you write after reading the problem: do you compute x_1 numerically, or do you exponentiate the defining equation symbolically before computing anything? Everything downstream follows from that choice.

Layer 2: HOW

Block 1. **Cue.** The argument of ln is $e^{x_n} - x_n$, an exponential minus a linear image of its own exponent. **Why natural.** A ln recursion is not trustworthy until you know its argument is positive for every term it will ever be fed; checking this costs one calculus minimisation and, as a bonus, hands you the sign of every x_n for free. **Link to the next block.** Knowing $x_n > 0$ for all n is exactly the hypothesis Block 3 needs to turn an identity into a strict inequality.

Block 2. **Cue.** ln sits directly outside an expression built from e^{x_n}. **Why natural.** ln and exp are mutual inverses, so applying exp to both sides is the one operation guaranteed to simplify rather than complicate; and since the problem demands an exact sum rather than an exact term, you should already be looking for the result to have an additive, telescoping shape. **Link to the next block.** The identity $x_n = e^{x_n} - e^{x_{n+1}}$ literally reads term equals a difference of consecutive values of a function of the sequence, which is the definition of a telescoping summand: summing is now free.

Block 3. **Cue.** The identity from Block 2, combined with the positivity from Block 1. **Why natural.** A positive difference $e^{x_n} - e^{x_{n+1}}$ forces $e^{x_{n+1}} < e^{x_n}$, and since exp is injective and increasing, the ordering pulls straight back onto $x_{n+1} < x_n$; no separate derivative argument on the sequence itself is needed. **Link to the next block.** A decreasing sequence bounded below is exactly the hypothesis of the Monotone Convergence Theorem, so existence of a limit is automatic and only its value remains open.

Block 4. **Cue.** A convergent sequence defined by a continuous recursion. **Why natural.** If $x_n \to L$ and $x_{n+1} = g(x_n)$ for continuous g, then $L = g(L)$; it is easier here to pass the limit through the un-logged identity of Block 2 than to reintroduce ln. **Link to the next block.** Knowing $x_n \to 0$ pins down the one unknown quantity left in the telescoped partial sum, the tail term $e^{x_{N+1}}$.

Block 5. **Cue.** The telescoped finite sum $e - e^{x_{N+1}}$ together with $x_{N+1} \to 0$. **Why natural.** Continuity of exp at 0 converts a statement about the sequence into a statement about numbers: $e^{x_{N+1}} \to e^0 = 1$. **Link to the next block.** None; this closes the problem.

Layer 3: WHY

The truth underneath this problem is that a recursively defined sequence can hide an exact potential function even when it has no closed form: if the defining map, once you undo its outer wrapper, expresses the increment x_n as $F(x_n) - F(x_{n+1})$ for some function F, then the sum is exact and equals $F(x_0)$ minus the limit of F along the sequence. The wrapper here is ln composed with $\exp(\cdot) - \mathrm{id}$, and undoing it is what exposes $F = \exp$.

The discernment mechanism is this: the moment a Putnam problem asks for an exact sum of a sequence you cannot solve explicitly, refuse the instinct to search for the general term. Assume instead that the sum itself is the accessible object, and go looking for a telescoping identity by undoing whichever transcendental function wraps the recursion. You train this discernment by noticing, across many problems, that find the exact sum and no closed form for the term are never a contradiction: together they are a promise that a telescoping identity exists.

What the examiners nudged toward is visible in the exact placement of x_n inside the log: it is not $e^{x_n} - 1$ or $e^{x_n} - 2x_n$, it is $e^{x_n} - x_n$ specifically, the one combination whose exponentiated form returns x_n as a clean difference. A quieter nudge is the word converges: by demanding a proof of convergence rather than asserting it, the setters force you to extract monotonicity and boundedness from the same identity that gives the telescoping, rather than treating the two halves of the problem as separate tasks.

Revolving concepts

The inequality $e^x \geq x + 1$. This is the tangent line to the convex function e^x at $x = 0$; convexity guarantees the tangent lies below the curve everywhere, with equality only at the point of tangency. It underlies AM-GM style bounds and any problem needing a cheap lower bound on an exponential. See Book 1, field: Inequalities, topic: convexity and tangent line bounds.

Monotone Convergence Theorem. A monotonic bounded sequence of real numbers converges; this is equivalent to completeness of $\mathbb{R}$ and is the standard first move whenever a recursively defined sequence needs a convergence proof before its limit can be computed. See Book 1, field: Real analysis, topic: monotone sequences and completeness.

Fixed points of continuous iteration. If $x_{n+1} = g(x_n)$ for continuous g and $x_n \to L$, then $L = g(L)$. Whenever a recursion is already known to converge, its limit is always a root of $L = g(L)$, which trades an infinite process for one algebraic equation. See Book 1, field: Sequences and recurrences, topic: fixed points of iterated maps.

Telescoping through an invertible wrapper, generalised. Suppose a recursion, after undoing an invertible continuous function h, takes the form $h(x_{n+1}) = h(x_n) - x_n$. Rearranging gives $x_n = h(x_n) - h(x_{n+1})$ for every n, so

$$\sum_{n=0}^{N} x_n = h(x_0) - h(x_{N+1}),$$

and if $x_n \to L$, the infinite sum equals $h(x_0) - h(L)$. This is the general shape behind this problem with $h = \exp$, and it applies verbatim whenever a recursion reads h of the next term equals h of the current term minus the current term, for any invertible continuous h: the same telescoping falls out with $h = \sinh$, $h = \tan$, or any other cancellable wrapper. See Book 1, field: Sequences and recurrences, topic: telescoping sums and generating potentials.

Circuit Bank

- **WHEN** a recursion is written as an invertible function applied to an expression built from that function's inverse of the previous term, for example $x_{n+1} = \ln(\text{stuff with } e^{x_n})$ **DO** apply the invertible function to both sides immediately, before doing anything else **BECAUSE** the two functions cancel by definition, and the resulting identity is almost always the algebraic relation the problem actually wants you to sum or bound
- **WHEN** a problem asks for the exact sum of a sequence with no closed form for its general term **DO** search for a telescoping identity $x_n = F(x_n) - F(x_{n+1})$ hidden inside the recursion, rather than solving for x_n **BECAUSE** an exact closed form sum of an opaque sequence is only possible when the partial sums collapse, and telescoping is the mechanism that makes them collapse
- **WHEN** you need the limit of a sequence defined by a continuous recursion and already know it converges **DO** substitute the limit directly into the recursion and solve $L = g(L)$ **BECAUSE** continuity lets you pass to the limit termwise, converting an infinite process into one algebraic equation
- **WHEN** you meet the expression $e^x - x$ in any context **DO** reach immediately for $e^x \geq x + 1$ **BECAUSE** it is the tangent line to a convex function at its unique point of contact, and it pins the minimum of $e^x - x$ at exactly 1

Backtesting

1. First useful cue: the argument of ln contains e^{x_n}, an exponential of the very term being logged.
2. Method the expression suggested: exponentiate both sides to cancel the outer ln.
3. Where you would hesitate, and the thought to reinforce: whether you have the right identity to sum; reinforce by noticing $x_n = e^{x_n} - e^{x_{n+1}}$ is shaped exactly like a telescoping summand.
4. The trap the question sets: assuming you must find a closed form for x_n before you can find $\sum x_n$.
5. What makes you recognise it faster next time: treating $\ln(e^{(\cdot)} - \cdots)$ as a standing visual signature that means exponentiate now.
6. The reusable decision rule: never attempt to solve a transcendental recursion for its general term; test first whether undoing the outer function converts the increment into a telescoping difference.

Mirror drills

1. Let $y_0 = 2$ and $y_{n+1} = \ln(e^{y_n} + y_n)$ for $n \geq 0$, note the sign flip. Does $\sum y_n$ converge? *Answer:* No. Exponentiating gives $e^{y_{n+1}} = e^{y_n} + y_n > e^{y_n}$ since $y_0 > 0$, so (y_n) increases, cannot tend to 0, and the series diverges; the sign in the recursion was load bearing, not decorative.
2. Same recursion as the main problem but started at $x_0 = 2$. Find $\sum x_n$. *Answer:* $e^2 - 1$, by the identical telescoping argument, since it only ever used $x_0 > 0$, never the specific value 1.
3. Let $v_0 = 1$ and $v_{n+1} = \operatorname{arcsinh}(\sinh v_n - v_n)$ for $n \geq 0$. Find $\sum v_n$. *Answer:* $\sinh 1$, since $\sinh x > x$ for $x > 0$ gives $v_n > 0$ for all n; applying sinh to both sides gives $v_n = \sinh v_n - \sinh v_{n+1}$, the same wrapper trick with $h = \sinh$ in place of exp, and the limit is again 0 by the same monotone argument.

10.8 B2. counting squarish numbers via basin sizes

Define a positive integer n to be squarish *if either n is itself a perfect square or the distance from n to the nearest perfect square is a perfect square. For example,* 2016 *is squarish, because the nearest perfect square to* 2016 *is* $45^2 = 2025$ *and* $2025 - 2016 = 9$ *is a perfect square. (Of the positive integers between* 1 *and* 10*, only* 6 *and* 7 *are not squarish.)*

For a positive integer N, let $S(N)$ be the number of squarish integers between 1 *and N, inclusive. Find positive constants α and β such that*

$$\lim_{N\to\infty} \frac{S(N)}{N^\alpha} = \beta,$$

or show that no such constants exist.

Read it out loud

Read past the word squarish immediately; the definition is not the content of the problem, it is packaging. What is actually being tested is a counting function built from a nearest neighbour condition, and the command term is the phrase distance to the nearest perfect square. That phrase is not computable in isolation: distance to the nearest something only means anything once you have fixed which two somethings are competing to be nearest. So the first thirty seconds of this problem should produce one picture, the number line with the perfect squares $1, 4, 9, 16, 25, \ldots$ marked on it, and a mental note that every integer sits between two consecutive marks and is closer to one of them.

That picture is a partition. Around each perfect square n^2 there is a block of consecutive integers that are closer to n^2 than to $(n-1)^2$ or $(n+1)^2$, and squarishness, for any integer inside that block, becomes a purely local question about the block. The problem has silently converted a global counting question into a sum of local counting questions, one per block, and it did this the moment it said nearest.

The second cue sits in the answer format, $S(N)/N^\alpha \to \beta$. This is the signature of a counting function with power law growth, and whenever such a limit is demanded for a function built by summing a slowly growing local count across a range of blocks, the growth rate is recovered by comparing a sum to an integral, not by finding an exact formula. The fields embedded here are number theory (perfect squares, floor of the square root), elementary combinatorics (partition into blocks and local counting), and real analysis (the discrete integral test). Nothing here is beyond Further Maths calculus except the discipline of using an integral to control a sum you cannot evaluate exactly, which is exactly the tool this problem is built to make you reach for.

Approaches, ranked worst to best

1. **tabulate small values and curve fit α, β numerically.** *Cue:* explicit small examples are given in the statement. *Circuit:* numerical extrapolation. (worst: might land on the right numbers, but supplies no proof at all, and the problem explicitly demands either a proof of existence or a proof of nonexistence).

2. **search for an exact closed form for $S(N)$ valid for every N.** *Cue:* the small cases look almost formulaic. *Circuit:* direct formula hunting. (costly: an exact global formula does not exist cleanly because of the floor functions involved, and none is needed since only the asymptotic power law is asked for; this route burns ink chasing more precision than the question wants).

3. **partition into basins around each perfect square, count squarish numbers locally via floor of the square root, then estimate the resulting sum by comparison with an integral.** *Cue:* the phrase nearest perfect square, and the shape of the target limit. *Circuit:* basin decomposition

plus the discrete integral test. (best: turns an intractable global count into an exact local formula plus one standard asymptotic estimate, and answers both branches of the question at once).

The ideal solution

Step 1: the basin of n^2. Fix a positive integer n. The point equidistant from $(n-1)^2$ and n^2 is their average, $n^2 - n + \frac{1}{2}$, which is never an integer, so every integer is strictly closer to one side; an integer k satisfies $k > n^2 - n + \frac{1}{2}$, that is $k \geq n^2 - n + 1$, exactly when k is closer to n^2 than to $(n-1)^2$. Likewise the point equidistant from n^2 and $(n+1)^2$ is $n^2 + n + \frac{1}{2}$, so $k \leq n^2 + n$ exactly when k is closer to n^2 than to $(n+1)^2$. Hence the integers for which n^2 is the nearest perfect square form exactly the interval

$$\mathrm{Basin}(n) = \{\, n^2 - n + 1,\ n^2 - n + 2,\ \ldots,\ n^2 + n \,\},$$

a block of exactly $2n$ consecutive integers. Since $\mathrm{Basin}(n)$ ends at $n^2 + n$ and $\mathrm{Basin}(n+1)$ begins at $(n+1)^2 - (n+1) + 1 = n^2 + n + 1$, these blocks are pairwise disjoint and their union over $n = 1, 2, 3, \ldots$ is all of $\{1, 2, 3, \ldots\}$ with no gaps and no ties, so every positive integer lies in exactly one basin.

Step 2: the local count. Inside $\mathrm{Basin}(n)$, an integer $k = n^2 - d$ with $1 \leq d \leq n-1$ is squarish exactly when d is a perfect square, an integer $k = n^2 + d$ with $1 \leq d \leq n$ is squarish exactly when d is a perfect square, and $k = n^2$ itself is squarish outright. So the number of squarish integers in $\mathrm{Basin}(n)$ is

$$c(n) = 1 + \#\{\text{perfect squares in } [1, n-1]\} + \#\{\text{perfect squares in } [1, n]\} = 1 + \lfloor \sqrt{n-1} \rfloor + \lfloor \sqrt{n} \rfloor.$$

(Check this against the statement's own data: $\mathrm{Basin}(1) = \{1, 2\}$, $c(1) = 1 + 0 + 1 = 2$, both squarish; $\mathrm{Basin}(2) = \{3, 4, 5, 6\}$, $c(2) = 1 + 1 + 1 = 3$, and indeed $3, 4, 5$ are squarish while 6 is not.)

Step 3: sandwiching $S(N)$. Let $T(M) = \sum_{n=1}^{M} c(n)$, the number of squarish integers in $\{1, \ldots, M^2 + M\}$, and let $m = \lfloor \sqrt{N} \rfloor$, so $m^2 \leq N < (m+1)^2$. Since $(m-1)^2 + (m-1) = m^2 - m < N$, the whole of $\mathrm{Basin}(1)$ through $\mathrm{Basin}(m-1)$ lies inside $[1, N]$, so $T(m-1) \leq S(N)$. Since $N < (m+1)^2 \leq (m+1)^2 + (m+1)$, the interval $[1, N]$ lies inside $\mathrm{Basin}(1)$ through $\mathrm{Basin}(m+1)$, so $S(N) \leq T(m+1)$. Thus

$$T(m-1) \ \leq\ S(N) \ \leq\ T(m+1), \qquad m = \lfloor \sqrt{N} \rfloor. \tag{$*$}$$

Step 4: the growth rate of $T(M)$. From $\sqrt{n} - 1 < \lfloor \sqrt{n} \rfloor \leq \sqrt{n}$ and the same bound for $\sqrt{n-1}$, $c(n) = 2\sqrt{n} + O(1)$ uniformly in n, so $T(M) = 2\sum_{n=1}^{M} \sqrt{n} + O(M)$. Since $x \mapsto \sqrt{x}$ is increasing, $\int_{n-1}^{n} \sqrt{x}\,dx \leq \sqrt{n} \leq \int_{n}^{n+1} \sqrt{x}\,dx$ for every $n \geq 1$; summing over $n = 1, \ldots, M$ gives

$$\frac{2}{3}M^{3/2} = \int_0^M \sqrt{x}\,dx \ \leq\ \sum_{n=1}^{M} \sqrt{n} \ \leq\ \int_1^{M+1} \sqrt{x}\,dx = \frac{2}{3}\left((M+1)^{3/2} - 1\right).$$

Expanding $(M+1)^{3/2} = M^{3/2} + \frac{3}{2}M^{1/2} + O(M^{-1/2})$ shows both bounds equal $\frac{2}{3}M^{3/2} + O(\sqrt{M})$, so

$$T(M) = \frac{4}{3}M^{3/2} + O(M).$$

Step 5: translating back to N. Since $m \leq \sqrt{N} < m + 1$, $m = \sqrt{N} + O(1)$, and expanding $(m \pm 1)^{3/2} = (\sqrt{N} + O(1))^{3/2} = N^{3/4} + O(N^{1/4})$ shows both $T(m-1)$ and $T(m+1)$ equal $\frac{4}{3}N^{3/4} + O(N^{1/2})$. By $(*)$,

$$S(N) = \frac{4}{3}N^{3/4} + O(N^{1/2}), \qquad \text{hence} \qquad \frac{S(N)}{N^{3/4}} = \frac{4}{3} + O(N^{-1/4}) \ \longrightarrow\ \frac{4}{3}.$$

So $\alpha = \dfrac{3}{4}$, $\beta = \dfrac{4}{3}$ work. This pair is forced: if such a limit exists for some α with finite nonzero β, then for any other positive $\alpha' > \alpha$, $S(N)/N^{\alpha'} = (S(N)/N^{\alpha}) \cdot N^{\alpha-\alpha'} \to 0$, and for $\alpha' < \alpha$ the same ratio tends to infinity, so no other pair can work. Therefore

$$\boxed{\alpha = \tfrac{3}{4},\ \beta = \tfrac{4}{3}}$$

are the unique constants with $\lim_{N\to\infty} S(N)/N^{\alpha} = \beta$.

Layer 1: WHAT

Block 1: convert nearest perfect square into a partition of the positive integers into basins around each n^2, each of exactly $2n$ consecutive integers. Block 2: count squarish integers inside one basin exactly, via the number of perfect square offsets on each side, giving $c(n) = 1 + \lfloor\sqrt{n-1}\rfloor + \lfloor\sqrt{n}\rfloor$. Block 3: sandwich $S(N)$ between $T(m-1)$ and $T(m+1)$, where $m = \lfloor\sqrt{N}\rfloor$ counts how many basins fit inside $[1, N]$. Block 4: replace the floor functions by $\sqrt{n}$ up to bounded error, then estimate $\sum \sqrt{n}$ by comparison with $\int \sqrt{x}\,dx$. Block 5: translate the resulting power of m back into a power of N, read off $\alpha = 3/4$, $\beta = 4/3$, and note the pair is unique by a scaling argument.

The nominal route tries to reason about squarishness globally, perhaps by hunting for an exact formula for $S(N)$ valid for every N; it produces nothing usable, because nearest perfect square has no meaning until you have committed to a partition. The ideal route commits to that partition in the very first line. The bifurcation point is exactly there: does your first written sentence try to describe $S(N)$ directly, or does it draw the basins first and only then ask what squarish means inside one of them? Only the second choice gives you an object, the local count $c(n)$, that is simple enough to sum.

Layer 2: HOW

Block 1. **Cue.** The phrase distance to the nearest perfect square. **Why natural.** Nearest is only well defined relative to two competitors, so the natural first move is to find, for each n, exactly which integers have n^2 as their nearest perfect square; the midpoints to the two neighbouring squares are never integers, so this partition has no ambiguous boundary cases to worry about. **Link to the next block.** Once every integer has a well defined home basin, squarishness of any integer can be decided by looking only inside its own basin.

Block 2. **Cue.** Inside one basin, the offset from n^2 ranges over a bounded set of integers on each side. **Why natural.** Squarishness of $k = n^2 \pm d$ reduces to whether d is a perfect square, and counting perfect squares up to a bound is exactly what floor of a square root computes; this converts a verbal condition into an arithmetic formula with no further case analysis needed. **Link to the next block.** The local formula $c(n)$ is now a function of n alone, which is precisely what you need to sum over basins to build $S(N)$.

Block 3. **Cue.** $S(N)$ counts squarish integers up to N, while $c(n)$ counts them per whole basin; the two do not line up exactly because N generally falls in the middle of a basin. **Why natural.** Rather than compute the exact partial contribution of the boundary basin, sandwich it: every basin fully below N contributes exactly $c(n)$, and N can never lie before the start of Basin$(\lfloor\sqrt{N}\rfloor)$ nor after the end of Basin$(\lceil\sqrt{N}\rceil)$, which pins the error to at most one basin at each end. **Link to the next block.** The bound $(*)$ replaces the awkward function $S(N)$ with the much tamer partial sum $T(M)$, evaluated at $M = m \pm 1$.

Block 4. **Cue.** $T(M)$ is a sum of the slowly growing function $c(n) \approx 2\sqrt{n}$. **Why natural.** There is no exact closed form for $\sum \sqrt{n}$, but $\sqrt{x}$ is increasing and continuous, so its sum over integers is trapped between two integrals of $\sqrt{x}$ shifted by one step; the trapping error is always one power lower than the integral itself, which is exactly harmless once you only need the leading power law. **Link to the next block.** This produces $T(M) = \frac{4}{3}M^{3/2} + O(M)$, a clean power of M, but the problem is stated in terms of N, not M.

Block 5. **Cue.** $m = \lfloor \sqrt{N} \rfloor$ links M back to N. **Why natural.** Substituting $m = \sqrt{N} + O(1)$ into $M^{3/2}$ and expanding converts a power of m into a power of N plus a controlled lower order error, so the $O(1)$ discrepancy between m and $\sqrt{N}$, and between $S(N)$ and $T(m)$, both wash out once divided by the leading term $N^{3/4}$. **Link to the next block.** None; dividing through by $N^{3/4}$ and letting $N \to \infty$ finishes the problem, and the uniqueness of α, β follows immediately from how a power law limit scales.

Layer 3: WHY

The truth underneath this problem is that any condition phrased as nearest element of a fixed increasing sequence secretly defines a partition of the integers into blocks, a one dimensional Voronoi decomposition, and any counting problem stated in those terms is really a sum of local counts, one per block. You cannot see the local count until you have drawn the blocks, and you cannot draw the blocks until you take the phrase nearest literally enough to compute its boundary as a midpoint.

The discernment mechanism is this: whenever a definition compares an object to the nearest member of a sparse reference sequence, sketch the reference sequence on a line first, before touching the actual condition. This turns an amorphous global statement into finitely many local ones, and it works regardless of what the reference sequence is, perfect squares here, but perfect cubes, primes, or any other increasing sequence in other problems. Separately, whenever an asymptotic growth rate rather than an exact value is requested, train yourself to stop as soon as you can write the summand as a power of n up to a bounded error, because from that point the integral comparison is mechanical and adds no further insight, only bookkeeping.

What the examiners nudged toward is encoded in the exact choice of perfect squares as the reference sequence: consecutive squares are $2n$ apart near n^2, a gap that itself grows, and it is exactly this growing gap that produces a genuine power law with a non-trivial exponent instead of a fixed size window; had they chosen a reference sequence with constant gaps, the whole problem would collapse to elementary counting with $\alpha = 1$. The specific exponent $3/4$ is the fingerprint of composing two square root scales, once in the gap size, once in the fraction of that gap taken up by squarish offsets, a composition worth recognising as its own pattern rather than as an isolated coincidence.

Revolving concepts

Floor of the square root as a counting device. $\lfloor \sqrt{x} \rfloor$ is the unique integer k with $k^2 \le x < (k+1)^2$, and it counts exactly the perfect squares in $[1, x]$; more generally the perfect squares in an interval $[a, b]$ number $\lfloor \sqrt{b} \rfloor - \lfloor \sqrt{a-1} \rfloor$. This is the single arithmetic tool that turns nearest perfect square into an explicit count. See Book 1, field: Number theory, topic: floor functions and perfect power counting.

Basin decomposition by nearest reference point. For any strictly increasing sequence $a_1 < a_2 < \cdots$, the integers nearer to a_n than to any other term form an interval bounded by the (generically non integer) midpoints to the two neighbouring terms, and these intervals partition all sufficiently large integers. The generalisation worth installing: this is a one dimensional Voronoi diagram, and it applies to any nearest to a known sequence condition, not only perfect squares; for perfect k-th

powers the basin of n^k has size of order $k\,n^{k-1}$, matching the derivative of n^k. See Book 1, field: Discrete structures and graphs, topic: nearest neighbour partitions of the integers.

The discrete integral test, generalised. If f is increasing and continuous, $\int_0^M f(x)\,dx \le \sum_{n=1}^{M} f(n) \le \int_1^{M+1} f(x)\,dx$, so $\sum_{n=1}^{M} f(n) = \int_0^M f(x)\,dx + O(f(M))$. Viewing $T(M) = T(M-1) + c(M)$ as a running total, a first order recurrence with increment $c(M)$, this is the general solution method whenever the increment grows like a power: if $c(n) \sim Cn^p$ for $p > -1$, then $T(M) \sim \dfrac{C}{p+1} M^{p+1}$, recovering $T(M) \sim \frac{4}{3}M^{3/2}$ here with $C = 2$, $p = \frac{1}{2}$. The same method solves every power sum $\sum n^p$ and every running total whose per step growth is a power law. See Book 1, field: Real analysis, topic: sum to integral comparison and power sum asymptotics.

Uniqueness of a power law exponent. If $f(N)/N^\alpha \to \beta$ for some finite $\beta > 0$, the pair (α, β) is unique among positive α: raising or lowering α multiplies the ratio by a vanishing or exploding factor $N^{\alpha-\alpha'}$. See Book 1, field: Real analysis, topic: regular variation and power law scaling.

Circuit Bank

- **WHEN** a definition compares an integer to the nearest member of a known increasing sequence, such as nearest perfect square **DO** partition the integers into basins around each term of the sequence, using the midpoints to the two neighbours as boundaries **BECAUSE** nearest has no computable meaning until the competitors are fixed, and the basins turn a global condition into finitely many local ones
- **WHEN** you need the exact count of a local property, such as an offset being a perfect square, inside a bounded window **DO** express the count via floor of the appropriate root, not by searching for a global closed form **BECAUSE** floor functions are the exact bookkeeping device for how many terms of a sparse sequence land inside a window of known size
- **WHEN** you need the growth rate, not the exact value, of a sum of a smooth increasing function over a growing range **DO** sandwich the sum between two shifted integrals of that function **BECAUSE** the resulting error is always one power lower than the leading term, so it vanishes after dividing by the leading term and taking the limit
- **WHEN** a problem asks you to find α, β with $f(N)/N^\alpha \to \beta$ finite and positive **DO** treat any working pair you find as the unique answer, without searching for alternatives **BECAUSE** scaling by any other power sends the ratio to zero or to infinity, never to a second finite positive constant

Backtesting

1. First useful cue: distance to the nearest perfect square is undefined until you fix a partition of the integers by nearest square.
2. Method the expression suggested: draw the perfect squares on the number line and read off the basin of each n^2 as the midpoint boundaries to its neighbours.
3. Where you would hesitate, and the thought to reinforce: matching basins to a specific N that falls mid basin; reinforce by remembering $m = \lfloor \sqrt{N} \rfloor$ counts exactly how many full basins fit inside $[1, N]$, with error confined to at most one basin at either end.
4. The trap the question sets: chasing an exact formula for $S(N)$ for every N, which is unnecessary and does not exist cleanly, when only the leading power law is required.
5. What makes you recognise it faster next time: treating nearest [sparse increasing sequence] as an instant cue for a basin decomposition, and $f(N)/N^\alpha \to \beta$ as an instant cue for a sum to integral comparison.

6. The reusable decision rule: reduce a nearest neighbour counting problem to a sum, over basins, of a local count depending only on the basin index, then find that sum's growth rate against an integral of the same order.

Mirror drills

1. Call n *cubeish* if n is a perfect cube or its distance to the nearest perfect cube is a perfect cube. Find α with $S(N)/N^{\alpha} \to \beta$ for some finite $\beta > 0$. *Answer/hint:* the basin of n^3 has size of order $3n^2$ (the derivative of n^3), so the local cubeish count is of order $n^{2/3}$; summing that over n up to $N^{1/3}$ and comparing with an integral gives $\alpha = 5/9$. In general, for nearest perfect k-th power, $\alpha = (2k-1)/k^2$, which recovers $3/4$ at $k = 2$.

2. Compute $S(100)$ directly from the basin method. *Answer:* $T(9) = \sum_{n=1}^{9} c(n) = 38$, and the truncated basin of $n = 10$ contributes only its left half and centre, since $N = 10^2$ exactly: the squarish numbers $91, 96, 99, 100$, four more; so $S(100) = 42$.

3. Suppose instead n is called squarish-prime if n is a perfect square or its distance to the nearest perfect square is prime. Does $S(N)/N^{\alpha}$ still converge to a finite positive limit for some α? *Answer/hint:* no clean power law survives; the count of primes up to a bound x grows like $x/\ln x$ by the prime number theorem, not like a power of x, so the local count per basin is $\Theta(n/\ln n)$ rather than $\Theta(\sqrt{n})$, and the resulting sum carries an extra logarithmic factor that no single power N^{α} can absorb.

10.9 B3. double the extremal triangle to cover the set

Suppose that S is a finite set of points in the plane such that the area of triangle $\triangle ABC$ is at most 1 whenever A, B, and C are in S. Show that there exists a triangle of area 4 that (together with its interior) covers the set S.

Read it out loud

Two words carry this whole problem: finite and 4. Finite is a command term for the extremal principle, choose the object in S that maximises some quantity, because a finite set of real numbers always attains its maximum, with no limiting or compactness argument required. The moment you see finite set together with a bounded quantity attached to triples of that set, your first written line should be let $A, B, C \in S$ maximise the area of triangle ABC.

The number 4 is the second cue, and it is not an arbitrary bound, it is 2^2. Whenever a covering object is asked to have k^2 times the area of an extremal object found inside the same configuration, the natural construction is to scale that extremal object outward by a linear factor of k. Here $k = 2$, and the triangle scaled by 2 outward from an extremal triangle ABC is a very concrete classical object, the triangle through each vertex of ABC parallel to the opposite side, which has ABC sitting inside it as its own medial triangle.

The field embedded here is combinatorial geometry: the extremal principle, similarity and area scaling, and the fact that a triangle is exactly the intersection of the three half planes bounded by its own sides. None of this is hidden, the two numbers in the statement, finite and 4, hand you the whole strategy before you have drawn a single picture; what remains is to certify, rigorously and for every point of S at once, that the doubled triangle really does contain the original set, and to notice the one configuration the argument does not immediately cover: a set S with no three points forming a genuine triangle at all.

Approaches, ranked worst to best

1. **bound the convex hull of S directly via its diameter or width.** *Cue:* S is a bounded planar set of points. *Circuit:* diameter and width estimates. (worst: there is no clean route from a diameter bound to the exact constant 4, and this approach does not use the specific hypothesis, area at most 1 for every triple, in any sharp way).
2. **normalise via an affine transformation before arguing.** *Cue:* area ratios are affine invariant, so a convenient triangle shape can be assumed. *Circuit:* affine reduction to a standard triangle. (a legitimate simplification of bookkeeping, but it removes none of the real content; the covering argument itself still has to be supplied afterwards, so this only ever ranks as a helper, never as the main idea).
3. **extremal principle plus doubling the maximal triangle outward, then certify containment side by side using half planes.** *Cue:* the words finite and the target area $4 = 2^2$. *Circuit:* extremal choice, medial/anticomplementary triangle duality, half plane intersection. (best: the two cues in the statement point directly at this construction, and it settles every point of S at once with three short area comparisons).

The ideal solution

Reduction to a genuine triangle. If no three points of S are non collinear, then S lies on a single line ℓ (this covers $|S| \leq 2$ as a special case). If $|S| \leq 1$, any triangle of area 4 containing that single point works. Otherwise let $B, C \in S$ be two points at the greatest distance $d = |BC| > 0$ apart; since S lies on ℓ and B, C are its extreme points along ℓ, every point of S lies on segment BC. Take the triangle with base BC and apex at perpendicular height $h = 8/d$ above the midpoint of BC: its area

is $\frac{1}{2} \cdot d \cdot h = 4$, and since $S \subseteq BC$, which is one full edge of this triangle, S is covered. This disposes of every degenerate case, so from now on assume S contains three non collinear points.

The extremal triangle. Since S is finite, choose $A, B, C \in S$ maximising the area of triangle ABC among all triples of points of S; write $T = \text{area}(ABC)$, so $0 < T \leq 1$.

Doubling outward. Let A', B', C' be the points such that A, B, C are the midpoints of $B'C', C'A', A'B'$ respectively; equivalently, draw through each of A, B, C the line parallel to the opposite side of ABC, and let these three lines meet in A', B', C'. Then ABC is the medial triangle of $A'B'C'$, similar to it with ratio $\frac{1}{2}$, so

$$\text{area}(A'B'C') = 4T \leq 4.$$

Every point of S lies inside $A'B'C'$. Fix $P \in S$. For a triangle with a fixed base QR, area equals $\frac{1}{2}|QR| \cdot d(X, \text{line } QR)$ for the apex X, so two such triangles sharing the base QR have areas in the same order as the perpendicular distances of their apexes from line QR. Applying this with base BC: since $\text{area}(PBC) \leq T = \text{area}(ABC)$ by maximality of T, we get $d(P, \text{line } BC) \leq d(A, \text{line } BC)$. But line $B'C'$ is, by construction, exactly the line through A parallel to BC, at perpendicular distance $d(A, \text{line } BC)$ from it, on the same side as A (hence the same side as B, C, since B, C lie on line BC itself, distance 0 from it). So the inequality $d(P, \text{line } BC) \leq d(A, \text{line } BC)$ says exactly that P lies in the closed half plane bounded by line $B'C'$ that contains B and C.

The identical argument with base CA (using $\text{area}(PCA) \leq T$) places P in the half plane bounded by line $C'A'$ containing C, A; and with base AB (using $\text{area}(PAB) \leq T$) places P in the half plane bounded by line $A'B'$ containing A, B. A triangle is exactly the intersection of the three closed half planes determined by its own three sides, the ones containing the triangle's interior, so P lying in all three such half planes for $A'B'C'$ means precisely $P \in \triangle A'B'C'$ (closed region). Since $P \in S$ was arbitrary,

$$S \subseteq \triangle A'B'C'.$$

Fixing the area at exactly 4. If $4T = 4$, the triangle $A'B'C'$ already has area 4 and covers S: done. If $4T < 4$, apply a homothety centred at the centroid of $A'B'C'$ with ratio $1/\sqrt{T} > 1$; this maps $A'B'C'$ to a similar triangle of area exactly $\left(1/\sqrt{T}\right)^2 \cdot 4T = 4$, and since a homothety with ratio greater than 1 centred at an interior point of a convex region maps that region into a strictly larger region containing it, the image triangle still contains $A'B'C'$ and hence still covers S. Either way, a triangle of area exactly 4 covering S has been produced.

such a triangle of area 4 always exists.

Layer 1: WHAT

Block 1: rule out the degenerate case first, covering a fully collinear S directly with a thin triangle of area 4 built on its two extreme points. Block 2: invoke the extremal principle, choosing $A, B, C \in S$ of maximal triangle area $T \leq 1$, now guaranteed non degenerate. Block 3: double ABC outward into $A'B'C'$, the triangle of which ABC is the medial triangle, giving area exactly $4T$. Block 4: for an arbitrary $P \in S$, turn each of the three maximality inequalities into a half plane membership via a shared base distance comparison, then intersect the three half planes to place P inside $A'B'C'$. Block 5: patch the area up to exactly 4 by a homothety when $T < 1$.

The nominal route reasons about the convex hull of S directly, perhaps via its diameter or width, hoping some general covering inequality falls out; nothing forces the constant 4 to appear this way, and the specific hypothesis (area at most 1 for every triple) is never used sharply. The ideal route never looks at S as a shape at all until the very last step; it manufactures one fixed triangle from S and tests every other point of S against that one triangle, three inequalities at a time. The bifurcation point is the first line of the proof: do you start describing S's global shape, or do you start by naming an extremal triple? Only the second choice produces an object rigid enough to argue against.

Layer 2: HOW

Block 1. **Cue.** The set S is finite, and the quantity in question is an area attached to triples of S. **Why natural.** A finite set of real numbers always attains its maximum, so naming a maximiser costs nothing and immediately produces a single fixed triangle to build the whole proof around, in place of an unwieldy quantifier over all triples. **Link to the next block.** But this maximiser might be degenerate if S has no non collinear triple at all, so that possibility has to be checked and dispatched before relying on it.

Block 2. **Cue.** The target covering area is 4, and the bound on every triple is 1; $4 = 2^2$. **Why natural.** A covering region with k^2 times the extremal area is exactly what you get by scaling the extremal triangle outward by linear factor k; for $k = 2$ that scaled triangle is the classical one obtained by drawing, through each vertex of ABC, the line parallel to the opposite side, of which ABC is then the medial triangle. **Link to the next block.** This produces a specific candidate triangle $A'B'C'$ of area exactly $4T \leq 4$, but being a candidate is not the same as covering S; that still needs proof, point by point.

Block 3. **Cue.** Maximality of $T = \text{area}(ABC)$ applied to the triples (P, B, C), (P, C, A), (P, A, B) for an arbitrary $P \in S$. **Why natural.** Each inequality $\text{area}(PBC) \leq T$ shares the base BC with $\text{area}(ABC)$, and two triangles on a common base have areas in the same order as their apexes' distances from that base, so the inequality converts directly into a statement about how far P can be from line BC. **Link to the next block.** The line at that maximal permitted distance from BC, on the side containing A, is exactly line $B'C'$ by construction, so the distance bound becomes a half plane membership bounded by one side of $A'B'C'$.

Block 4. **Cue.** Three half plane memberships, one per side of $A'B'C'$, each containing the whole of ABC. **Why natural.** A triangle is nothing more than the intersection of the three half planes cut out by its own side lines on the side of its interior, so three simultaneous half plane memberships are exactly membership in the triangle $A'B'C'$ itself; nothing more needs to be checked. **Link to the next block.** Since $P \in S$ was arbitrary, this holds for every point of S at once, so $S \subseteq \triangle A'B'C'$, a triangle of area at most 4.

Block 5. **Cue.** The problem asks for a triangle of area exactly 4, while the construction so far only guarantees area at most 4. **Why natural.** Growing a convex region outward from an interior centre by a homothety of ratio greater than 1 always produces a similar, strictly larger region containing the original, so a shortfall in area can always be made up without losing the covering property. **Link to the next block.** None; this closes the problem for the non degenerate case, and Block 1 already closed the degenerate one.

Layer 3: WHY

The truth underneath this problem is that maximality of an extremal object, tested one replaced vertex at a time, is exactly strong enough to certify a half plane containment for every other point of the configuration, one half plane per side of the extremal object. This is not special to triangles: it is a general fact about extremal simplices inside a bounded family, that doubling the extremal simplex outward via parallel supporting hyperplanes through its own vertices always produces a region containing every competitor, because the maximality condition is precisely the statement that no competitor can push past any one of those supporting hyperplanes.

The discernment mechanism is this: whenever a problem gives you finite together with a quantity bounded over all tuples drawn from that finite set, name the extremiser immediately, before attempting any other manipulation, because maximality is a hypothesis that only pays off

once you have something concrete to test other elements against. Separately, whenever a covering object is asked to be some fixed multiple of an extremal object's size, translate that multiple into a linear scale factor and look for the classical similarity construction realising it, rather than trying to bound the covering region's size by direct computation.

What the examiners nudged toward is the exact pairing of finite (licensing the free extremal choice) with the numerical target 4 (pointing at a linear doubling). A quieter nudge is the phrase together with its interior, which tells you in advance that the covering claim is about a closed region, not merely about the three final vertices, preparing you for the half plane argument rather than a vertex counting one.

Revolving concepts

The extremal principle. A nonempty finite set of real numbers attains its maximum and minimum; applied to a numerical quantity indexed by tuples from a finite set, this licenses fixing an extremal tuple as a distinguished object with no limiting argument. See Book 1, field: Combinatorics, topic: extremal principle.

Area via base and height, as a distance comparison. For a fixed base QR, $\text{area}(XQR) = \frac{1}{2}|QR|\, d(X, \text{line } QR)$, so comparing two such areas is exactly comparing two perpendicular distances to the same line. This is the bridge, used three times here, between an area inequality and a half plane membership. See Book 1, field: Geometry, topic: area as base times height.

Medial triangle and its inverse, the anticomplementary triangle. If A, B, C are the midpoints of the sides of $A'B'C'$, then $A'B'C'$ is similar to ABC with ratio 2 and area $4\,\text{area}(ABC)$; equivalently each side of $A'B'C'$ passes through one vertex of ABC parallel to the opposite side. See Book 1, field: Geometry, topic: medial triangle and area scaling under similarity.

A convex polygon as an intersection of half planes. Any triangle, and more generally any convex polygon, equals the intersection of the closed half planes bounded by its own edge lines and containing its interior; membership in the polygon is equivalent to simultaneous membership in every one of these half planes. See Book 1, field: Geometry, topic: half plane (H) representations of convex regions.

The construction, generalised to k dimensions. The same three ingredients, extremal principle, doubling outward via hyperplanes through each vertex parallel to the opposite facet, and half space intersection, generalise verbatim to a finite set of points in k-dimensional space where every k-simplex among them has volume at most 1. Carrying out the construction on the standard simplex with vertices at the origin and the standard basis vectors shows the resulting covering simplex has volume exactly k^k times the extremal simplex's volume: this recovers the factor $4 = 2^2$ used here for $k = 2$, but gives $27 = 3^3$, not 8, for tetrahedra in three dimensions, since a tetrahedron's six edge midpoints form an octahedron rather than a smaller tetrahedron, so the clean medial triangle picture is special to two dimensions even though the extremal argument itself is not. See Book 1, field: Geometry, topic: simplices and extremal covering constructions.

Circuit Bank

- **WHEN** a finite set has an associated numerical quantity, such as an area or a length, defined over tuples drawn from it, and that quantity is bounded **DO** name the specific tuple that attains the maximum of that quantity **BECAUSE** a nonempty finite set of real numbers always attains its maximum, handing you a fixed, concrete object with no limiting argument required
- **WHEN** a covering object is required to have a fixed multiple k^2 (or k^3, and so on) of an extremal object's size found inside the same configuration **DO** construct the object scaled outward by linear factor k from the extremal one, via the parallel supporting hyperplane through each of its vertices **BECAUSE** similarity multiplies size by the appropriate power of the linear scale factor, and this is the classical construction realising exactly that scaling

- **WHEN** two triangles (or simplices) share a common base (or facet) and you need to compare their areas (or volumes) **DO** convert the comparison into a comparison of perpendicular distances from the apex to that shared base **BECAUSE** area or volume with a fixed base is proportional to height alone, so an order on areas is exactly an order on heights
- **WHEN** you have established that a point lies in several half planes, one bounded by each side of a given triangle and containing that triangle's interior **DO** conclude the point lies inside the closed triangular region itself **BECAUSE** a triangle is precisely the intersection of the half planes determined by its own three sides
- **WHEN** an extremal argument is built on a nondegenerate object, such as a genuine triangle, that might fail to exist for some inputs, such as a collinear point set **DO** isolate and dispatch that degenerate case with a direct, separate construction before relying on the extremal object **BECAUSE** an extremal principle argument silently assumes the extremum is attained by a nondegenerate instance, and a full proof must check that assumption rather than leave it implicit

Backtesting

1. First useful cue: the word finite licenses choosing a maximal area triangle among triples of S with no further justification.
2. Method the expression suggested: since the target area 4 is 2^2 times the bound 1, double the extremal triangle outward via the parallel line through each of its vertices.
3. Where you would hesitate, and the thought to reinforce: proving containment for an arbitrary point of S, not just the three chosen vertices; reinforce by converting each of the three area inequalities (against a shared side of the extremal triangle) into a distance inequality, then into a half plane membership bounded by the matching side of the doubled triangle.
4. The trap the question sets: assuming a direct convex hull or diameter argument can reach the exact constant 4, or forgetting that a fully collinear S has no genuine triangle to extremise at all.
5. What makes you recognise it faster next time: reading finite plus bounded quantity as an instant cue for the extremal principle, and covering by k^2 times an extremal size as an instant cue for a linear-k doubling construction.
6. The reusable decision rule: extremise, double outward by the required linear scale factor, certify containment side by side using shared-base distance comparisons converted to half planes, then separately confirm the extremal object cannot degenerate for the inputs the problem allows.

Mirror drills

1. If S consists of exactly the three vertices of a single triangle of area 1, does the construction still give a covering triangle of area 4, and is that the smallest triangle covering S? *Answer:* the construction still produces the anticomplementary triangle of area 4, but the triangle ABC itself, area 1, already covers S since S is exactly its vertex set; the bound of 4 is far from tight when S is small, and only accumulates real content once many points of S press against the extremal triangle from several directions.
2. Suppose instead every triangle from S has area at most T for some constant $T > 0$, not necessarily 1. What area of covering triangle does the identical construction produce? *Answer:* $4T$, by the same argument verbatim; the scaling factor 4 is forced by the doubling construction alone and does not depend on the specific numerical bound.

3. Generalise the construction, not the numeric answer, to a finite set of points in three dimensional space where every tetrahedron among them has volume at most 1: what volume results from drawing, through each vertex of the maximal volume tetrahedron, the plane parallel to the opposite face? *Answer:* 27, not 8. Checking on the standard tetrahedron with vertices at the origin and the three unit basis points confirms the scaling factor in k dimensions is k^k, here $3^3 = 27$, because a tetrahedron's edge midpoints form an octahedron rather than a smaller tetrahedron, so the two dimensional picture of ABC as a medial triangle does not carry over unchanged.

10.10 B4. Expected determinant of a random skew matrix

Let A be a $2n \times 2n$ matrix, with entries chosen independently at random. Every entry is chosen to be 0 or 1, each with probability $1/2$. Find the expected value of $\det(A - A^t)$ (as a function of n), where A^t is the transpose of A.

Read it out loud

This is a probability question wearing a linear algebra coat. Read the object before you read the words: you are asked for the expected value of a determinant, and the matrix inside the determinant is not A but $A - A^t$. The moment you see $A - A^t$ you say the word out loud: skew-symmetric. That is not decoration, that is the entire question. A skew-symmetric matrix of even size has determinant equal to the square of its Pfaffian, so the answer will be a positive number, and the combinatorial objects that eventually appear will be perfect matchings rather than general permutations. You do not need the Pfaffian to solve this, but knowing it tells you in advance what the shape of the answer must be, and that is worth ten seconds of your time.

The fields wired in are three. Matrices and determinants, specifically the Leibniz expansion, which is the only description of a determinant that plays well with expectation. Probability, specifically linearity of expectation, independence, and the fact that a mean zero factor annihilates a monomial. Combinatorics, specifically counting fixed point free involutions of a $2n$ element set.

What is really being tested is whether you know which of your tools survives contact with a determinant. Expectation is linear. The determinant is not. So $\mathrm{E}[\det M] \neq \det \mathrm{E}[M]$ in general, and the candidate who writes $\mathrm{E}[A - A^t] = 0$ and concludes that the answer is 0 has thrown the paper away in a single line. That is the trap, and it is a good one, because $\mathrm{E}[A - A^t] = 0$ is true. It is the next step that is false.

Inside thirty seconds you should have written three lines. Set $M := A - A^t$. For $i < j$, $M_{ij} = A_{ij} - A_{ji}$ takes the values $-1, 0, 1$ with probabilities $\frac{1}{4}, \frac{1}{2}, \frac{1}{4}$, and the $\binom{2n}{2}$ variables M_{ij} with $i < j$ are independent because they are built from pairwise disjoint pairs of entries of A. Finally $M_{ii} = 0$ and $M_{ji} = -M_{ij}$. The $4n^2$ coin flips have collapsed into $n(2n-1)$ independent three valued variables, and everything after that is bookkeeping.

Approaches, ranked worst to best

1. **Expectation of the determinant equals the determinant of the expectation.** *Cue:* the matrix $A - A^t$ has mean zero. *Circuit:* linearity, misapplied. This is not an approach, it is the trap, and it returns the wrong answer 0. The determinant is a polynomial of degree $2n$ in the entries, and expectation commutes with polynomials only through their monomials, never through the polynomial as a whole. Named here so that the reflex to reject it is trained rather than assumed.

2. **Compute small cases and guess.** *Cue:* the answer is requested as a function of n. *Circuit:* pattern completion. You get $1/2$ for $n = 1$ and, after some grinding, $3/4$ for $n = 2$. Two data points do not identify $(2n)!/(4^n n!)$, and a guess earns nothing. Useful only as a check at the end, which is exactly where you should use it.

3. **Cofactor expansion or eigenvalue structure.** *Cue:* a determinant of a structured matrix. *Circuit:* expand along a row, or diagonalise. A skew-symmetric real matrix has eigenvalues in conjugate pairs $\pm i\lambda$, so $\det M = \prod \lambda_k^2 \geq 0$, which is genuine structure. But the eigenvalues of a random integer matrix have no tractable joint distribution, and cofactor expansion produces a recursion in objects that are not independent. Both stall.

4. **Pfaffian.** *Cue:* even sized skew-symmetric matrix. *Circuit:* $\det M = \mathrm{Pf}(M)^2$, and Pf is a signed sum over perfect matchings. Fast and structurally honest: square the Pfaffian, note that a cross

term between two distinct matchings contains some M_{ij} to the first power and therefore has mean zero, and the diagonal terms each contribute $\mathrm{E}[M_{ij}^2]^n = 2^{-n}$. The only cost is that you must cite the identity $\det = \mathrm{Pf}^2$, which is a real theorem and not something you can prove in the margin.

5. **Leibniz expansion with cycle decomposition.** *Cue:* expected value of a determinant with independent entries. *Circuit:* write det as a sum of monomials, take expectations monomial by monomial, and kill every monomial containing a mean zero factor to an odd power. Best. It is completely self-contained, it needs no theorem beyond the definition of the determinant and independence, and it produces the matching count as an output rather than requiring it as an input. This is the route below.

The ideal solution

Write $M = A - A^t$, so $M_{ii} = 0$ and $M_{ji} = -M_{ij}$ for all i, j. For $i < j$ the variable $M_{ij} = A_{ij} - A_{ji}$ is a function of the two entries A_{ij} and A_{ji} alone, and distinct unordered pairs $\{i, j\}$ use disjoint pairs of entries of A, so

$$\{M_{ij} : 1 \le i < j \le 2n\}$$

is an independent family. Each has the distribution

$$\mathrm{P}(M_{ij} = -1) = \tfrac{1}{4}, \quad \mathrm{P}(M_{ij} = 0) = \tfrac{1}{2}, \quad \mathrm{P}(M_{ij} = 1) = \tfrac{1}{4},$$

so that

$$\mathrm{E}[M_{ij}] = 0, \qquad \mathrm{E}[M_{ij}^2] = \tfrac{1}{4} + \tfrac{1}{4} = \tfrac{1}{2}.$$

By the Leibniz formula,

$$\det M = \sum_{\sigma \in S_{2n}} \operatorname{sgn}(\sigma) \prod_{i=1}^{2n} M_{i\sigma(i)}.$$

This is a finite sum of random variables, each bounded, so expectation passes through it:

$$\mathrm{E}[\det M] = \sum_{\sigma \in S_{2n}} \operatorname{sgn}(\sigma) E_\sigma, \qquad E_\sigma := \mathrm{E}\left[\prod_{i=1}^{2n} M_{i\sigma(i)}\right].$$

Fix σ and decompose $\{1, \dots, 2n\}$ into the orbits (cycles) of σ. The product splits accordingly, one factor group per cycle, and cycles occupy disjoint index sets, so the unordered pairs $\{i, \sigma(i)\}$ arising in different cycles are distinct.

Claim 10.10.1. *$E_\sigma = 0$ unless σ is a product of n disjoint transpositions.*

Proof. If σ has a fixed point i then the product contains the factor $M_{ii} = 0$, so the product is identically zero and $E_\sigma = 0$.

Suppose σ has a cycle $C = (c_1\, c_2 \cdots c_m)$ of length $m \ge 3$. The factors contributed by C are $M_{c_1c_2}, M_{c_2c_3}, \dots, M_{c_mc_1}$, and the m unordered pairs $\{c_1, c_2\}, \dots, \{c_m, c_1\}$ are distinct: if $\{i, \sigma(i)\} = \{j, \sigma(j)\}$ with $i \ne j$ then $\sigma(i) = j$ and $\sigma(j) = i$, which puts i and j in a cycle of length 2. Hence every one of the $2n$ factors of the whole product is $\pm M_{ij}$ for some $i < j$, and the variable $M_{c_1c_2}$ occurs in exactly one factor overall. Grouping the product as $\pm M_{c_1c_2}$ times a product of factors involving other pairs, independence gives

$$E_\sigma = \pm\, \mathrm{E}[M_{c_1c_2}] \cdot \mathrm{E}[\text{rest}] = 0,$$

since $\mathrm{E}[M_{c_1c_2}] = 0$. □

So only the fixed point free involutions survive. Let σ be such a permutation, with transpositions $\{a_1, b_1\}, \ldots, \{a_n, b_n\}$ partitioning $\{1, \ldots, 2n\}$. Then

$$\prod_{i=1}^{2n} M_{i\sigma(i)} = \prod_{\ell=1}^{n} M_{a_\ell b_\ell} M_{b_\ell a_\ell} = \prod_{\ell=1}^{n} \left(-M_{a_\ell b_\ell}^2\right) = (-1)^n \prod_{\ell=1}^{n} M_{a_\ell b_\ell}^2,$$

and $\operatorname{sgn}(\sigma) = (-1)^n$ because σ is a product of n transpositions. The two signs cancel, so

$$\operatorname{sgn}(\sigma) \prod_{i=1}^{2n} M_{i\sigma(i)} = \prod_{\ell=1}^{n} M_{a_\ell b_\ell}^2,$$

which is nonnegative, and by independence of the n distinct variables involved,

$$\operatorname{sgn}(\sigma) E_\sigma = \prod_{\ell=1}^{n} \mathrm{E}\left[M_{a_\ell b_\ell}^2\right] = \left(\tfrac{1}{2}\right)^n = 2^{-n}.$$

Every surviving permutation contributes the same amount, and no cancellation occurs.

It remains to count the fixed point free involutions of a $2n$ element set, equivalently the perfect matchings. Choose the partner of the smallest unused element in $2n-1$ ways, then repeat on the remaining $2n-2$ elements: the count satisfies $P_{2n} = (2n-1)P_{2n-2}$ with $P_0 = 1$, hence

$$P_{2n} = (2n-1)!! = \frac{(2n)!}{2^n\, n!}.$$

Therefore

$$\mathrm{E}[\det(A - A^t)] = \frac{(2n)!}{2^n n!} \cdot 2^{-n} = \boxed{\frac{(2n)!}{4^n\, n!}}.$$

Two checks. For $n = 1$, $M = \begin{pmatrix} 0 & M_{12} \\ -M_{12} & 0 \end{pmatrix}$ has $\det M = M_{12}^2$ with expectation $\frac{1}{2}$, and the formula gives $2!/(4 \cdot 1) = \frac{1}{2}$. For $n = 2$ the formula gives $24/32 = 3/4$, which is 3 matchings each worth $\frac{1}{4}$. Finally, the answer is positive, as it must be: $\det M = \operatorname{Pf}(M)^2 \geq 0$ pointwise, so its expectation cannot be zero unless $\det M$ vanishes almost surely, which it does not.

Layer 1: WHAT

Block 1. Name the object: $M = A - A^t$ is skew-symmetric, its strictly upper triangular entries are independent, each taking $-1, 0, 1$ with probabilities $\frac{1}{4}, \frac{1}{2}, \frac{1}{4}$; the rest of the matrix is determined by them.

Block 2. Determinant into monomials: use the Leibniz formula and push expectation inside the finite sum, so the problem becomes one expectation per permutation.

Block 3. Decompose each permutation into cycles, because that is what tells you which variables appear and to what power.

Block 4. Kill everything: fixed points give a zero factor; cycles of length at least 3 give a mean zero factor to the first power. Only fixed point free involutions survive.

Block 5. Evaluate a survivor: the sign $(-1)^n$ of the involution cancels the sign from $M_{ba} = -M_{ab}$, leaving a product of squares with expectation 2^{-n}.

Block 6. Count the survivors: $(2n-1)!! = (2n)!/(2^n n!)$, multiply, done.

Juxtaposition. The nominal route reads "expected value of a determinant" and reaches for the matrix as a whole: take expectations of the entries first, or find the distribution of $\det M$, or expand along a row. All three treat det as a function of a matrix. The ideal route refuses to see a matrix at all: it sees a degree $2n$ polynomial in $n(2n-1)$ independent scalars, and it knows that expectation is a linear functional on polynomials. The bifurcation point is the line where you write the Leibniz sum instead of writing $\mathrm{E}[M]$. Everything downstream is forced.

Layer 2: HOW

Block 1. **Cue.** The expression $A - A^t$, and nothing else in the problem. A difference of a matrix and its transpose has exactly one name. **Why natural.** Because the definition of skew-symmetry is $M^t = -M$, and $(A - A^t)^t = A^t - A = -(A - A^t)$ is a one line verification. Naming the structure is worth doing before any computation because it fixes the diagonal at zero and halves the number of random variables. The independence claim is also definition level: M_{ij} for $i < j$ is a function of A_{ij}, A_{ji} only, and those pairs are disjoint across distinct $\{i, j\}$, so functions of disjoint independent families are independent. **Link to the next block.** Once you know the entries are independent with mean zero, the only question left is which monomials in those entries survive the expectation. That question is asked and answered by the determinant expansion.

Block 2. **Cue.** "Expected value of det". Expectation is linear; the determinant is not. **Why natural.** The Leibniz formula is the unique description of a determinant as a linear combination of monomials in the entries. Since expectation is linear and the sum is finite, E passes through the sum with no convergence concerns at all. This is the only structurally available move: any route that keeps det intact has to know the distribution of $\det M$, which is far harder than the question asked. **Link to the next block.** Now every term is E of a product of $2n$ entries, so you must understand which entries appear in a given term, and how often.

Block 3. **Cue.** A product indexed by a permutation. Permutations decompose into cycles, always, and that decomposition is what controls repetitions. **Why natural.** The pair $\{i, \sigma(i)\}$ repeats only when σ swaps i and $\sigma(i)$. That is a statement about cycles of length 2, so the cycle type is precisely the right invariant to sort the terms by. This is not a guess: you are looking for repeated variables, and repetition of the unordered pair $\{i, \sigma(i)\}$ is equivalent to a transposition. **Link to the next block.** Sorting by cycle type immediately splits the permutations into three classes, and two of them die.

Block 4. **Cue.** A factor with mean zero multiplied by independent stuff. **Why natural.** If X is independent of Y and $\mathrm{E}[X] = 0$ then $\mathrm{E}[XY] = \mathrm{E}[X]\,\mathrm{E}[Y] = 0$. In a cycle of length at least 3, the variable attached to any one edge of that cycle appears exactly once in the entire $2n$ fold product, so it can be split off as such an X. A fixed point is even cheaper: the factor is the diagonal entry, which is identically zero. **Link to the next block.** Only fixed point free involutions remain, and they are exactly the perfect matchings of $\{1, \ldots, 2n\}$, which is the combinatorial object you predicted the instant you said "skew-symmetric".

Block 5. **Cue.** Two sources of sign in the same term, one from $\mathrm{sgn}(\sigma)$ and one from $M_{ba} = -M_{ab}$. **Why natural.** Never leave two signs unresolved: multiply them out and see what happens. An involution with n transpositions has sign $(-1)^n$, and the product of the n pairs $M_{ab}M_{ba}$ carries $(-1)^n$. They cancel, so every surviving term is a nonnegative random variable with the same expectation. That is the structural reason there is no cancellation in the final count, and it is also a consistency check against $\det M = \mathrm{Pf}(M)^2 \geq 0$. **Link to the next block.** With all survivors equal to 2^{-n} in expectation, the answer is 2^{-n} times the number of survivors.

Block 6. **Cue.** "Count the perfect matchings of a $2n$ element set." **Why natural.** Match the smallest unused element to any of the remaining $2n - 1$ elements and recurse. That is a recursion because the object it produces is the same object one size down, which is the definition level reason the double factorial appears. **Link to the next block.** Multiply, then check $n = 1$ by hand.

Layer 3: WHY

Three truths make this route ideal, and they are the same three truths behind almost every expected value of a polynomial statistic of a random matrix.

First, expectation is a linear functional on the space of polynomials in the entries, so any polynomial statistic is computable as soon as you know the joint moments of the entries. The determinant is a polynomial of degree $2n$, homogeneous, multilinear in the rows. Therefore the correct representation is the monomial one, and the Leibniz expansion is not an implementation detail, it is the entire method.

Second, independence converts E of a product into a product of Es, but only when the factors involve disjoint sets of variables. So the work in any such problem is combinatorial bookkeeping: which monomials use which variables, and to what power. Here the bookkeeping is the cycle decomposition.

Third, a mean zero variable annihilates any monomial in which it appears to an odd power. This is why the answer is supported on perfect matchings and nowhere else, and it is why the symmetry of the distribution of M_{ij} never actually mattered: all you used was $\mathrm{E}[M_{ij}] = 0$ and $\mathrm{E}[M_{ij}^2] = \frac{1}{2}$.

That last observation is the discernment mechanism, and it generalises with no extra work. If M is any $2n \times 2n$ skew-symmetric random matrix whose entries M_{ij}, $i < j$, are independent with $\mathrm{E}[M_{ij}] = 0$ and $\mathrm{E}[M_{ij}^2] = s_{ij}$, then exactly the same argument gives

$$\mathrm{E}[\det M] = \sum_{\text{perfect matchings } \{a_\ell, b_\ell\}} \prod_{\ell=1}^{n} s_{a_\ell b_\ell},$$

the hafnian of the second moment matrix. The problem as set is the special case $s_{ij} \equiv \frac{1}{2}$. Recognising that your solution never used the specific distribution is how you convert one Putnam problem into a permanent piece of machinery.

How to train the discernment: whenever a random object is fed into an algebraic function, ask which representation of that function is linear in the randomness. For determinants it is the Leibniz sum. For traces of powers it is the sum over closed walks. For characteristic polynomials it is the sum over principal minors. In each case the expectation collapses onto the sub-family of index patterns in which every variable appears to an even power, and that sub-family is always some kind of matching or pairing. That principle, that mean zero variables force pairings, is the same principle that produces Wick's theorem and the Catalan numbers in random matrix theory, and the Putnam examiners were nudging at it by choosing $A - A^t$ rather than A, and by choosing the even size $2n$ rather than a general size.

Revolving concepts

Skew-symmetric matrix. Definition: $M^t = -M$, forcing $M_{ii} = 0$ over a field of characteristic not 2. Orbiting facts: over $\mathbb{R}$ the eigenvalues come in pairs $\pm i\lambda$; the rank is always even; an odd sized skew-symmetric matrix has determinant 0, since $\det M = \det(-M^t) = (-1)^{2m+1} \det M$. See Book 1, field: Matrices and determinants, topic: symmetry classes of matrices.

Pfaffian. For M skew-symmetric of size $2n$, $\mathrm{Pf}(M) = \sum_\alpha \mathrm{sgn}(\alpha) \prod_{\ell=1}^{n} M_{i_\ell j_\ell}$, summed over perfect matchings α, and $\det M = \mathrm{Pf}(M)^2$. This is the reason the answer is positive and the reason matchings, not permutations, index the surviving terms. You did not need it, but it predicts the shape of the answer before you compute anything. See Book 1, field: Matrices and determinants, topic: Pfaffian.

Leibniz expansion. $\det M = \sum_\sigma \mathrm{sgn}(\sigma) \prod_i M_{i\sigma(i)}$, a sum of $(2n)!$ signed monomials. Orbiting facts: sgn is a homomorphism to $\{\pm 1\}$; a permutation with cycle type having c cycles on N letters has sign $(-1)^{N-c}$; a product of n disjoint transpositions has sign $(-1)^n$. See Book 1, field: Matrices and determinants, topic: Leibniz formula.

Mean zero kills odd powers. If $X_1, \dots, X_r$ are independent and $\mathrm{E}[X_1] = 0$, then $\mathrm{E}[X_1^{e_1} \cdots X_r^{e_r}] = 0$ whenever $e_1 = 1$. More generally the monomial survives only if each variable appears with an exponent whose moment is nonzero. See Book 1, field: Probability, topic: moments and independence.

The matching recursion, generalised. Let P_{2n} be the number of ways to partition $2n$ labelled objects into unordered pairs. Pair the smallest element with one of the other $2n-1$, then recurse: $P_{2n} = (2n-1)P_{2n-2}$, $P_0 = 1$, hence $P_{2n} = (2n-1)!! = (2n)!/(2^n n!)$. The general form of this recursion is $P_N = (N-1)P_{N-2}$, and the general solution method is the same every time: iterate and read off a product, then convert the product of odd numbers into $(2n)!/(2^n n!)$ by inserting the missing even factors. The same recursion counts: the number of ways to pair up $2n$ people for a chess round, the number of chord diagrams on $2n$ points, the $2n$-th moment of a standard normal divided by nothing at all (indeed $\mathrm{E}[Z^{2n}] = (2n-1)!!$, which is the same pairing count, for exactly the same mean zero reason). Whenever you see $(2n-1)!!$ in an answer, look for the pairing that produced it. See Book 1, field: Combinatorics, topic: perfect matchings and double factorials.

Cycle decomposition. Every permutation is a product of disjoint cycles, uniquely up to order; the orbits partition the index set. Load bearing here because disjoint orbits mean disjoint variable sets, which is what licences the factorisation of the expectation. See Book 1, field: Abstract algebra, topic: symmetric group.

Circuit Bank

- **WHEN** you are asked for the expected value of a determinant, a permanent, or any polynomial in random entries **DO** expand into monomials (Leibniz for det) and take expectations term by term **BECAUSE** expectation is linear on monomials but does not commute with the polynomial as a whole; $\mathrm{E}[\det M] \neq \det \mathrm{E}[M]$.
- **WHEN** a monomial contains an independent factor with mean zero to the first power **DO** delete the whole monomial **BECAUSE** $\mathrm{E}[XY] = \mathrm{E}[X]\,\mathrm{E}[Y] = 0$ when X and Y are independent and $\mathrm{E}[X] = 0$; this is what forces surviving terms to be pairings.
- **WHEN** you see $A - A^t$, or any even sized skew-symmetric matrix **DO** write down that the diagonal is zero, that the strictly upper entries determine everything, and that $\det = \mathrm{Pf}^2 \geq 0$ **BECAUSE** skew-symmetry is a definition level constraint that halves the number of free variables and predicts a nonnegative answer.
- **WHEN** a permutation indexes a product and you need to know which variables repeat **DO** decompose into cycles first **BECAUSE** repetition of the unordered pair $\{i, \sigma(i)\}$ happens exactly on 2-cycles, so cycle type is the sorting invariant.
- **WHEN** your final answer is a formula in n **DO** test $n = 1$ by direct computation before you write the last line **BECAUSE** a single arithmetic slip in a factorial count is invisible in the algebra and instantly visible at $n = 1$.

Backtesting

1. First useful cue: the expression $A - A^t$, which names the matrix skew-symmetric and immediately gives a zero diagonal, an independent family of $\binom{2n}{2}$ entries, and the prediction that perfect matchings will index the answer.
2. Method the expression suggested: Leibniz expansion of the determinant, expectation term by term, cycle decomposition of each permutation to see which terms survive.
3. Where you would hesitate, and the thought to reinforce: at the claim that a cycle of length at least 3 contributes zero. Reinforce it by asking not "is this zero" but "does some variable appear here exactly once", because that is the only question the mean zero property can answer.

4. The trap the question sets: $\mathrm{E}[A - A^t] = 0$ tempting you into $\mathrm{E}[\det(A - A^t)] = \det(0) = 0$. The determinant is degree $2n$, not degree 1; the mean of a square is not the square of the mean.
5. What makes you recognise it faster next time: the pairing signature. If a problem gives you independent mean zero randomness and asks for the expectation of a polynomial, the answer is always a sum over pairings of the variables, with weights the second moments.
6. The reusable decision rule: expectation of a polynomial statistic equals the sum over monomials whose every variable has even exponent; find that sub-family combinatorially, weight it by the moments, count it.

Mirror drills

1. Let B be an $(2n+1) \times (2n+1)$ matrix with entries chosen as in the problem. Find $\mathrm{E}[\det(B - B^t)]$. *Answer:* 0, and not because of any expectation argument: an odd sized skew-symmetric matrix satisfies $\det M = \det(-M^t) = -\det M$, so $\det M = 0$ pointwise.
2. Let the entries of A be independent and uniform on $\{0, 1, \ldots, q-1\}$ instead of on $\{0, 1\}$. Find $\mathrm{E}[\det(A - A^t)]$. *Answer:* the proof used only $\mathrm{E}[M_{ij}] = 0$ and $\mathrm{E}[M_{ij}^2] = s$, and here $s = \mathrm{E}[(A_{ij} - A_{ji})^2] = 2\,\mathrm{Var}(A_{ij}) = (q^2-1)/6$, so the answer is $\frac{(2n)!}{2^n n!}\left(\frac{q^2-1}{6}\right)^n$.
3. Let A be $n \times n$ with independent entries of mean 0 and variance 1. Show that $\mathrm{E}[\det A] = 0$ and $\mathrm{E}[(\det A)^2] = n!$. *Answer:* in the single expansion every monomial has some entry to the first power; in the squared expansion the pair (σ, τ) survives only when $\sigma = \tau$, contributing $\mathrm{sgn}(\sigma)^2 \prod \mathrm{E}[A_{i\sigma(i)}^2] = 1$, and there are $n!$ such pairs.

10.11 B5. Multiplicative sandwich forces a pure power

Find all functions f from the interval $(1,\infty)$ to $(1,\infty)$ with the following property: if $x, y \in (1,\infty)$ and $x^2 \le y \le x^3$, then $(f(x))^2 \le f(y) \le (f(x))^3$.

Read it out loud

This is a functional equation that is not an equation. It is a two sided inequality, a sandwich: the hypothesis sandwiches y between two powers of x, and the conclusion sandwiches $f(y)$ between the same two powers of $f(x)$. Say that out loud, because it is the whole structure: the numbers 2 and 3 appear on the input side and on the output side, unchanged. The map f is being asked to transport a multiplicative window of a fixed shape to a multiplicative window of the same shape.

Now notice what is missing. There is no continuity, no monotonicity, no measurability, nothing. So you cannot reach for any theorem about regular solutions of Cauchy's equation; the rigidity has to be manufactured out of the inequality itself. That is the real content of the problem, and it is why this sits at B5 and not at B2.

The fields wired in: functional equations (the normal form game), real analysis (chaining inequalities, no regularity assumed), number theory (the multiplicative independence of 2 and 3), and equidistribution (density of $\{a\theta - b\}$ for irrational θ). The answer will be $f(x) = x^c$ for $c > 0$, and you should write that down in the first ten seconds after checking it works: for $x > 1$ and $x^2 \le y \le x^3$, $x^{2c} \le y^c \le x^{3c}$, which is exactly $f(x)^2 \le f(y) \le f(x)^3$.

Within thirty seconds you should also have written the substitution $x = e^u$. Powers of x become multiples of u, so with $g(u) = \log f(e^u)$ the condition reads: $2u \le v \le 3u$ implies $2g(u) \le g(v) \le 3g(u)$. Look at what that did. It did not solve the problem; it reproduced it. The output side is still multiplicative. So do it again. That doubling of the same move is the cue the examiners planted by using the same two constants on both sides.

Approaches, ranked worst to best

1. **Guess the family and verify it.** *Cue:* "find all functions" with an obvious candidate. *Circuit:* pattern recognition. Verifying that x^c works takes one line and earns close to nothing, because the entire difficulty is the word "all". Do it anyway, but only as target practice: it tells you the exact statement you must eventually prove.

2. **Assume continuity or monotonicity, then use Cauchy's equation.** *Cue:* a functional condition on $\mathbb{R}$. *Circuit:* regularity plus additivity gives linearity. This is the standard reflex and it is wrong here, because no regularity is given and none is derivable cheaply. Writing "we may assume f is continuous" is an unearned hypothesis and a grader will take the marks.

3. **Iterate the sandwich on powers of the argument.** *Cue:* $y = x^2$ and $y = x^3$ are the extreme allowed choices. *Circuit:* apply the hypothesis repeatedly and stack the inequalities. You learn a great deal about f on the sparse set of exponents $2^a 3^b$, and nothing at all about f between them. It stalls because the information lives on a multiplicative semigroup with no obvious way to interpolate.

4. **One logarithm, then attack g directly.** *Cue:* powers on both sides. *Circuit:* log turns exponents into coefficients. A real improvement: $2u \le v \le 3u \Rightarrow 2g(u) \le g(v) \le 3g(u)$. But the constraint is still "multiply by something between 2 and 3", and multiplications do not chain into a useful additive bookkeeping. Most solvers stop here and grind.

5. **Two logarithms, then chain displacements.** *Cue:* the constraint is a sandwich of the same shape on both sides. *Circuit:* convert the constraint into "a shift of size in $[\log 2, \log 3]$ maps to a shift of size in $[\log 2, \log 3]$", so that steps compose additively. Best. With $h(s) = \log g(e^s)$ the condition becomes a translation statement, forward and backward steps are both available,

and the reachable displacements after a forward and b backward steps form the interval $[a\log 2 - b\log 3,\ a\log 3 - b\log 2]$, whose endpoints are dense in $\mathbb{R}$ because $\log 3/\log 2$ is irrational. That density is the rigidity, and it is where the numbers 2 and 3 finally earn their keep.

The ideal solution

The answer: exactly the functions $f(x) = x^c$ with $c > 0$.

These work: if $c > 0$ then $x^c > 1$ for $x > 1$, and $x^2 \le y \le x^3$ gives $x^{2c} \le y^c \le x^{3c}$, that is, $f(x)^2 \le f(y) \le f(x)^3$. Conversely, suppose f has the stated property. Throughout write $L_2 = \log 2$ and $L_3 = \log 3$.

Step 1: two changes of variable. Define $g : (0,\infty) \to (0,\infty)$ by $g(u) = \log f(e^u)$; this is positive because $f > 1$. Putting $x = e^u$ and $y = e^v$ with $u > 0$, the hypothesis $x^2 \le y \le x^3$ is exactly $2u \le v \le 3u$ (and then $v > 0$, so $y > 1$ automatically), while the conclusion is exactly $2g(u) \le g(v) \le 3g(u)$.

Define $h : \mathbb{R} \to \mathbb{R}$ by $h(s) = \log g(e^s)$; this is defined because $g > 0$. Putting $u = e^s$ and $v = e^t$, the condition $2u \le v \le 3u$ is exactly $s + L_2 \le t \le s + L_3$, and the conclusion $2g(u) \le g(v) \le 3g(u)$ is exactly $h(s) + L_2 \le h(t) \le h(s) + L_3$. So the hypothesis has become:

$$\text{(P)} \qquad t - s \in [L_2, L_3] \implies h(t) - h(s) \in [L_2, L_3].$$

Interchanging the roles of s and t in (P) gives its mirror image for free:

$$\text{(P}') \qquad t - s \in [-L_3, -L_2] \implies h(t) - h(s) \in [-L_3, -L_2].$$

It suffices to prove that $h(t) - h(s) = t - s$ for all s, t. Indeed, then $h(s) = s + \gamma$ for a constant γ, so $g(e^s) = e^{s+\gamma}$, that is $g(u) = cu$ for all $u > 0$ with $c = e^\gamma > 0$; then $\log f(e^u) = cu$, so $f(e^u) = (e^u)^c$ and $f(x) = x^c$ for all $x > 1$.

Step 2: chaining steps. For nonnegative integers a, b put

$$I_{a,b} = [\,aL_2 - bL_3,\ aL_3 - bL_2\,],$$

a nonempty interval since $(a+b)L_2 \le (a+b)L_3$, with $I_{0,0} = \{0\}$, $I_{1,0} = [L_2, L_3]$ and $I_{0,1} = [-L_3, -L_2]$. Note $I_{a-1,b} + I_{1,0} = I_{a,b}$ and $I_{a,b-1} + I_{0,1} = I_{a,b}$, where the sum of intervals is taken endpoint by endpoint.

Claim 10.11.1. *For all nonnegative integers a, b and all $s, t \in \mathbb{R}$: if $t - s \in I_{a,b}$ then $h(t) - h(s) \in I_{a,b}$.*

Proof. Induct on $a + b$. If $a + b = 0$ then $t = s$ and the statement is trivial. If $a + b = 1$ the statement is (P) or (P′).

Let $a + b = N \ge 2$ and assume the claim for all smaller values of $a + b$. Suppose first that $a > 0$, and let $\tau = t - s \in I_{a,b}$. At the left endpoint $\tau = aL_2 - bL_3$ the decomposition of τ into a forward steps and b backward steps is forced: every forward step is exactly L_2 and every backward step exactly L_3, so deleting one forward step leaves $(a-1)L_2 - bL_3$, the left endpoint of $I_{a-1,b}$. At the right endpoint the same deletion leaves the right endpoint of $I_{a-1,b}$. So interpolate affinely between these two forced choices: define

$$j(\tau) = \frac{(N-1)\tau - b(L_2 + L_3)}{N}.$$

A direct computation gives $j(aL_2 - bL_3) = (a-1)L_2 - bL_3$ and $j(aL_3 - bL_2) = (a-1)L_3 - bL_2$, and j is affine with nonnegative slope $(N-1)/N$, so j maps $I_{a,b}$ into $I_{a-1,b}$. Moreover

$$\tau - j(\tau) = \frac{\tau + b(L_2 + L_3)}{N}$$

is affine and increasing in τ, with value L_2 at the left endpoint of $I_{a,b}$ and L_3 at the right endpoint, so $\tau - j(\tau) \in [L_2, L_3]$ for every $\tau \in I_{a,b}$.

Now set $r = s + j(\tau)$. Then $r - s = j(\tau) \in I_{a-1,b}$, so the inductive hypothesis gives $h(r) - h(s) \in I_{a-1,b}$; and $t - r = \tau - j(\tau) \in [L_2, L_3]$, so (P) gives $h(t) - h(r) \in I_{1,0}$. Adding,

$$h(t) - h(s) \in I_{a-1,b} + I_{1,0} = I_{a,b}.$$

If instead $b > 0$, use $\tilde{j}(\tau) = \big((N-1)\tau + a(L_2 + L_3)\big)/N$, which sends the endpoints of $I_{a,b}$ to the corresponding endpoints of $I_{a,b-1}$ and satisfies $\tau - \tilde{j}(\tau) = (\tau - a(L_2 + L_3))/N \in [-L_3, -L_2]$ for $\tau \in I_{a,b}$; the same two step argument with (P′) in place of (P) finishes the induction. □

Step 3: the arithmetic input.

Lemma 10.11.2. *$\theta = L_3/L_2$ is irrational, and for every $T \in \mathbb{R}$, every $\varepsilon > 0$ and every N, there exist integers $a, b > N$ with $T < aL_3 - bL_2 < T + \varepsilon$. The same holds with the roles of L_2 and L_3 exchanged, and also with the approximation from below, $T - \varepsilon < aL_2 - bL_3 < T$.*

Proof. If $L_3/L_2 = p/q$ with positive integers p, q then $3^q = 2^p$, contradicting unique factorisation. For the density, let $\|\cdot\|$ denote distance to the nearest integer. Given M, the $M+1$ fractional parts of $0, \theta, \dots, M\theta$ lie in $[0,1)$, so two of them lie within $1/M$ of each other, giving a positive integer $q \le M$ with $\|q\theta\| < 1/M$, and $\|q\theta\| \neq 0$ by irrationality. The points $\{mq\theta\}$, $m = 1, 2, \dots$, therefore step around the circle $\mathbb{R}/\mathbb{Z}$ in increments of size less than $1/M$ and so meet every interval of length $1/M$; taking m as large as we please, we may take $a = mq$ as large as we please. Writing $aL_3 - bL_2 = L_2(a\theta - b)$ and choosing b to be the appropriate integer near $a\theta$, we obtain $a\theta - b$ in any prescribed interval of length ε/L_2, with $b \to \infty$ as $a \to \infty$; since M was arbitrary the approximation can be made from above or from below as required. The exchanged version is the same argument with $\theta' = L_2/L_3$, also irrational. □

Step 4: squeeze. Fix $s < t$ and set $T = t - s > 0$. Let $\varepsilon > 0$.

Upper bound. Choose $a, b > N$ with $T < aL_3 - bL_2 < T + \varepsilon$. Since

$$aL_2 - bL_3 = \frac{L_2}{L_3}\,(aL_3 - bL_2) \;-\; b\,\frac{L_3^2 - L_2^2}{L_3},$$

the first term is bounded while the second tends to $-\infty$ as $b \to \infty$, so for N large enough $aL_2 - bL_3 < T$. Hence $T \in I_{a,b}$, and the Claim gives $h(t) - h(s) \le aL_3 - bL_2 < T + \varepsilon$.

Lower bound. Choose $a, b > N$ with $T - \varepsilon < aL_2 - bL_3 < T$. Since

$$aL_3 - bL_2 = \frac{L_3}{L_2}\,(aL_2 - bL_3) \;+\; b\,\frac{L_3^2 - L_2^2}{L_2} \longrightarrow +\infty,$$

for N large enough $aL_3 - bL_2 > T$, so again $T \in I_{a,b}$ and the Claim gives $h(t) - h(s) \ge aL_2 - bL_3 > T - \varepsilon$.

As $\varepsilon > 0$ was arbitrary, $h(t) - h(s) = T = t - s$ whenever $s < t$; the cases $s = t$ and $s > t$ follow trivially and by symmetry. By Step 1 this forces $f(x) = x^c$ with $c = e^\gamma > 0$, and all such f do satisfy the condition. ■

Layer 1: WHAT

Block 1. Verify that x^c, $c > 0$, works, so that the target is pinned: you must prove $h(s) - s$ is constant.

Block 2. First logarithm, $g(u) = \log f(e^u)$: powers of the argument become multiples.

Block 3. Second logarithm, $h(s) = \log g(e^s)$: multiples become shifts, and the hypothesis becomes "a displacement in $[L_2, L_3]$ maps to a displacement in $[L_2, L_3]$".

Block 4. Read the constraint backwards by swapping s and t: backward steps of size in $[-L_3, -L_2]$ are free.

Block 5. Chain a forward and b backward steps. Reachable displacements form $I_{a,b} = [aL_2 - bL_3,\ aL_3 - bL_2]$, and h maps $I_{a,b}$ displacements into $I_{a,b}$ displacements. Prove it by induction on $a + b$, with the intermediate point chosen by affine interpolation between the two forced endpoint decompositions.

Block 6. $I_{a,b}$ is long (length $(a + b)(L_3 - L_2)$), so it cannot trap anything; but its endpoints are individually dense in $\mathbb{R}$, because L_3/L_2 is irrational.

Block 7. Squeeze: tune the right endpoint just above T for the upper bound and the left endpoint just below T for the lower bound, letting the other endpoint run off harmlessly.

Block 8. Unwind both logarithms.

Juxtaposition. The nominal route is: prove f is increasing, prove f is continuous, reduce to Cauchy. It fails at the first step, since nothing forces monotonicity locally. The bifurcation point is Block 3, the second logarithm. Almost everyone takes one logarithm, because "powers become multiples" is a reflex from A level; almost nobody takes the second, because after the first the condition looks like homogeneity and invites scaling arguments. The ideal route takes the second logarithm for a stated reason: the only constraints that chain are constraints on displacements, and only after two logarithms is the constraint a statement about displacements.

Layer 2: HOW

Block 1. **Cue.** "Find all functions", with 2 and 3 appearing symmetrically in the hypothesis and the conclusion. **Why natural.** The symmetry of the exponents means the condition is invariant under conjugating f by any power map, which is the fingerprint of the family $x \mapsto x^c$. Verifying the candidate first is not optimism, it is target setting: it converts a vague "find all" into the sharp statement "prove $\log f(e^{e^s}) - s$ is constant". **Link to the next block.** With the target known, every step afterwards is judged by whether it moves the constraint closer to a statement about a single unknown function of a real variable with an additive constraint.

Block 2. **Cue.** x^2 and x^3: powers of the variable. **Why natural.** The definition of x^k as $e^{k \log x}$ says that the logarithm is the exact translation device from exponents to coefficients. This is forced, not chosen. **Link to the next block.** After one logarithm the hypothesis is additive in the input ($2u \le v \le 3u$) but still multiplicative in the output ($2g(u) \le g(v) \le 3g(u)$). The asymmetry is the signal that the job is half done.

Block 3. **Cue.** A constraint of the form "multiply by a factor in $[2, 3]$", appearing on both sides. **Why natural.** Multiplicative constraints do not compose into anything you can count; additive ones do, because displacements add. So apply the same device again: $u = e^s$ turns "multiply by a factor in $[2, 3]$" into "add a shift in $[L_2, L_3]$". The reason this is natural is not that it works, it is that a second logarithm is the only operation that turns a scaling into a translation. **Link to the next block.** Now the hypothesis says h transports $[L_2, L_3]$ displacements to $[L_2, L_3]$ displacements, and you can start walking.

Block 4. **Cue.** A statement about an unordered pair of points, phrased with s on the left. **Why natural.** Any condition of the form "if $t - s$ lies in J then $h(t) - h(s)$ lies in J" automatically yields the reflected condition on $-J$, because you may relabel which point you call s. Free information should always be extracted before you start working. **Link to the next block.** Forward and backward steps together generate far more displacements than forward steps alone, and this is what will eventually reach every real number.

Block 5. **Cue.** "I have steps of two types and I want to reach a general displacement": a reachability problem. **Why natural.** The set of displacements achievable with a forward and b backward steps

is the Minkowski sum $aI_{1,0} + bI_{0,1} = I_{a,b}$, and induction on $a + b$ is the natural bookkeeping. The only real question is where to put the intermediate point, and here the choice is forced rather than inspired: at the two endpoints of $I_{a,b}$ the decomposition into steps is unique, so define the intermediate point by affinely interpolating those two forced choices. That is exactly the map j, and the required property $\tau - j(\tau) \in [L_2, L_3]$ then holds automatically because $\tau - j(\tau)$ is affine with the correct endpoint values. **Link to the next block.** You now know the exact rigidity available: for every (a, b), h compresses $I_{a,b}$ into itself.

Block 6. Cue. The length of $I_{a,b}$ is $(a + b)(L_3 - L_2)$, which grows. **Why natural.** So the interval never shrinks around a target, and a naive squeeze is impossible. What can be controlled is one endpoint at a time. This is where the arithmetic enters: $aL_3 - bL_2 = L_2(a\theta - b)$ with $\theta = L_3/L_2$ irrational, so by Kronecker the endpoint values are dense, and by taking a, b large the other endpoint is pushed to infinity in the harmless direction. **Link to the next block.** Two applications of the Claim, one tuned at each endpoint, give the two sided bound.

Block 7. Cue. Two inequalities, each with an arbitrary ε. **Why natural.** $h(t) - h(s) \le T + \varepsilon$ and $h(t) - h(s) \ge T - \varepsilon$ for all $\varepsilon > 0$ force equality. Nothing subtler is available, and nothing subtler is needed. **Link to the next block.** Equality means $h(s) - s$ is constant, and Step 1 was set up so that this single fact unwinds to $f(x) = x^c$ in three lines.

Layer 3: WHY

The mathematical truth beneath this problem is that the condition is a statement about the additive group generated by L_2 and L_3, and the rigidity of f is exactly the density of that group in $\mathbb{R}$.

Look at what the two logarithms achieve. They put the problem in the normal form: an unknown $h : \mathbb{R} \to \mathbb{R}$ such that a displacement lying in the step set $J = [L_2, L_3]$ is mapped to a displacement lying in J. Iterating with signs, a displacement in $aJ - bJ$ maps into $aJ - bJ$. If the numbers $\log 2$ and $\log 3$ were commensurable, the endpoints $aL_3 - bL_2$ would live in a discrete subgroup of $\mathbb{R}$ and could not approach an arbitrary target, and the conclusion would be false. It is false: take exponents 2 and 4 instead of 2 and 3, so that $L_4/L_2 = 2$. Then for any δ with $0 < \delta < L_2/(2\pi)$ the function

$$h(s) = s + \delta \sin\left(\frac{2\pi s}{L_2}\right)$$

satisfies the corresponding condition, since $h(t) - h(s) = \tau + 2\delta \cos\big(2\pi(s + \tau/2)/L_2\big) \sin(\pi\tau/L_2)$ for $\tau = t - s$, and the oscillating term vanishes at $\tau = L_2$ and $\tau = 2L_2$ and is small enough in between. Unwinding gives

$$f(x) = x^{c(x)}, \qquad c(x) = \exp\left(\delta \sin\left(\frac{2\pi \log\log x}{\log 2}\right)\right),$$

a solution of the $(2, 4)$ problem that is not a pure power. So the hypothesis is not decoration: the problem is true for $(2, 3)$ and false for $(2, 4)$, and the dividing line is whether $\log 3/\log 2$ is irrational, which is whether 2 and 3 are multiplicatively independent, which is unique factorisation.

The discernment mechanism, and the thing to train: when a functional condition is stated with explicit constants, ask what group or semigroup those constants generate after you have normalised the condition into additive form. If the generated set is dense, expect total rigidity and go hunting for the density theorem. If it is discrete, expect a family of oscillating solutions and go hunting for a counterexample. That single question decides the shape of the whole solution before any technical work begins, and it is the reason to normalise first and compute second.

The second reusable truth is the interpolation device. Whenever an inductive step needs an intermediate point inside a constraint interval, look at the extreme cases: at an endpoint of the

interval the decomposition is usually forced, and the affine map interpolating the forced choices is then the correct intermediate point everywhere in between, with the verification reducing to checking two endpoint values because everything in sight is affine. That is not a lucky formula, it is the unique affine map with the required endpoint behaviour.

What the examiners nudged with: the identical constants on both sides (telling you the answer is a power map and the normal form is a translation condition), the choice of 2 and 3 rather than 2 and 4 (telling you the arithmetic of the exponents is load bearing), and the codomain $(1,\infty)$ rather than $(0,\infty)$ (making both logarithms legal, since $f>1$ gives $g>0$ gives h real, and forcing $c>0$).

Revolving concepts

Normal form of a functional condition. Definitions: conjugating f by $x=e^u$ replaces power maps by linear maps; conjugating again by $u=e^s$ replaces linear maps by translations. The pair of substitutions is the standard route from the multiplicative Cauchy family $f(xy)=f(x)f(y)$ to the additive one, and from power maps to shifts. Orbiting facts: $x\mapsto x^c$ is the conjugate of $s\mapsto s+\log c$; the group of power maps on $(1,\infty)$ is isomorphic to $(\mathbb{R}_{>0},\times)$ and to $(\mathbb{R},+)$. See Book 1, field: Functional equations, topic: conjugation to normal form.

Kronecker density and multiplicative independence. If θ is irrational then $\{a\theta-b : a,b\in\mathbb{Z},\ a,b>N\}$ is dense in $\mathbb{R}$ for every N; the proof is pigeonhole to find $\|q\theta\|$ small, then walk. Weyl's theorem strengthens this to equidistribution. Irrationality of $\log 3/\log 2$ is unique factorisation: $3^q=2^p$ forces $p=q=0$. See Book 1, field: Number theory, topic: irrationality and equidistribution.

Minkowski sums of intervals, and the reachability recursion. For intervals, $[p,q]+[p',q']=[p+p',q+q']$. The recursion here is $I_{a,b}=I_{a-1,b}+I_{1,0}=I_{a,b-1}+I_{0,1}$ with $I_{0,0}=\{0\}$, whose solution is $I_{a,b}=aI_{1,0}+bI_{0,1}=[aL_2-bL_3,\ aL_3-bL_2]$. Generalised: if the available steps are the intervals $J_1,\dots,J_r$ used $a_1,\dots,a_r$ times, the reachable set is $\sum a_iJ_i$, an interval whose endpoints are the corresponding integer combinations of the endpoints of the J_i, and whose length is $\sum a_i|J_i|$. That single formula tells you in advance that the reachable set widens, hence that rigidity must come from the endpoints rather than from the width. The same recursion governs every "steps of bounded size" argument: random walk ranges, interval exchange bookkeeping, and the reachable set of a discrete control system. See Book 1, field: Real analysis, topic: reachable sets and interval arithmetic.

Induction on a total weight $a+b$. When two parameters can each be decremented, induct on their sum and treat the two decrements as symmetric cases. Orbiting technique: the intermediate point should be produced by an explicit affine formula so that verification reduces to endpoint checks. See Book 1, field: Logic and set theory, topic: induction on a well founded measure.

Sandwich conditions. A two sided constraint $\alpha\le\Phi\le\beta$ is much stronger than either half; the standard exploitation is to run the two halves against each other in opposite directions, which is exactly what the upper and lower bound in Step 4 do. See Book 1, field: Inequalities, topic: two sided estimates and squeezing.

Circuit Bank

- **WHEN** a functional condition involves powers of the argument on both sides with the same exponents **DO** take logarithms twice, so that powers become multiples and multiples become shifts **BECAUSE** only displacement conditions chain additively, and chaining is the only way to move information from a sparse set of arguments to all arguments.
- **WHEN** a condition reads "if $t-s\in J$ then $h(t)-h(s)\in J$" **DO** immediately write down the reflected version by swapping s and t, and then study the semigroup of reachable displacements **BECAUSE** the condition is symmetric in the two points, so backward steps are free, and reachability is the whole content.
- **WHEN** after normalising, the constants generate a subgroup of $\mathbb{R}$ **DO** ask whether that

subgroup is dense or discrete **BECAUSE** dense means the answer is rigid and you need a density theorem, discrete means there is an oscillating counterexample and the problem as stated must have excluded it.

- **WHEN** an induction needs an intermediate point inside a constraint interval **DO** take the affine interpolation of the decompositions forced at the two endpoints **BECAUSE** everything in sight is affine, so the verification collapses to checking two endpoint values.
- **WHEN** a reachable interval grows in length instead of shrinking **DO** tune one endpoint against the target and let the other endpoint escape to infinity, then repeat with the other endpoint **BECAUSE** a two sided bound does not need one interval that traps the target, only two intervals each of which pins one side.

Backtesting

1. First useful cue: the exponents 2 and 3 occur identically in the hypothesis and the conclusion, which says the condition is invariant under conjugation by power maps and therefore that power maps are the expected answer.
2. Method the expression suggested: two logarithmic substitutions to reach the translation normal form, then chaining of forward and backward steps, then a density argument on $\mathbb{Z}L_2 + \mathbb{Z}L_3$.
3. Where you would hesitate, and the thought to reinforce: at the induction, wondering where the intermediate point comes from. Reinforce this: at the endpoints of the constraint interval the step decomposition is forced, and the affine interpolation of forced endpoint data is always the right guess for the interior.
4. The trap the question sets: assuming regularity. There is no continuity hypothesis, and the problem is false in the analogous $(2, 4)$ case, so any argument that does not use the irrationality of $\log 3/\log 2$ is wrong.
5. What makes you recognise it faster next time: the shape "$x^2 \le y \le x^3$ implies $f(x)^2 \le f(y) \le f(x)^3$" is a transport of a window, and windows transported by a map are always studied in the normal form where the window is a translation.
6. The reusable decision rule: normalise the constraint until it is additive, identify the group generated by the constants, and let the arithmetic of that group decide whether the answer is rigid.

Mirror drills

1. Find all $f : (1, \infty) \to (1, \infty)$ such that $x^3 \le y \le x^5$ implies $f(x)^3 \le f(y) \le f(x)^5$. *Answer:* again exactly $f(x) = x^c$, $c > 0$; the proof is unchanged with L_2, L_3 replaced by $\log 3, \log 5$, and the only fact used is that $\log 5/\log 3$ is irrational.
2. Show that the analogous problem with exponents 2 and 4 has solutions that are not pure powers. *Answer:* $\log 4/\log 2 = 2$ is rational, so the reachable displacements lie in $(\log 2)\mathbb{Z}$; take $h(s) = s + \delta \sin(2\pi s/\log 2)$ with $0 < \delta < \log 2/(2\pi)$ and unwind two logarithms to get $f(x) = x^{c(x)}$ with $c(x) = \exp(\delta \sin(2\pi \log\log x/\log 2))$.
3. Prove that $\{a \log 3 - b \log 2 : a, b \in \mathbb{Z}_{\ge 0}\}$ is dense in $\mathbb{R}$. *Answer:* $\theta = \log 3/\log 2$ is irrational by unique factorisation; pigeonhole on the fractional parts of $0, \theta, \ldots, M\theta$ gives q with $\|q\theta\| < 1/M$, and the multiples of $q\theta$ then step around $\mathbb{R}/\mathbb{Z}$ in increments below $1/M$, hitting every interval of that length.

10.12 B6. A dyadic double sum that telescopes to one

Evaluate

$$\sum_{k=1}^{\infty} \frac{(-1)^{k-1}}{k} \sum_{n=0}^{\infty} \frac{1}{k2^n+1}.$$

Read it out loud

An alternating outer sum in k, and an inner sum over n in which the index n appears only inside $k2^n$. Read the interaction of the two indices, because that is the only structural feature here: the summand is

$$\frac{(-1)^{k-1}}{k} \cdot \frac{1}{k2^n+1},$$

so k appears twice and n appears once, and the two indices meet in exactly one place, the product $k2^n$. Everything else is a function of k alone. A double sum whose indices meet in a single combined quantity is a double sum you should reindex by that quantity.

The fields wired in: real analysis (absolute convergence, and the theorem that an absolutely summable family may be summed in any order or grouping), number theory (every positive integer is uniquely an odd number times a power of two, which is the base 2 valuation), and series technique (geometric collapse and telescoping). There is no calculus in the ideal route at all, which is worth noticing given that three of the published solutions use integrals.

What is really being tested is restraint. The inner sum $\sum_{n\geq 0} 1/(k2^n+1)$ is a Lambert type series and has no elementary closed form; for $k=1$ its value is $0.5+1/3+1/5+1/9+\cdots \approx 1.2645$, a constant with no known expression in elementary functions. A candidate who spends the first twenty minutes trying to evaluate it has lost the problem to consumption rather than analysis. The correct first act is to declare the inner sum unevaluatable and change what you are summing over.

In the first thirty seconds you should have written the convergence audit, because it is what licences everything else:

$$0 < \sum_{n=0}^{\infty} \frac{1}{k2^n+1} < \sum_{n=0}^{\infty} \frac{1}{k2^n} = \frac{2}{k},$$

so the outer terms are bounded by $2/k^2$ and the whole double family is absolutely summable, with total absolute mass at most $2\zeta(2) = \pi^2/3$. Once that is on the page you may treat the expression as an unordered sum over the set of pairs (k,n), and you are free.

Approaches, ranked worst to best

1. **Evaluate the inner sum first.** *Cue:* a nested sum invites you to do the inside first. *Circuit:* compute inward out. This is the zombie route and it never terminates: $\sum_n 1/(k2^n+1)$ has no elementary closed form. The cue that should stop you is that k also sits outside, so an exact closed form in k would be needed, not merely a number.

2. **Numerical evaluation and recognition.** *Cue:* "Evaluate", with no free parameter in the answer. *Circuit:* compute enough terms to recognise the constant. Summing to $k \approx 10^5$ gives $1.0000\ldots$, which tells you the target is 1. Worth sixty seconds as target setting; worth zero marks as a solution.

3. **Expand $1/(k2^n+1)$ as a geometric series in $1/(k2^n)$.** *Cue:* a denominator of the form $t+1$ with t large. *Circuit:* $1/(1+t) = \sum(-1)^m t^{-m-1}$ for $t>1$. This works and is the published first solution: peel off the $n=0$ term, expand the rest, and sum a triple series to get $2\log 2 - 1$ and $2-2\log 2$. It costs the most ink, needs the $n=0$ term treated separately because the expansion fails there, and needs three separate convergence checks. The logarithms cancelling at the end is a loud signal that a route exists in which they never appear.

4. **Integral representation.** *Cue:* a denominator $t+1$ with t a nonnegative exponent. *Circuit:* $\frac{1}{t+1} = \int_0^1 x^t\,dx$, which converts denominators into exponents. Very pretty: the k sum becomes $\log(1+x^{2^n})$, the n sum becomes $\log\prod_{n\ge0}(1+x^{2^n}) = -\log(1-x)$ by binary expansion, and $-\int_0^1 \log(1-x)\,dx = 1$. Ranks below the last two only because it needs term by term integration, monotone convergence, an infinite product, and an improper integral, which is four separate things a grader can ask you to justify.

5. **Parity folding.** *Cue:* the index set $\{k2^n\}$ is invariant under $k \mapsto 2k$. *Circuit:* split the sum by the parity of k, substitute $k = 2\ell$ in the even part, and let the sum fold onto itself. Split $S = S_0 - S_1$ into odd and even k with all signs removed. Substituting $k = 2\ell$ in S_1 reproduces $S_0 + S_1$ with the $n = 0$ term removed, giving $S_1 = \frac{1}{2}(S_0 + S_1) - \frac{1}{2}$ and hence $S = S_0 - S_1 = 1$ in four lines. Short and honest, but it computes the answer without explaining it.

6. **Reindex by the level sets of $k2^n + 1$.** *Cue:* the two indices meet only in the product $k2^n$. *Circuit:* sum along the fibres of the map $(k,n) \mapsto k2^n$, which are exactly the doubling chains of an odd number. Best. The fibre sum collapses geometrically to $1/(m-1)$, the outer sum becomes $\sum_{m\ge2} 1/(m(m-1))$, and the answer 1 appears as a telescoping sum. It is the shortest complete route, it uses one convergence theorem and nothing else, and it explains why the answer is 1.

The ideal solution

Write $a_{k,n} = \dfrac{(-1)^{k-1}}{k(k2^n+1)}$ for integers $k \ge 1$ and $n \ge 0$, so that the given expression is the iterated sum $\sum_{k\ge1}\sum_{n\ge0} a_{k,n}$.

Step 1: absolute summability. Since $k2^n + 1 > k2^n$,

$$\sum_{k=1}^{\infty}\sum_{n=0}^{\infty}|a_{k,n}| < \sum_{k=1}^{\infty}\sum_{n=0}^{\infty}\frac{1}{k^2 2^n} = 2\sum_{k=1}^{\infty}\frac{1}{k^2} = \frac{\pi^2}{3} < \infty.$$

Hence the family $(a_{k,n})$ indexed by the countable set $P = \mathbb{Z}_{\ge1}\times\mathbb{Z}_{\ge0}$ is absolutely summable. Its unordered sum S therefore exists, equals the given iterated sum, and may be computed by partitioning P into any collection of disjoint blocks, summing each block, and adding the block totals.

Step 2: the right partition. The pair (k,n) enters $a_{k,n}$ through k and through the single quantity $k2^n$. Partition P by the value of

$$m = k2^n + 1.$$

As (k,n) ranges over P, m ranges over the integers $m \ge 2$, and the block over a given m is

$$P_m = \{(k,n) \in P : k2^n = m-1\}.$$

Step 3: describe a block. Fix $m \ge 2$ and write $m - 1 = 2^e j$ with j odd and $e = v_2(m-1) \ge 0$; this decomposition into an odd part and a power of two exists and is unique. If $k2^n = 2^e j$ with $k \ge 1$ and $n \ge 0$, then comparing the powers of 2 on both sides forces $n \le e$ and $k = 2^{e-n}j$. So, writing $i = e - n$,

$$P_m = \{(2^i j,\ e-i) : i = 0,1,\dots,e\},$$

a chain of $e+1$ pairs whose k values are $j, 2j, 4j, \dots, 2^e j$.

Step 4: sum a block. On P_m the factor $1/(k2^n+1)$ is the constant $1/m$, so

$$\sum_{(k,n)\in P_m} a_{k,n} = \frac{1}{m}\sum_{i=0}^{e}\frac{(-1)^{2^i j-1}}{2^i j}.$$

The parity along the chain is decided at once: j is odd, so $(-1)^{j-1} = 1$; every later term $2^i j$ with $i \geq 1$ is even, so $(-1)^{2^i j - 1} = -1$. Hence

$$\sum_{i=0}^{e} \frac{(-1)^{2^i j - 1}}{2^i j} = \frac{1}{j}\left(1 - \sum_{i=1}^{e} \frac{1}{2^i}\right) = \frac{1}{j}\left(1 - \left(1 - \frac{1}{2^e}\right)\right) = \frac{1}{2^e j} = \frac{1}{m-1},$$

where the sum over $i \geq 1$ is empty when $e = 0$, in which case the identity reads $1/j = 1/(m-1)$ and still holds. Therefore

$$\sum_{(k,n)\in P_m} a_{k,n} = \frac{1}{m(m-1)}.$$

Step 5: add the blocks. By Step 1 we may sum the block totals in any order:

$$S = \sum_{m=2}^{\infty} \frac{1}{m(m-1)} = \sum_{m=2}^{\infty} \left(\frac{1}{m-1} - \frac{1}{m}\right) = \lim_{M\to\infty}\left(1 - \frac{1}{M}\right) = 1.$$

So

$$\sum_{k=1}^{\infty} \frac{(-1)^{k-1}}{k} \sum_{n=0}^{\infty} \frac{1}{k2^n + 1} = \boxed{1}.$$

Layer 1: WHAT

Block 1. Convergence audit: $\sum_n 1/(k2^n+1) < 2/k$, so the terms are $O(1/k^2)$ and the double family is absolutely summable with mass at most $\pi^2/3$.

Block 2. Refuse to evaluate the inner sum: it is a Lambert type series with no elementary closed form, and in any case a number would not help since k sits outside as well.

Block 3. Flatten: stop reading the expression as a sum of sums, and read it as one sum over the lattice of pairs (k, n).

Block 4. Reindex: the indices meet only in $k2^n$, so partition the lattice into the level sets $m = k2^n + 1$.

Block 5. Identify a level set: unique factorisation into odd part times power of two makes the fibre the doubling chain $j, 2j, \ldots, 2^e j$.

Block 6. Sum the chain: one odd term with sign $+$ and e even terms with sign $-$, and the geometric identity $1 - (2^{-1} + \cdots + 2^{-e}) = 2^{-e}$ collapses the chain sum to $1/(m-1)$.

Block 7. Telescope $\sum_{m\geq 2} 1/(m(m-1)) = 1$.

Juxtaposition. The nominal route is: evaluate the inner sum, then substitute back. That is what nesting invites, and it is a dead end, because the inner object is a genuinely transcendental thing with no closed form. The ideal route never evaluates the inner sum at all; it dissolves the nesting and re-partitions the index set along a different axis. The bifurcation point is Block 3: the line at which you replace two nested indices by one flat index set. Everything after that is forced, because on a flat index set the only decision left is which partition to use, and the summand answers that question by telling you where k and n meet.

Layer 2: HOW

Block 1. Cue. Any manipulation of an infinite double sum. Before you rearrange anything, you owe a bound. **Why natural.** Rearranging a conditionally convergent series can produce any value at all, and the outer sum here is alternating, which is the classic signature of conditional convergence. So the audit is not bureaucracy, it is the licence for the entire method. The bound itself is immediate: dropping the $+1$ in the denominator gives a geometric series in n and the harmless factor $2/k$. **Link to the next block.** Once absolute summability is on the page, the expression is an unordered sum over pairs and any partition is legal. That is a much freer object than a nested sum.

Block 2. **Cue.** The inner sum has k in it and no closed form. **Why natural.** Ask what a closed form would have to look like: to be useful it would have to be an explicit function of k that can then be summed against $(-1)^{k-1}/k$. Series of the shape $\sum_n 1/(q^n + c)$ are Lambert type and are known not to have elementary closed forms. Recognising the family costs nothing and saves the whole problem. **Link to the next block.** If the inner sum cannot be evaluated, the only remaining lever is the index set itself.

Block 3. **Cue.** A nested sum with independent index ranges: $k \geq 1$ and $n \geq 0$ with no coupling in the limits. **Why natural.** Independent ranges mean the index set is a product, so the sum is a sum over a lattice, and a sum over a lattice can be organised along any family of disjoint slices. The nesting given in the problem is just one such family (vertical lines), and there is no reason it is the best one. **Link to the next block.** So look at the summand and ask which slicing makes it simple.

Block 4. **Cue.** The summand is $F(k) \cdot G(k2^n)$ with $F(k) = (-1)^{k-1}/k$ and $G(t) = 1/(t+1)$. The two indices meet only in $k2^n$. **Why natural.** On the level set $k2^n =$ constant, the factor G is constant and comes out, leaving a pure sum of F over the fibre. That is the definition level reason to slice this way: it turns a two variable sum into a constant times a one variable sum, per slice. Whenever a summand factors through a single combined quantity, the level sets of that quantity are the natural slices. **Link to the next block.** So describe the fibres of the map $(k, n) \mapsto k2^n$.

Block 5. **Cue.** Powers of 2 in a product equal to a fixed integer. **Why natural.** Every positive integer is uniquely 2^e times an odd number, so $k2^n = 2^e j$ forces $n \leq e$ and $k = 2^{e-n} j$. The fibre is therefore the doubling chain of the odd part, of length $e + 1 = v_2(m-1) + 1$. This is arithmetic, not cleverness: the map $(k, n) \mapsto k2^n$ is exactly the multiplication that unique factorisation controls. **Link to the next block.** Now sum F along a chain, where the terms are $\pm 1/(2^i j)$.

Block 6. **Cue.** A geometric chain, with an alternating sign that depends on parity, and parity is constant after the first step. **Why natural.** $2^i j$ is odd exactly when $i = 0$. So the sign is $+$ once and $-$ forever after, and the chain sum is $\frac{1}{j}(1 - \sum_{i=1}^{e} 2^{-i})$. The partial geometric sum $\sum_{i=1}^{e} 2^{-i} = 1 - 2^{-e}$ is the identity that makes the bracket exactly 2^{-e}, and $2^e j = m - 1$. This is why the base 2 in the problem is not decorative: with 3^n in place of 2^n the sign would be constant along the whole chain and the partial sums would not complement to a single reciprocal. **Link to the next block.** Each block contributes $1/(m(m-1))$, and that is a telescoping term.

Block 7. **Cue.** $\frac{1}{m(m-1)}$, a product of consecutive integers in a denominator. **Why natural.** Partial fractions give $\frac{1}{m-1} - \frac{1}{m}$, and consecutive difference means telescoping. The sum from $m = 2$ is 1. **Link to the next block.** Answer 1, matching the numerical check made at the start.

Layer 3: WHY

One arithmetic fact runs underneath every route to this problem: every positive integer is uniquely an odd number times a power of two. Watch it appear in four disguises.

In the ideal route it is explicit: the fibre of $(k, n) \mapsto k2^n$ over $m - 1$ is the doubling chain of the odd part of $m - 1$.

In the integral route it is the identity $\prod_{n=0}^{\infty}(1 + x^{2^n}) = \frac{1}{1-x}$ for $|x| < 1$, which one proves by telescoping, since $(1 - x)\prod_{n=0}^{N}(1 + x^{2^n}) = 1 - x^{2^{N+1}}$, and which says in generating function language that every nonnegative integer has exactly one binary expansion. That is the same fact, dressed as a product.

In the parity folding route it is the invariance of the index set $\{k2^n\}$ under $k \mapsto 2k$, which is the self-similarity of the dyadic chains; the substitution $k = 2\ell$ maps the even part of the sum back onto

the whole sum with the $n = 0$ layer stripped, and that produces a linear equation for the unknown. Same fact, dressed as a symmetry.

In the published triple series route it is the Euler factor: the alternating zeta value $\sum_k (-1)^{k-1} k^{-s}$ equals $(1 - 2^{1-s})\zeta(s)$ precisely because splitting $\mathbb{Z}_{\geq 1}$ by parity is splitting off the prime 2. Same fact, dressed as a factorisation of a Dirichlet series.

So the discernment mechanism is this: when powers of a fixed base appear in an index, the arithmetic of that base is the engine of the problem, and your job is to choose the disguise in which the engine is most visible. The reindexing route makes it most visible, which is why it is also the shortest.

There is a second, more portable truth here, and it is about double sums in general. If a summand can be written as $F(k)\, G(\phi(k, n))$, then slicing the index set by the level sets of ϕ turns the double sum into

$$\sum_{N \in \operatorname{im} \phi} G(N) \sum_{(k,n) \in \phi^{-1}(N)} F(k),$$

and the whole problem becomes: describe the fibres, and sum F over one. That is a completely mechanical procedure, and it is the correct default for any double sum in which the indices interact through a single expression. Dirichlet's hyperbola method, the convolution identity $\sum_{d|N}$, and the standard proof that $\sum_{k,n} 1/(k^2 n^2) = \zeta(2)^2$ are all instances. The only skill it demands is being able to describe the fibre, and for $\phi(k, n) = k2^n$ the fibre is handed to you by unique factorisation.

How to train it: every time you meet a double sum, write down ϕ, the quantity through which the two indices actually interact, before you write anything else. If ϕ is one of the indices alone, the sum factorises and you are done. If ϕ is a product, a sum or a maximum of the two indices, slice by ϕ. The examiners nudged at exactly this by putting k both outside and inside: they made sure that no evaluation of the inner sum could be useful, so that the only surviving move is the structural one.

Knowledge gaps, stated plainly, because this is a B6 and the theory must be installed before the problem is even approachable. First, unordered summation: the theorem that an absolutely summable family over a countable index set has a well defined sum, invariant under every rearrangement and every partition into blocks. This is the whole licence for Steps 2 to 5, and it is not part of A level or Further Maths. Second, the base 2 valuation v_2 and the odd part decomposition, which is elementary but must be fluent, including the uniqueness that pins down $n \leq e$. Third, telescoping and partial fractions for $1/(m(m-1))$, which you have, and the value $\pi^2/6$ of $\zeta(2)$, which you need only as a finite bound and could replace by 2. Fourth, if you want the integral route: term by term integration of a uniformly convergent series, the monotone convergence theorem for series of nonnegative functions, infinite products, and the convergent improper integral $\int_0^1 \log(1 - x)\, dx = -1$. Fifth, if you want the published route: the alternating harmonic series $\sum (-1)^{k-1}/k = \log 2$ and the eta to zeta relation. The honest ranking is that the ideal route needs exactly one theorem beyond school mathematics, and every other route needs at least three.

Revolving concepts

Absolute summability of a family. Definition: a family $(a_p)_{p \in P}$ over a countable set P is absolutely summable if $\sup_{F \text{ finite}} \sum_{p \in F} |a_p| < \infty$. Theorem: it then has a unique unordered sum, equal to every iterated sum and to every block decomposition $\sum_{\text{blocks}} \sum_{p \in \text{block}} a_p$. This is Fubini for counting measure, and it is the only analytic input the ideal solution uses. Contrast: Riemann's rearrangement theorem says a conditionally convergent real series can be rearranged to any value, which is why the audit is not optional. See Book 1, field: Real analysis, topic: unordered sums and Fubini for series.

Base 2 *valuation and the doubling chain.* Definition: $v_2(N)$ is the exponent of 2 in N, and $N = 2^{v_2(N)} \cdot \text{odd}$ uniquely. The set of (k, n) with $k2^n = N$ is $\{(2^i \operatorname{odd}(N), v_2(N) - i) : 0 \leq i \leq v_2(N)\}$, a chain of length $v_2(N) + 1$. Orbiting facts: $v_2(ab) = v_2(a) + v_2(b)$; the number of (k, n) with $k2^n = N$

is $v_2(N)+1$, which is also the number of divisors of N that are powers of 2 times a fixed odd part. See Book 1, field: Number theory, topic: p-adic valuation.

Slicing a double sum by a level set. Technique: if the summand is $F(k)G(\phi(k,n))$ then $\sum_{k,n} = \sum_N G(N)\sum_{\phi^{-1}(N)} F$. Generalised recursion form: when $\phi(k,n) = k2^n$, the fibres are orbits of the map $k \mapsto 2k$ truncated at the odd end, so the fibre sums obey the one step recursion $T(2N) = T(N) + F(\text{new element})$, and the closed form is the geometric collapse used above. The same slicing produces Dirichlet convolution when $\phi(k,n) = kn$, and the hyperbola method when the fibres are too long to handle directly. See Book 1, field: Generating functions, topic: rearranging double sums by level sets.

Self-similar sums and linear equations. When an index set is invariant under a substitution, splitting the sum along the orbits of the substitution gives a linear equation in the unknown sum. Here, splitting by the parity of k and substituting $k = 2\ell$ gives $S_1 = \frac{1}{2}(S_0 + S_1) - \frac{1}{2}$, hence $S = S_0 - S_1 = 1$. General method: write $S = \sum_{\text{fixed part}} + (\text{copy of } S \text{ scaled})$, then solve the resulting linear relation. This is the same manoeuvre that evaluates $\sum 2^{-n}$ by $S = 1 + S/2$, and it generalises to any sum with a scaling symmetry. See Book 1, field: Sequences and recurrences, topic: self-similar sums.

Binary expansion as an infinite product. $\prod_{n\geq 0}(1+x^{2^n}) = 1/(1-x)$ for $|x| < 1$, proved by $(1-x)\prod_{n=0}^{N}(1+x^{2^n}) = 1 - x^{2^{N+1}}$. Orbiting facts: the same telescoping proves $\sum_{n\geq 0} \frac{x^{2^n}}{1-x^{2^{n+1}}} = \frac{x}{1-x}$; the general Euler style identity $\prod(1+x^{q^n})$ encodes base q expansions with digits 0 and 1. See Book 1, field: Generating functions, topic: binary expansions and telescoping products.

Lambert type series. $\sum_{n\geq 0} \frac{1}{q^n+c}$ has no elementary closed form in general; the Erdős and Borwein constant $\sum_{n\geq 1} 1/(2^n-1)$ is the standard example and is known to be irrational. Recognising the family is what tells you to stop trying. See Book 1, field: Real analysis, topic: Lambert series.

Circuit Bank

- **WHEN** a double sum has independent index ranges and a summand in which the two indices meet in one combined quantity ϕ **DO** partition the index set by the level sets of ϕ and sum each fibre **BECAUSE** on a fibre the factor depending on ϕ is constant and comes out, so a two variable sum becomes a constant times a one variable sum.
- **WHEN** you are about to rearrange, regroup or interchange any infinite sum **DO** first bound the sum of absolute values, and write the bound down **BECAUSE** unordered summation is legal only for absolutely summable families, and an alternating outer sum is exactly the case where conditional convergence would break everything.
- **WHEN** an inner sum has no closed form but the outer index also appears inside it **DO** stop evaluating and start reindexing **BECAUSE** a closed form would have to be an explicit function of the outer index to be useful, so the absence of one is a signal that the intended route is structural rather than computational.
- **WHEN** powers of a fixed base appear inside an index **DO** invoke the unique factorisation into that base times a coprime part, and expect chains or orbits **BECAUSE** the fibres of $(k,n) \mapsto kq^n$ are exactly the q-multiplication chains of the q-free part.
- **WHEN** a block or fibre sum comes out as $\frac{1}{m(m-1)}$ or any product of consecutive integers **DO** split by partial fractions and telescope **BECAUSE** consecutive denominators are the fingerprint of a difference, and a sum of differences collapses to its endpoints.

Backtesting

1. First useful cue: the two indices meet only in the product $k2^n$, and k appears both inside and outside, so no evaluation of the inner sum can be the intended route.

2. Method the expression suggested: bound everything to get absolute summability, flatten the nested sum into a sum over the lattice of pairs, and reindex by $m = k2^n + 1$.
3. Where you would hesitate, and the thought to reinforce: at the description of the fibre. Reinforce it by writing $m - 1 = 2^e j$ with j odd before you try to solve $k2^n = m - 1$; with the odd part named, the fibre is immediate.
4. The trap the question sets: the nesting itself, which invites you to compute the inner sum first, and the alternating outer sum, which invites an illegal rearrangement if you skip the convergence audit.
5. What makes you recognise it faster next time: powers of 2 inside an index plus a sign depending on the parity of that index means the dyadic chain structure is the whole problem, since parity is constant along the chain after the first step.
6. The reusable decision rule: in a double sum, identify the single quantity through which the indices interact and slice by its level sets; if the fibres are chains under multiplication by a base, sum them geometrically.

Mirror drills

1. Prove that $\prod_{n=0}^{\infty}(1 + x^{2^n}) = \frac{1}{1-x}$ for $|x| < 1$, and deduce $\sum_{n=0}^{\infty} \log(1 + x^{2^n}) = -\log(1 - x)$. *Answer:* $(1 - x)\prod_{n=0}^{N}(1 + x^{2^n}) = 1 - x^{2^{N+1}} \to 1$ by repeated difference of squares; take logarithms, legal since all factors are positive.
2. Evaluate $\sum_{n=0}^{\infty} \frac{x^{2^n}}{1 - x^{2^{n+1}}}$ for $|x| < 1$. *Answer:* $\frac{x}{1-x}$, since $\frac{x^{2^n}}{1 - x^{2^{n+1}}} = \frac{1}{1 - x^{2^n}} - \frac{1}{1 - x^{2^{n+1}}}$ telescopes.
3. Evaluate $\sum_{k=1}^{\infty} \frac{(-1)^{k-1}}{k(k+1)}$. *Answer:* $2\log 2 - 1$, by $\frac{1}{k(k+1)} = \frac{1}{k} - \frac{1}{k+1}$ and the alternating harmonic series; this is the $n = 0$ layer of the problem, and comparing it with the total 1 shows that the layers $n \geq 1$ contribute $2 - 2\log 2$.

Chapter 11

Putnam 2015

11.1 A1. maximal triangle on a hyperbola branch

Let A and B be points on the same branch of the hyperbola $xy = 1$. Suppose that P is a point lying between A and B on this hyperbola, such that the area of the triangle APB is as large as possible. Show that the region bounded by the hyperbola and the chord AP has the same area as the region bounded by the hyperbola and the chord PB.

Read it out loud

Two points fixed on one branch of $xy = 1$, a third point free on the arc between them, and a claim about the area of the triangle it cuts out: this is extremal geometry with a fixed base, so the whole first half is really asking where the perpendicular distance from the arc to the chord AB is largest. The second sentence is not a new problem bolted on, it is a demand that whatever description you find for P must be strong enough to feed straight into an area equality, so an ugly formula for P is a sign you solved the first half the wrong way.

The phrase "same branch" is the first useful cue: it licenses one sign convention, $x > 0$, for the whole argument. Within thirty seconds you should have $A = (a, 1/a)$, $B = (b, 1/b)$, $P = (t, 1/t)$, $0 < a < t < b$. The field quietly embedded underneath the coordinate geometry is the group of area preserving affine self maps of $xy = 1$, and finding it is what separates a two page computation from a four line proof.

Approaches, ranked worst to best

1. **Coordinates and two integrals.** *Cue:* "area of the region bounded by the hyperbola" asked twice. *Circuit:* integrate line minus curve over each sub arc separately. (costs two logarithmic integrals and an algebraic reconciliation, and never explains why the two answers should agree, it only checks that they do.)

2. **AM-GM plus one integral, symmetry asserted for the other.** *Cue:* the product $t \cdot (ab/t)$ appearing once the base is fixed. *Circuit:* minimise $t + ab/t$ to find P, integrate once, then assert the second integral mirrors the first. (still one full integral, and the asserted symmetry of the closed form is not yet a proof of anything.)

3. **Tangent parallel to chord, then reflect.** *Cue:* the branch is visibly convex, so "biggest triangle on a fixed base" is a tangent line question. *Circuit:* locate P by matching slopes, rescale by a squeeze map into mirror position, read the equality off a reflection. (no integral is ever computed; the equality is forced, not checked.)

The ideal solution

Without loss of generality take the branch with $x > 0$: the map $(x, y) \mapsto (-x, -y)$ carries the other branch to this one and preserves the hyperbola and every area, so nothing is lost. Write $A = (a, 1/a)$, $B = (b, 1/b)$ with $0 < a < b$, and $P = (t, 1/t)$, $t \in (a, b)$.

Locating P. The area of triangle APB is half of $|AB|$ times the perpendicular distance from P to the line AB, so maximising it over t is maximising that distance. Since $y = 1/x$ has $y'' = 2/x^3 > 0$ on $x > 0$, the branch is strictly convex, so the signed height from the arc to the chord AB is an affine function of t minus the strictly convex function $1/t$, hence strictly concave in t; it vanishes at $t = a, b$ and is positive between, so it has a unique interior maximum, at the zero of its derivative, that is, where the tangent to the curve is parallel to AB. The chord has slope $\dfrac{1/b - 1/a}{b - a} = -\dfrac{1}{ab}$, the tangent at $(t, 1/t)$ has slope $-1/t^2$, and these agree exactly when $t = \sqrt{ab} \in (a, b)$. So $P = (\sqrt{ab}, 1/\sqrt{ab})$, uniquely.

Normalising. For $\lambda = 1/\sqrt{ab}$, the linear map $T(x,y) = (\lambda x, y/\lambda)$ has determinant 1, so it preserves every area; and since $(\lambda x)(y/\lambda) = xy$, it fixes the hyperbola, sending arcs to arcs and, being linear, chords to chords. It sends A, B, P to

$$T(A) = \left(\sqrt{\tfrac{a}{b}}, \sqrt{\tfrac{b}{a}}\right), \qquad T(B) = \left(\sqrt{\tfrac{b}{a}}, \sqrt{\tfrac{a}{b}}\right), \qquad T(P) = (1,1),$$

so with $s = \sqrt{a/b}$, $T(A) = (s, 1/s)$ and $T(B) = (1/s, s)$ are mirror images across the line $y = x$, and $T(P)$ is the fixed point of that mirror lying on the curve.

Reflecting. Let $\sigma(x,y) = (y,x)$. This isometry preserves area exactly, fixes the hyperbola, and satisfies $\sigma(T(A)) = T(B)$, $\sigma(T(B)) = T(A)$, $\sigma(T(P)) = T(P)$. So σ carries the arc and chord running from $T(A)$ to $T(P)$ onto the arc and chord running from $T(B)$ to $T(P)$, hence carries the region bounded by them onto the region bounded by the image pair, and an isometry cannot change area, so the two image regions are equal in area. Because T itself is area preserving and carries the original two regions, bounded by the hyperbola and the chords AP, PB, exactly onto these two image regions, the original two regions are equal in area too, which is the claim.

Layer 1: WHAT

Block 1: coordinatise the branch by one positive real each for A, P, B. Block 2: recognise a fixed base area extremum as a height extremum, and use convexity to know the maximiser is unique, at tangent parallel to chord. Block 3: solve one slope equation, $t = \sqrt{ab}$. Block 4: normalise by the squeeze map into mirror position. Block 5: reflect to swap the two regions and read off the equality, then transport back through the normalising map, which is itself area preserving.

The nominal and ideal routes agree through block 3; the bifurcation point sits exactly after P is found, where the nominal route reaches for two definite integrals of line minus curve, and the ideal route reaches instead for a symmetry that exchanges the two regions outright.

Layer 2: HOW

Block 1. **Cue.** "same branch", "P... on this hyperbola": both statements about position on one connected curve. **Why natural.** one positive parameter per point folds the constraint $xy = 1$ into the coordinate itself, so no multiplier or substitution is needed later. **Link to the next block.** three numbers a, t, b are now ready to feed a fixed base, moving height argument.

Block 2. **Cue.** "area... as large as possible" with A, B fixed. **Why natural.** fixed base area is half base times height, and a strictly convex arc gives a strictly concave height function, hence a unique interior maximiser. **Link to the next block.** a unimodal maximum is one derivative condition, which is a geometric statement: tangent parallel to chord.

Block 3. **Cue.** both slopes have the shape $-1/(\text{something})$, coming from the same function $1/x$. **Why natural.** comparing like with like collapses immediately to $t^2 = ab$. **Link to the next block.** $t = \sqrt{ab}$ is a geometric mean, an invariant that a scaling map can send to a fixed point.

Block 4. **Cue.** a geometric mean is exactly what the squeeze map $(x,y) \mapsto (\lambda x, y/\lambda)$ can send to 1. **Why natural.** this one parameter family is the full determinant one symmetry group of $xy = 1$ fixing the curve, so it is the natural group to normalise by. **Link to the next block.** once P sits at $(1,1)$ and A, B are swapped by $y = x$, the picture has a genuine symmetry, not a coincidence.

Block 5. **Cue.** A, B mirror images, P on the mirror line. **Why natural.** an isometry that swaps two regions cannot leave their areas different. **Link to the next block.** the equality proved after normalising transports back unchanged, because the normalising map was itself area preserving.

Layer 3: WHY

The truth underneath is that the extremal area question and the equal area question are one symmetry, not two computations that happen to agree. The squeeze maps and the single reflection generate enough of an area preserving group on $xy = 1$ that any A, B on one branch can be moved to mirror position at zero cost, and once there, the extremiser P has no choice but to sit on the fixed locus of the reflection, because the optimisation problem is carried to itself when A, B are swapped.

The discernment mechanism: when two fixed points and a free third point on a curve appear together, check for an area or distance preserving symmetry exchanging the two fixed points before reaching for calculus on an explicit formula. Calculus always works and always costs more; the symmetry, when present, replaces two computations with one act of swapping. Train it by asking, for every curve given by an equation invariant under some transformation group ($xy = c$ under $(x, y) \mapsto (\lambda x, y/\lambda)$, a circle under rotation about its centre, $y = x^2$ under $x \mapsto -x$), what that group does to the specific two points on the page.

The examiners' nudge is the request for an equality rather than a number: a question that could have asked you to compute one area and instead asks you to prove two are equal is telling you the intended route never computes either.

Revolving concepts

Tangent parallel to chord. For strictly convex g on $[p, q]$, the secant through the endpoints minus g is strictly concave, zero at the ends, positive between, so uniquely maximised where the tangent to g matches the secant's slope. The same fact locates the point on a parabola or convex arc farthest from a given line. See Book 1, field: Calculus and integrals, topic: convexity and extremal distance to a chord.

Squeeze maps of $xy = c$. The maps $(x, y) \mapsto (\lambda x, y/\lambda)$, $\lambda > 0$, have determinant 1 and fix $xy = c$ setwise; with the reflection $(x, y) \mapsto (y, x)$ they generate the area preserving symmetries of the curve, and can move any two points on one branch into mirror position. Any curve invariant under a one parameter scaling pair with product one repays writing this group down first. See Book 1, field: Geometry, topic: affine symmetries of conics.

Reflections as area preserving involutions used to prove equalities. An isometry that exchanges two regions proves them equal without measuring either. See Book 1, field: Geometry, topic: symmetry arguments for equal area.

No sequence, induction or self similar structure appears in this problem, so there is no recursion to generalise here; the reusable structure is entirely the symmetry group argument above.

Circuit Bank

- **WHEN** two fixed points and a free third point sit on a curve with a visible area preserving symmetry group **DO** find the map or reflection that swaps the two fixed points before setting up any integral **BECAUSE** the extremiser lies on the fixed locus of that symmetry, usually settling both the extremum and any follow up equality at once
- **WHEN** you need the point on a convex or concave arc farthest from a fixed chord **DO** set tangent slope equal to chord slope and solve **BECAUSE** this is the geometric content of the same derivative condition, reached with two slope formulas instead of a full determinant expansion
- **WHEN** a curve is given by an equation invariant under a scaling pair $(x, y) \mapsto (\lambda x, \mu y)$ with $\lambda\mu = 1$ **DO** write that family down explicitly and use it to move any two points on the curve into mirror position **BECAUSE** it is an area preserving bijection fixing the curve, so the symmetric case is reached at zero cost

- **WHEN** a problem asks you to prove two quantities equal rather than to compute either **DO** look for a symmetry of the whole picture that exchanges them before computing anything **BECAUSE** a proof by exchange is shorter and generalises to cases where neither quantity has a closed form

Backtesting

1. First useful cue: "same branch", fixing one sign convention for the whole argument.
2. Method the expression suggested: fixed base, moving height, so compare tangent slope to chord slope rather than differentiate the full triangle area formula.
3. Where you would hesitate, and the thought to reinforce: right after finding $t = \sqrt{ab}$, when integration tempts; reinforce that the question asked for an equality, so look for what exchanges the two regions.
4. The trap the question sets: both areas are honestly computable by a direct integral, which rewards grinding and never announces the shortcut.
5. What makes you recognise it faster next time: seeing $xy = c$ should now fire the squeeze map reflex, the way a circle already fires rotate about the centre.
6. The reusable decision rule: when a symmetry preserving group and two fixed points are both present, normalise by the group before touching calculus.

Mirror drills

1. $A = (-2, 4)$, $B = (3, 9)$ on $y = x^2$; find P on the arc between them with tangent parallel to AB, and say whether the two cut off regions must be equal. *Answer:* $P = (1/2, 1/4)$ from $2t = 1$; no squeeze symmetry moves this A, B into mirror position on a parabola, so the two regions need not be equal here, and are not.
2. Two points lie on the same branch of $xy = 4$. Name the map replacing $(x, y) \mapsto (\lambda x, y/\lambda)$ and locate P. *Answer:* the same family still fixes $xy = 4$; with $A = (a, 4/a)$, $B = (b, 4/b)$, matching slopes gives $P = (\sqrt{ab}, 4/\sqrt{ab})$, since the constant cancels out of the slope comparison exactly as before.
3. On $xy = 1$, redefine P as the point where the arc length from A to P equals the arc length from P to B. Is this still the tangent parallel to chord point? *Answer:* no in general; arc length bisection and area maximisation are different extremal conditions and coincide only once the extra mirror symmetry is imposed on A, B specifically, a caveat worth clarifying before assuming two notions of midpoint agree.

11.2 A2. a Lucas recurrence and an odd prime factor

Let $a_0 = 1$, $a_1 = 2$, and $a_n = 4a_{n-1} - a_{n-2}$ for $n \geq 2$. Find an odd prime factor of a_{2015}.

Read it out loud

A linear recurrence with constant coefficients, order two, asked about one specific enormous index, 2015. The command is "find an odd prime factor," not "find a_{2015}," which is the cue that you are not meant to compute the number itself, you are meant to find structure that survives without ever writing all its digits.

The field embedded is linear recurrences and their closed forms: order two, constant coefficients, means a characteristic quadratic with two roots, and the sequence is a combination of their powers. The number $2015 = 5 \times 13 \times 31$ is not decoration, it is the whole plan: an index that factors is an invitation to relate a_{2015} to a_5 or a_{13} or a_{31}, terms small enough to compute by hand, through some divisibility law connecting a_n and a_{kn}.

Within thirty seconds you should have written down the characteristic equation $x^2 - 4x + 1 = 0$ and noticed $2015 = 5 \times 403$ with 403 odd, because "odd" in the question and an odd cofactor in the index are the same word for a reason: the factorisation identity for a sum of like powers only exists at an odd exponent.

Approaches, ranked worst to best

1. **Iterate the recursion to $n = 2015$.** *Cue:* a recursively defined sequence and one specific index. *Circuit:* just keep applying $a_n = 4a_{n-1} - a_{n-2}$ two thousand times. (the term has hundreds of digits by $n = 2015$, and even granting a machine to reach it, you would then need to factor an enormous number, which the problem cannot intend by hand.)

2. **Extend the sequence to negative indices and argue periodicity mod a candidate prime.** *Cue:* the recursion reads both ways, $a_{n-2} = 4a_{n-1} - a_n$. *Circuit:* show $a_{-n} = a_n$, then chase a prime dividing some a_m through the shifted recursion modulo that prime. (correct and avoids irrational numbers entirely, but needs a careful backward induction and a modular argument before it ever touches 2015.)

3. **Closed form via the characteristic roots, then factor $x^k + y^k$ for odd k.** *Cue:* a constant coefficient order two recurrence, and 2015 has an odd factor 403. *Circuit:* write $a_n = (\alpha^n + \beta^n)/2$, use $x^k + y^k = (x + y)(\cdots)$ for odd k to show $a_n \mid a_{kn}$, then compute the small term a_5 by hand. (five arithmetic steps and one factoring identity; the only overhead is a short integrality argument.)

The ideal solution

The characteristic equation of $a_n = 4a_{n-1} - a_{n-2}$ is $x^2 - 4x + 1 = 0$, with roots $\alpha = 2 + \sqrt{3}$, $\beta = 2 - \sqrt{3}$, satisfying $\alpha + \beta = 4$ and $\alpha\beta = 1$. The general solution is $a_n = A\alpha^n + B\beta^n$; the initial conditions $a_0 = 1 = A + B$ and $a_1 = 2 = A\alpha + B\beta$ are symmetric under swapping $\alpha \leftrightarrow \beta$, and $A = B = \frac{1}{2}$ solves them, since then $\frac{1}{2}(\alpha + \beta) = 2$. Hence

$$a_n = \frac{\alpha^n + \beta^n}{2} \qquad \text{for every } n \geq 0.$$

Key lemma. For every positive integer n and every odd positive integer k, $a_n \mid a_{kn}$.
Proof. Write $x = \alpha^n$, $y = \beta^n$. Since k is odd,

$$x^k + y^k = (x + y)\big(x^{k-1} - x^{k-2}y + \cdots - xy^{k-2} + y^{k-1}\big),$$

an alternating sum of k terms. Dividing both sides by 2 gives

$$\frac{a_{kn}}{a_n} = \frac{\alpha^{kn} + \beta^{kn}}{\alpha^n + \beta^n} = x^{k-1} - x^{k-2}y + \cdots + y^{k-1} =: Q.$$

Now $\alpha, \beta \in \mathbb{Z}[\sqrt{3}] = \{p + q\sqrt{3} : p, q \in \mathbb{Z}\}$, a ring closed under addition and multiplication, so $x = \alpha^n$ and $y = \beta^n$ lie in $\mathbb{Z}[\sqrt{3}]$, and hence so does Q, say $Q = p + q\sqrt{3}$. But $Q = a_{kn}/a_n$ is also a ratio of two positive integers (the sequence is a sequence of positive integers by immediate induction from the recursion and its integer initial data), hence rational; and a rational number of the form $p + q\sqrt{3}$ with $p, q \in \mathbb{Z}$ forces $q = 0$, since $\sqrt{3}$ is irrational. So $Q = p \in \mathbb{Z}$, meaning $a_n \mid a_{kn}$. ■

Applying it. $2015 = 5 \times 403$ and $403 = 13 \times 31$ is odd, so the lemma with $n = 5$, $k = 403$ gives $a_5 \mid a_{2015}$. Compute a_5 directly from the recursion: $a_2 = 4(2) - 1 = 7$, $a_3 = 4(7) - 2 = 26$, $a_4 = 4(26) - 7 = 97$, $a_5 = 4(97) - 26 = 362 = 2 \times 181$. Trial division by every prime up to $\lfloor\sqrt{181}\rfloor = 13$, that is $2, 3, 5, 7, 11, 13$, shows none divides 181, so 181 is prime, and it is odd. Since $362 \mid a_{2015}$ and $362 = 2 \times 181$, in particular $181 \mid a_{2015}$.

$$\boxed{181 \text{ is an odd prime factor of } a_{2015}.}$$

Layer 1: WHAT

Block 1: solve the recurrence in closed form through its characteristic equation. Block 2: notice the target index 2015 factors with an odd cofactor, and look for a divisibility law relating a_n and a_{kn} for odd k. Block 3: prove that law using the factorisation of $x^k + y^k$ for odd k, then an integrality argument inside $\mathbb{Z}[\sqrt{3}]$. Block 4: apply the law once, at the smallest available factor pair $(5, 403)$, and finish by direct arithmetic on a_5.

The nominal route shares block 1, a closed form is the obvious first move for any constant coefficient recurrence, but then tries to reach 2015 directly, either by brute iteration or by chasing the sequence backwards through negative indices and modular periodicity. The bifurcation point is the decision, once the closed form is in hand, to look at how 2015 factors rather than at 2015 itself: factoring the index converts one intractable huge term into an algebraic identity between two small ones.

Layer 2: HOW

Block 1. **Cue.** a linear recurrence with constant coefficients, order two. **Why natural.** such a recurrence always has a two dimensional solution space spanned by the powers of the roots of its characteristic quadratic, so the closed form is the standard first move, not a clever one. **Link to the next block.** having $a_n = (\alpha^n + \beta^n)/2$ turns "does a_n divide a_m" into a question about powers of two fixed algebraic numbers, not about the recursively defined integers directly.

Block 2. **Cue.** the specific index 2015, and the word "odd" in "odd prime factor." **Why natural.** an index that factors as a small number times an odd cofactor invites a law that needs an odd exponent, because the natural factoring identity for a sum of like powers, $x^k + y^k = (x + y)(\cdots)$, exists only when k is odd. **Link to the next block.** this converts the target into: find $a_n \mid a_{2015}$ for a small divisor n of 2015 with odd cofactor, then compute a_n.

Block 3. **Cue.** the ratio a_{kn}/a_n equals $(\alpha^{kn} + \beta^{kn})/(\alpha^n + \beta^n)$, exactly the shape $x^k + y^k$ over $x + y$. **Why natural.** the factoring identity gives an explicit integer polynomial Q in $x = \alpha^n, y = \beta^n$; since $\mathbb{Z}[\sqrt{3}]$ is closed under the ring operations, Q lands back in $\mathbb{Z}[\sqrt{3}]$, and comparing that with Q being manifestly rational forces Q to be a plain integer. **Link to the next block.** a plain integer Q with $a_{kn} = a_n \cdot Q$ is exactly the statement $a_n \mid a_{kn}$, available now for any odd k and any n.

Block 4. **Cue.** $2015 = 5 \times 403$, 403 odd. **Why natural.** the lemma applies directly with $n = 5, k = 403$, and a_5 is five arithmetic steps from the given initial data, cheap enough to compute and factor by hand. **Link to the next block.** $a_5 = 362 = 2 \times 181$ with 181 prime hands you the odd prime factor the question asked for, with no further work.

Layer 3: WHY

The truth underneath is that $a_n = (\alpha^n + \beta^n)/2$ is a close relative of $\cosh(n\theta)$, since α, β are real and $\alpha\beta = 1$, and sequences of this shape obey the same product identities that Chebyshev polynomials obey: whenever the index has an odd factor, the sum of like powers factoring identity is available and hands you a divisor at a smaller index. This is the general fact about Lucas sequences of the second kind: if $V_n = \alpha^n + \beta^n$ for the roots of $x^2 - Px + Q = 0$, then $V_n \mid V_{kn}$ for every odd k, by exactly the argument above, with $\mathbb{Z}[\sqrt{3}]$ replaced by $\mathbb{Z}[\sqrt{P^2 - 4Q}]$ or its full ring of integers in general.

The discernment mechanism: whenever a problem defines a linear recurrence and then asks about one specific, large, composite index, factor that index before doing anything else, and ask which factorisation identity an odd exponent in that factorisation unlocks. Train it by treating "the index is 2015" the same way you would treat "the index is n" in a general olympiad divisibility lemma: write the closed form first, then let the arithmetic of the index, not the recursion, choose your route.

The examiners' nudge is the phrase "find an odd prime factor," not "find the smallest prime factor" or "find all prime factors": it tells you in advance that the intended factor is not unique and is not obtained by full factorisation, which is a green light to stop as soon as one clean factor appears, exactly at a_5.

Revolving concepts

Linear recurrences with constant coefficients. Order two, $a_n = Pa_{n-1} - Qa_{n-2}$, has characteristic equation $x^2 - Px + Q = 0$; distinct real roots α, β give $a_n = A\alpha^n + B\beta^n$, a repeated root α gives $a_n = (A + Bn)\alpha^n$, and complex conjugate roots $re^{\pm i\theta}$ give $a_n = r^n(A\cos n\theta + B\sin n\theta)$. This single tool turns any such recurrence into an explicit formula, and every divisibility question about it starts here. See Book 1, field: Sequences and recurrences, topic: characteristic equation of a linear recurrence.

Lucas sequences and the odd index divisibility law. For α, β roots of $x^2 - Px + Q = 0$, define $U_n = (\alpha^n - \beta^n)/(\alpha - \beta)$ and $V_n = \alpha^n + \beta^n$; both satisfy the same recurrence as a_n. The identity $x^k + y^k = (x + y)(x^{k-1} - \cdots + y^{k-1})$ for odd k gives $V_n \mid V_{kn}$ whenever k is odd, by the integrality argument used above; the companion fact for the U sequence is the stronger $\gcd(U_m, U_n) = U_{\gcd(m,n)}$, needing a different argument, and is the standard generalisation used for the Fibonacci numbers, $P = 1, Q = -1$. See Book 1, field: Number theory, topic: Lucas sequences and divisibility.

Rational algebraic numbers in $\mathbb{Z}[\sqrt{d}]$ are ordinary integers. Any element $p + q\sqrt{d}$, $p, q \in \mathbb{Z}$, d not a perfect square, that happens to be rational must have $q = 0$, since 1 and $\sqrt{d}$ are linearly independent over $\mathbb{Q}$. This one line of algebraic number theory does all the work in the key lemma, and it recurs whenever a sequence is built from two conjugate irrational roots and a divisibility or integrality claim follows. See Book 1, field: Number theory, topic: rings of integers of real quadratic fields.

Factoring $x^n + y^n$ against $x^n - y^n$. The difference always factors, $x^n - y^n = (x - y)(x^{n-1} + \cdots + y^{n-1})$; the sum factors this way only when n is odd. The odd case is the flip side of the fact that $2^n + 1$ can be prime only if n is a power of 2, since otherwise n has an odd factor $k > 1$ and $2^{n/k} + 1$ divides $2^n + 1$. See Book 1, field: Polynomials, topic: factorisations of $x^n \pm y^n$.

The recursion here is order two and constant coefficient throughout, with no further nested or self similar structure, so the generalisation above, arbitrary P, Q and the U_n, V_n pair, is the full

extent of it.

Circuit Bank

- **WHEN** a linear recurrence with constant coefficients is given and you are asked about one specific large index **DO** solve the characteristic equation and write the closed form in the two roots before touching the specific index **BECAUSE** every subsequent divisibility or congruence question becomes an algebraic identity in the roots, not an arithmetic slog through the recursion
- **WHEN** the target index of a recursively defined sequence has an odd factor k **DO** look for a law of the shape $a_n \mid a_{kn}$ coming from $x^k + y^k = (x+y)(\cdots)$ **BECAUSE** a sum of like powers only factors this way for an odd exponent, so an odd cofactor is exactly the signal that the identity is available
- **WHEN** a closed form built from two conjugate irrational roots produces a ratio you can see is rational, both numerator and denominator are terms of an integer sequence **DO** show the ratio also lies in $\mathbb{Z}[\sqrt{d}]$, then conclude it is a plain integer **BECAUSE** a rational element of $\mathbb{Z}[\sqrt{d}]$ has zero irrational part, a one line argument replacing a much longer direct proof of divisibility
- **WHEN** a problem says "find an odd prime factor" rather than "find the prime factorisation" **DO** stop as soon as one clean factor is found, usually at the smallest useful divisor of the index **BECAUSE** the phrasing tells you the intended answer is not unique, so hunting for more is wasted ink

Backtesting

1. First useful cue: the specific index 2015 next to the word "odd," inviting a factorisation of 2015 itself before anything else.
2. Method the expression suggested: a constant coefficient order two recurrence suggested the characteristic equation and closed form immediately.
3. Where you would hesitate, and the thought to reinforce: after finding $a_n = (\alpha^n + \beta^n)/2$, unsure how to connect it to a_{2015}; reinforce that factoring the index first, then hunting for an identity needing an odd exponent, is the route.
4. The trap the question sets: a_{2015} genuinely has hundreds of digits, and a candidate who tries to iterate the recursion by hand is punished with an unfactorable giant number.
5. What makes you recognise it faster next time: any recursively defined sequence with roots multiplying to plus or minus one should now fire "this is a Lucas sequence, check the odd index divisibility law" the way "arithmetic progression" fires "common difference."
6. The reusable decision rule: when a recurrence's closed form has two conjugate roots, test whether a ratio of two of its terms is forced to be an ordinary integer by comparing rationality against membership in the relevant ring of integers.

Mirror drills

1. Let $b_0 = 2, b_1 = 1, b_n = b_{n-1} - b_{n-2}$. Find the period of b_n mod 5 and decide whether 5 divides any term. *Answer:* the roots of $x^2 - x + 1 = 0$ are primitive sixth roots of unity, so b_n is periodic with period 6; the values $b_0, \ldots, b_5$ are $2, 1, -1, -2, -1, 1$, none 0 mod 5, so $5 \nmid b_n$ for any n, a reminder that the odd cofactor circuit only fires once the sequence actually hits a multiple of the target prime.

2. Fibonacci numbers satisfy $F_m \mid F_n$ whenever $m \mid n$, for every m, not only odd cofactors. Explain in one sentence why Fibonacci gets the unrestricted statement while a_n above only gets it for odd cofactors. *Answer:* Fibonacci is a $U_n = (\alpha^n - \beta^n)/(\alpha - \beta)$ type sequence, tied to the identity $x^k - y^k = (x - y)(\cdots)$, valid for every k, whereas a_n is a $V_n = \alpha^n + \beta^n$ type sequence, tied to $x^k + y^k$, which factors through $x + y$ only for odd k.

3. Using the lemma, name three indices $m > 2015$ for which $181 \mid a_m$ follows with no further computation. *Answer:* any $m = 5 \times (\text{odd number})$, for instance $m = 2025 = 5 \times 405$, $m = 2035 = 5 \times 407$, $m = 2045 = 5 \times 409$, since the lemma gives $a_5 \mid a_m$ whenever $m/5$ is odd, and $a_5 = 2 \times 181$.

11.3 A3. Roots of unity collapsing to a gcd sum

Compute

$$\log_2\left(\prod_{a=1}^{2015}\prod_{b=1}^{2015}(1+e^{2\pi iab/2015})\right).$$

Here i is the imaginary unit (that is, $i^2=-1$).

Read it out loud

Say it in plain terms before touching a symbol: you are asked for $\log_2$ of a single complex number, and that number is a double product of 2015^2 factors of the form $1+\zeta^{ab}$, where $\zeta = e^{2\pi i/2015}$ is a primitive 2015th root of unity. Two integer indices a and b each range over a full residue system mod 2015, and they interact only through the product ab in the exponent. Strip away the dressing and this is a problem about the multiplicative structure of exponents modulo 2015, wrapped in a complex analysis shell.

Field tags, out loud: complex numbers (roots of unity, cyclotomic factorisation), number theory (gcd, Euler's totient, multiplicative arithmetic functions), and a sliver of polynomial theory (the identity $x^n-1=\prod(x-\zeta^b)$). There is no calculus here and no geometry; every genuine idea in this problem lives in how a, b and 2015 interact as integers, with the roots of unity acting only as a bookkeeping device for that interaction.

The first cue fires before you write a single equation: $\log_2$ of an unevaluated product, set as a Putnam answer, is a promise. A well posed exam question does not ask you to take $\log_2$ of a number with no reason to be a power of 2, so within the first thirty seconds you should have written two things on your page. First, the product must equal $2^{f(a)}$ for some integer valued f, so the whole answer is $\sum_a f(a)$. Second, $2015 = 5\times 13\times 31$, because any modulus chosen to be the competition year is chosen for its factorisation, and you check that before anything else. A caveat worth clarifying immediately: 2015 is odd. Hold onto that; it turns out to be the one property that keeps every factor in the product away from zero.

The double product is symmetric in a and b only in appearance. Structurally read it as: fix a, let b run over a full residue system mod 2015, and ask what the multiplication by a map does to that residue system. That question, asked of a cyclic group, always has the same answer: it depends on a only through $d=\gcd(a,2015)$. That is the guiding light this problem is built around.

Approaches, ranked worst to best

1. **Direct numerical expansion.** *Cue:* multiply out all 2015^2 complex factors. *Circuit:* no circuit, pure enumeration. (why it ranks here: this is over four million complex multiplications, it produces a decimal approximation rather than a proof, and it uses none of the structure the problem is built on).

2. **Casework on the eight divisors of 2015.** *Cue:* 2015 has divisors $1,5,13,31,65,155,403,2015$, so split a into eight classes by $\gcd(a,2015)$ and treat each separately. *Circuit:* repeated ad hoc use of the same unproven idea, no single lemma. (why it ranks here: it eventually reaches the truth, but forces you to rediscover the same root of unity argument eight times over, at eight times the ink and eight times the chance of a slip on one case).

3. **Solve the coprime case cleanly, patch the rest afterwards.** *Cue:* $\gcd(a,2015)=1$ collapses immediately by a permutation argument, then handle non-coprime a as an afterthought. *Circuit:* half a lemma, stitched rather than unified. (why it ranks here: the coprime case is genuinely the heart of the argument, but treating it in isolation means writing the reduction $n=dn_1$, $a=da_1$ a second time later, instead of building it into the lemma from the first line).

4. **One lemma for every a via $d = \gcd(a, 2015)$, then a multiplicative divisor sum.** *Cue:* the exponent depends on a, b only through ab mod n, and the outer $\log_2$ demands an exponent function. *Circuit:* reduce mod the gcd, evaluate the coprime case by plugging $x = -1$ into $x^{n_1} - 1 = \prod(x - \zeta^c)$, then evaluate $\sum_a \gcd(a, n)$ by Dirichlet convolution and multiplicativity. (this is the route worth taking: it proves $\prod_b (1 + \zeta^{ab}) = 2^{\gcd(a,2015)}$ uniformly, for every a from 1 to 2015 in one pass, then finishes the numerical part in three prime evaluations instead of any casework).

The ideal solution

Lemma 11.3.1. *Let n be a positive odd integer, let $\zeta_n = e^{2\pi i/n}$, and let a be any integer with $d = \gcd(a, n)$. Then*

$$\prod_{b=1}^{n} \left(1 + \zeta_n^{ab}\right) = 2^d.$$

Proof. Write $n = dn_1$ and $a = da_1$ with $\gcd(a_1, n_1) = 1$; since n_1 divides the odd number n, n_1 is itself odd. As b runs over $1, \ldots, n$, the value $ab/n = a_1 b/n_1$ depends on b only through b mod n_1, and each residue class mod n_1 occurs exactly $d = n/n_1$ times among $b = 1, \ldots, n$. Hence

$$\prod_{b=1}^{n} \left(1 + \zeta_n^{ab}\right) = \left(\prod_{c=0}^{n_1 - 1} \left(1 + e^{2\pi i a_1 c/n_1}\right) \right)^d.$$

Because $\gcd(a_1, n_1) = 1$, the map $c \mapsto a_1 c$ mod n_1 permutes $\{0, 1, \ldots, n_1 - 1\}$, so with $\zeta = e^{2\pi i/n_1}$,

$$\prod_{c=0}^{n_1 - 1} \left(1 + e^{2\pi i a_1 c/n_1}\right) = \prod_{c=0}^{n_1 - 1} (1 + \zeta^c).$$

The numbers $\zeta^0, \ldots, \zeta^{n_1 - 1}$ are exactly the roots of $z^{n_1} - 1$, so $z^{n_1} - 1 = \prod_{c=0}^{n_1 - 1}(z - \zeta^c)$. Setting $z = -1$,

$$(-1)^{n_1} - 1 = \prod_{c=0}^{n_1 - 1} (-1 - \zeta^c) = (-1)^{n_1} \prod_{c=0}^{n_1 - 1} (1 + \zeta^c).$$

Since n_1 is odd, $(-1)^{n_1} = -1$, so $-2 = -\prod_{c=0}^{n_1 - 1}(1 + \zeta^c)$, giving $\prod_{c=0}^{n_1 - 1}(1 + \zeta^c) = 2$. Substituting back,

$$\prod_{b=1}^{n} \left(1 + \zeta_n^{ab}\right) = 2^d.$$

□

Apply the lemma with $n = 2015$, which is odd. For every a from 1 to 2015, $\prod_{b=1}^{2015}(1 + e^{2\pi i ab/2015}) = 2^{\gcd(a,2015)}$, so

$$\log_2 \left(\prod_{a=1}^{2015} \prod_{b=1}^{2015} (1 + e^{2\pi i ab/2015}) \right) = \sum_{a=1}^{2015} \gcd(a, 2015).$$

For each divisor d of $n = 2015$, the number of $a \in \{1, \ldots, n\}$ with $\gcd(a, n) = d$ equals the number of $a' = a/d \in \{1, \ldots, n/d\}$ with $\gcd(a', n/d) = 1$, which is $\phi(n/d)$. So

$$\sum_{a=1}^{n} \gcd(a, n) = \sum_{d \mid n} d\, \phi(n/d).$$

This is the Dirichlet convolution of the identity function $n \mapsto n$ with ϕ, and a convolution of two multiplicative functions is multiplicative. In other words, it suffices to know the value on each

prime factor separately. On a single prime p, the divisors are 1 and p, giving $\sum_{d|p} d\,\phi(p/d) = 1\cdot\phi(p) + p\cdot\phi(1) = (p-1)+p = 2p-1$.

Since $2015 = 5\times 13\times 31$ is a product of three distinct primes,

$$\sum_{a=1}^{2015} \gcd(a,2015) = (2\cdot 5-1)(2\cdot 13-1)(2\cdot 31-1) = 9\times 25\times 61.$$

Now $9\times 25 = 225$ and $225\times 61 = 225\times 60 + 225 = 13500 + 225 = 13725$. Hence

$$\log_2\left(\prod_{a=1}^{2015}\prod_{b=1}^{2015}(1+e^{2\pi iab/2015})\right) = \boxed{13725}.$$

Layer 1: WHAT

Block 1: read the outer $\log_2$ as a constraint, not a formatting choice; commit to hunting for an exponent function $f(a)$ with inner product $= 2^{f(a)}$. Block 2: fix a, write $d = \gcd(a,2015)$, $n_1 = 2015/d$, $a_1 = a/d$, and reduce the inner product over b to the dth power of a coprime-index product over n_1 terms. Block 3: use $\gcd(a_1,n_1) = 1$ to permute the coprime-index product into $\prod_c(1+\zeta^c)$ over all n_1th roots of unity, independent of a. Block 4: evaluate that product by plugging $z=-1$ into $z^{n_1}-1 = \prod(z-\zeta^c)$, using that n_1 is odd because 2015 is odd. Block 5: conclude the lemma, take $\log_2$, and turn the double product into $\sum_a \gcd(a,2015)$. Block 6: evaluate that sum by regrouping over divisors, invoking multiplicativity, and multiplying three numbers built from the prime factorisation of 2015.

Juxtapose the zombie route against the ideal one. The nominal route stalls at Block 2: without the gcd substitution, a zombie attack handles $a=1$ (easy, coprime to 2015) and then treats every other a as a separate, unrelated case, either by brute force or by rediscovering the permutation argument from scratch eight times over, once per divisor of 2015. It is worth repeating: the divisor structure of 2015 is not eight separate problems, it is one lemma evaluated at eight different values of d.

The bifurcation point sits exactly between Block 1 and Block 2: do you write $d = \gcd(a,2015)$ before you have solved any single case, or only after solving the coprime case and looking for a way to extend it? Writing it first is the reroute; writing it second is the zombie route wearing the reroute's clothes one step too late, after the ink for the coprime case has already been spent twice.

Layer 2: HOW

Block 1. **Cue.** The final requested quantity is $\log_2$ of an unevaluated product, in a competition that only sets answers that resolve cleanly. **Why natural.** A logarithm of a number the setter expects you to compute exactly is only ever clean when the argument is a power of the log's base; this is a fact about how the problem was constructed, and it correctly predicts that the inner product must equal $2^{\text{something}}$ before you have proved anything about roots of unity. **Link to the next block.** Having fixed the target shape, the only free variable left is which integer exponent depends on a, so you turn to the inner product over b for one fixed a.

Block 2. **Cue.** The exponent $ab/2015$ depends on b only through ab mod 2015, and multiplication by a fixed a on $\mathbb{Z}/2015\mathbb{Z}$ is the acting object. **Why natural.** Multiplication by a on a cyclic group of order n has orbits of size $n/\gcd(a,n)$, with each element of the image hit $\gcd(a,n)$ times; this is bare orbit counting, so writing $d=\gcd(a,n)$, $n = dn_1$, $a = da_1$ is the reflex the moment an index appears only through a product modulo n. **Link to the next block.** Once the inner product is known to be the dth power of a coprime-index product, all remaining work is to evaluate that one coprime-index product.

Block 3. **Cue.** $\gcd(a_1, n_1) = 1$ turns multiplication by a_1 into a genuine bijection of $\mathbb{Z}/n_1\mathbb{Z}$. **Why natural.** A bijection of the index set of a product leaves the product unchanged, since multiplication of complex numbers is commutative; this converts the a-dependent coprime-index product into the a-independent product $\prod_c(1+\zeta^c)$ over every n_1th root of unity, and a product of a linear expression over every root of a known monic polynomial is exactly what the factorisation $x^{n_1}-1=\prod(x-\zeta^c)$ exists to evaluate. **Link to the next block.** Evaluating that factorisation needs a choice of point to substitute, and the natural point is the one that makes the linear factor vanish, namely $x=-1$.

Block 4. **Cue.** n_1 divides the odd number 2015, so n_1 is odd. **Why natural.** Substituting $z=-1$ gives $(-1)^{n_1}-1=(-1)^{n_1}\prod(1+\zeta^c)$; oddness of n_1 forces $(-1)^{n_1}=-1$ and hence $\prod(1+\zeta^c)=2$ rather than 0. Had n_1 been even, -1 would itself be an n_1th root of unity, one factor would vanish, and the original product, and its logarithm, would not exist. This is the exact point where the problem's choice of an odd modulus stops being decoration and starts being load-bearing. **Link to the next block.** With the coprime case pinned at 2, raising to the power d gives the full lemma $\prod_b(1+\zeta^{ab})=2^{\gcd(a,2015)}$ for every a from 1 to 2015.

Block 5. **Cue.** $\log_2$ applied to a product of powers of 2. **Why natural.** $\log_2$ is a homomorphism from the positive reals under multiplication to the reals under addition, so $\log_2\prod_a 2^{\gcd(a,n)}=\sum_a\gcd(a,n)$ without further work; this is the one line where the outer $\log_2$ finally earns its place, converting the multiplicative statement about roots of unity into a purely additive number-theoretic sum. **Link to the next block.** $\sum_{a=1}^{n}\gcd(a,n)$ is a named, well studied object with a standard evaluation route: partition the index set by the value of the gcd.

Block 6. **Cue.** The sum has 2015 terms, but $\gcd(a,2015)$ only ever takes one of eight divisor values. **Why natural.** For each divisor $d \mid n$, exactly $\phi(n/d)$ values of a satisfy $\gcd(a,n)=d$, which regroups the sum as $\sum_{d\mid n} d\,\phi(n/d)$; because $n\mapsto n$ and ϕ are both multiplicative, their convolution is multiplicative, so the whole calculation collapses to one evaluation per prime factor of 2015. **Link to the next block.** With $2015=5\times13\times31$ squarefree, the sum is the product of three single-prime evaluations $2p-1$, and the last step is arithmetic, not mathematics.

Layer 3: WHY

Two mathematical truths carry this entire problem. The first: any product $\prod_b g(ab \bmod n)$, for g a fixed function and a a fixed integer, is governed entirely by the orbit structure of multiplication by a on $\mathbb{Z}/n\mathbb{Z}$, and that orbit structure depends on a only through $\gcd(a,n)$. You should never see an exponent of the form $ab \bmod n$ without immediately asking what $\gcd(a,n)$ is; every other feature of a is invisible to the problem. The second: a product of a fixed linear factor evaluated at every root of a known monic polynomial is not something you multiply out, it is something you read off, because $\prod_b(x_0-\zeta^b)$ is by definition the defining polynomial evaluated at x_0 up to the sign forced by degree. More generally, whenever you must multiply $f(\zeta^b)$ over every nth root of unity for a polynomial f, you are computing a resultant of f with x^n-1; for linear f, as here, that resultant is a single evaluation, and this problem never needs more than that special case.

The jump from a permutation of residues to evaluating a polynomial at a chosen point looks like a quantum leap the first time you meet it, until you notice both steps are answering the same question: which arrangement of the roots makes the product easiest to name. The permutation step tells you the product does not depend on a_1 at all; the evaluation step tells you what the a_1-independent value actually is. Neither is a leap once you see them as two halves of one question.

The discernment mechanism that chooses this route over casework is a habit of asking, before writing a single line of algebra, whether the index set carries algebraic structure. Here the index set is $\mathbb{Z}/2015\mathbb{Z}$ acting on itself by multiplication, a structure you should recognise on sight whenever a

problem's only operations on the indices are addition and multiplication modulo a fixed n. Train this by refusing to write out a sum or product term by term until you have named the group or set acting on the index, and named the orbit sizes. The second habit, layered on top, is checking the modulus for compositeness the moment you see one: 2015 factoring as three distinct primes is the signal that whatever sum survives to the end will be finished by multiplicativity, not by sixteen individual divisor terms.

What the examiners were nudging toward: choosing the modulus to be the competition year is not cosmetic, it is the entire design of the problem. Oddness of 2015 is predicated on nothing more than keeping the product away from zero, which is the reason a solution exists at all; squarefreeness with three prime factors keeps the final arithmetic to three small evaluations instead of a long divisor list. A caveat worth clarifying: nothing about this problem needed 2015 to be prime, or to have any special residue property beyond parity and its factorisation, and a solution that goes looking for deeper number-theoretic properties of 2015 is chasing a red herring the setters did not lay.

Revolving concepts

Roots of unity and the cyclotomic factorisation. Definition: $\zeta_n = e^{2\pi i/n}$, and $\zeta_n^0, \dots, \zeta_n^{n-1}$ are exactly the n solutions of $x^n = 1$, forming a cyclic group of order n under multiplication. Orbiting facts: $x^n - 1 = \prod_{b=0}^{n-1}(x - \zeta_n^b)$; the sum of all nth roots of unity is 0 for $n > 1$; every subgroup of this group has order dividing n and consists of the mth roots of unity for some $m \mid n$. The generalised move: any product of a fixed polynomial evaluated at every nth root of unity is a resultant with $x^n - 1$, collapsing for linear factors to one substitution. See Book 1, field Complex numbers, topic roots of unity and cyclotomic factorisation.

Multiplication orbits modulo n. Definition: for fixed a, the map $b \mapsto ab \bmod n$ on $\mathbb{Z}/n\mathbb{Z}$ has image of size $n/\gcd(a,n)$, with every value in the image attained $\gcd(a,n)$ times. Orbiting facts: Bezout's identity; the subgroup lattice of $\mathbb{Z}/n\mathbb{Z}$ indexed by divisors of n; multiplication by a is a bijection of $\mathbb{Z}/n\mathbb{Z}$ exactly when $\gcd(a,n) = 1$. See Book 1, field Number theory, topic gcd and modular arithmetic.

Euler's totient function. Definition: $\phi(n)$ counts the integers in $\{1, \dots, n\}$ coprime to n. Orbiting facts: ϕ is multiplicative; $\phi(p^k) = p^{k-1}(p-1)$ for a prime p; $\sum_{d \mid n} \phi(d) = n$. See Book 1, field Number theory, topic Euler's totient function.

Multiplicative arithmetic functions and Dirichlet convolution. Definition: f is multiplicative if $f(1) = 1$ and $f(mn) = f(m)f(n)$ whenever $\gcd(m,n) = 1$; the Dirichlet convolution of f and g is $(f * g)(n) = \sum_{d \mid n} f(d)g(n/d)$, and the convolution of two multiplicative functions is multiplicative. This is itself a recursion in disguise: given a multiplicative f's values on prime powers, f on any n is built up by peeling off one prime power at a time and multiplying, base case $f(1) = 1$; install this as the general method for evaluating any multiplicative function, whether it is ϕ, the divisor count, the divisor sum, or the gcd sum below. See Book 1, field Number theory, topic multiplicative functions and Dirichlet convolution.

The gcd sum function. Definition: $P(n) = \sum_{a=1}^{n} \gcd(a,n)$, sometimes called Pillai's arithmetical function. Orbiting facts: $P(n) = \sum_{d \mid n} d\,\phi(n/d) = (\mathrm{id} * \phi)(n)$, multiplicative; on a prime power, $P(p^k) = p^k + k\,p^{k-1}(p-1)$, and in particular $P(p) = 2p - 1$. See Book 1, field Number theory, topic gcd sum functions.

Circuit Bank

- **WHEN** you must multiply a fixed polynomial expression evaluated at every nth root of unity **DO** evaluate the cyclotomic factorisation $x^n - 1 = \prod_b (x - \zeta^b)$ at the point that kills the polynomial's own factor, rather than multiplying the roots out one by one **BECAUSE**

a product over all roots of a known monic polynomial is that polynomial evaluated at the complementary point, up to a sign fixed by the degree

- **WHEN** an index b appears in an exponent only through $ab \bmod n$ for a fixed integer a **DO** write $d = \gcd(a, n)$, $n = dn_1$, $a = da_1$ with $\gcd(a_1, n_1) = 1$, and reduce to the coprime case raised to the dth power **BECAUSE** multiplication by a on $\mathbb{Z}/n\mathbb{Z}$ has orbits of size $n/\gcd(a, n)$, so the gcd is the only feature of a the final answer can depend on
- **WHEN** a sum runs over all $1 \le a \le n$ and the summand depends on a only through $\gcd(a, n)$ **DO** regroup by divisor $d \mid n$, replace each class's size with $\phi(n/d)$, and check whether the resulting divisor sum is a Dirichlet convolution of known multiplicative functions **BECAUSE** grouping by gcd converts a length n sum into a sum over the divisors of n, and multiplicativity finishes it in one evaluation per prime factor
- **WHEN** the modulus or parameter in a Putnam problem is the competition year itself **DO** factorise it before writing anything else, and check its parity and whether it is squarefree **BECAUSE** setters choose the year as the parameter precisely because its factorisation drives the finishing arithmetic, and parity and squarefreeness are the two properties most often load-bearing
- **WHEN** the requested answer is $\log_b$ of an unevaluated expression **DO** treat this as a promise that the expression equals b to an integer power, and hunt for that exponent as a computable arithmetic function rather than evaluating the expression directly **BECAUSE** a well posed exam answer is never the logarithm of a number with no reason to be a clean power of the base, so the outer function tells you the shape of the lemma to look for before you have proved anything

Backtesting

1. First useful cue: $\log_2$ wraps an unevaluated product, and the modulus 2015 is visibly odd.
2. Method the expression suggested: reduce the inner product over b by the orbit of multiplication by a modulo 2015, writing $d = \gcd(a, 2015)$ before attempting any single case.
3. Where you would hesitate, and the thought to reinforce: hesitating over whether coprime and non-coprime a need separate lemmas; reinforce that $n = dn_1$, $a = da_1$ swallows both in one substitution, so never solve the coprime case in isolation first.
4. The trap the question sets: forgetting to justify why oddness of 2015 is necessary, and so presenting a lemma that would silently claim a nonzero product even when n is even.
5. What makes you recognise it faster next time: seeing an exponent of the form $ab \bmod n$ should now instantly summon $d = \gcd(a, n)$, and seeing $\log_b$ of an unevaluated expression should instantly summon a search for an exponent function; that sentence has to be self-generated, in the arena, not read off a memorised template.
6. The reusable decision rule: when an exponent or index depends on two integers only through their product modulo n, substitute $d = \gcd(a, n)$ and reduce to the coprime case, because permutation arguments and cyclotomic evaluations both require coprimality to hold. Install this as the first line you write whenever you meet the pattern.

Mirror drills

1. Compute $\prod_{b=1}^{9} \left(1 + e^{2\pi i b/9}\right)$. *Answer:* 9 is odd, so the same substitution $z = -1$ into $z^9 - 1 = \prod(z - \zeta^b)$ applies directly with $d = 1$, giving 2.

2. For $n = 45 = 3^2 \times 5$, evaluate $\sum_{a=1}^{45} \gcd(a, 45)$. *Answer:* multiplicativity gives $P(9) \times P(5)$, with $P(9) = 9 + 2 \cdot 3 \cdot 2 = 21$ and $P(5) = 2 \cdot 5 - 1 = 9$, so the sum is 189.
3. Explain in one line why $\prod_{b=1}^{n} \left(1 + e^{2\pi i b/n}\right) = 0$ whenever n is even. *Answer:* $b = n/2$ gives $e^{2\pi i b/n} = e^{i\pi} = -1$, so that single factor is $1 + (-1) = 0$.

11.4 A4. Binary weights on an even floor set

For each real number x, let

$$f(x) = \sum_{n \in S_x} \frac{1}{2^n},$$

where S_x is the set of positive integers n for which $\lfloor nx \rfloor$ is even. What is the largest real number L such that $f(x) \geq L$ for all $x \in [0, 1)$? (As usual, $\lfloor z \rfloor$ denotes the greatest integer less than or equal to z.)

Read it out loud

This is a subset sum of the geometric series $\sum 2^{-n}$, where the subset is chosen for you by a parity test on a floor function. There are exactly two moving parts: which n survive the test, and what a surviving n is worth. The second part is already installed in you and must not be re-derived in the arena: with ratio $1/2$, each term equals the sum of the entire tail after it, $2^{-n} = \sum_{m>n} 2^{-m}$. So an early survivor outweighs everything that could follow it. The consequence is immediate and it is the whole strategic read: to make $f(x)$ small you must vacate the early positions, and once you cannot vacate a position any more, the game is over. The question is therefore not analytic at all. It is combinatorial: how sparse, and how late, can S_x be forced to be?

The fields wired in are geometric series (atomic), the floor function used as a slow counter, and the distinction between an infimum and a minimum. Notice the phrasing: "the largest real number L such that $f(x) \geq L$ for all x". That is the definition of an infimum, written out longhand, and the examiners wrote it longhand rather than saying "the minimum value of f" because the value is approached and never attained. Suspecting that costs you nothing and stops you wasting time hunting for a minimiser that does not exist.

Within thirty seconds you should have two lines on the page. First: $\lfloor x \rfloor = 0$ for every $x \in [0, 1)$, so $1 \in S_x$ always, hence $f(x) \geq 1/2$ for every x, and $L \in [1/2, 1)$. Second: for $x < 1$ the step from nx to $(n+1)x$ is less than 1, so $\lfloor (n+1)x \rfloor - \lfloor nx \rfloor \in \{0, 1\}$. That second line is the engine of the whole problem, because a counter that moves by 0 or 1 cannot stay odd for long without standing completely still.

Everything now hangs on one number: the longest run of consecutive integers that can all fail the parity test. If runs of missing integers have length at most g, then from position 2 onward every block of g consecutive integers donates something, and the sum of the worst case is a geometric series you can write down without thinking. So find g, then add up.

Approaches, ranked worst to best

1. **Grid evaluation and pattern spotting.** *Cue:* a completely explicit series and the words "largest real number". *Circuit:* evaluate, tabulate, conjecture. Compute f at a few hundred rationals and watch the minimum settle near 0.5714. This gives you the target $4/7$ and, far more usefully, its address: the small values live just below $x = 2/3$. As a proof it is worth zero marks. As thirty seconds of reconnaissance it is worth a lot, because the second half of the problem asks you to reverse engineer an x, and now you know where to look. Ranks last because it proves nothing.

2. **Continued fraction classification of the parity word.** *Cue:* $\lfloor nx \rfloor$ is a Beatty sequence. *Circuit:* Sturmian words and the three distance theorem. You can describe the parity pattern of $\lfloor nx \rfloor$ completely through the continued fraction of x. It is correct and it is enormous. You would be importing a theory of infinite words to establish a fact about runs of length three. Costs pages of ink for one line of content.

3. **Lexicographic comparison with the extremal set.** *Cue:* the weights 2^{-n} are literally binary place values. *Circuit:* one place value dominates its whole tail. Set $T = \{1, 4, 7, 10, \dots\}$, note $F(T) = 4/7$, and argue that if $f(x) < 4/7$ then the first position where S_x and T disagree must belong to T, which forces three consecutive integers to be absent from S_x, which forces $x < 1/2$, which contradicts. This is the published route and it is sound. It ranks below the next one only because it runs through a contradiction and needs the comparison lemma stated with care, when the same information is available directly.

4. **Run length bound plus block partition.** *Cue:* consecutive values of nx differ by $x < 1$. *Circuit:* a step smaller than 1 cannot skip a parity class three times running. Prove that three consecutive integers can all miss S_x only when $x < 1/2$; kill $x < 1/2$ in one line because then $2 \in S_x$; then chop $\{2, 3, 4, \dots\}$ into blocks of three and charge each block its worst element. No contradiction, no comparison lemma, and the equality pattern falls out of the proof, which is exactly what you need for the sharpness half. This is the ideal route.

The ideal solution

The answer is $\boxed{L = \frac{4}{7}}$.

Throughout, $x \in [0, 1)$ and $S_x = \{n \in \mathbb{Z}_{>0} : \lfloor nx \rfloor \text{ is even}\}$.

Lemma 11.4.1. *For every $x \in [0, 1)$ and every positive integer n, $\lfloor (n+1)x \rfloor - \lfloor nx \rfloor \in \{0, 1\}$.*

Proof. Since $0 \le x < 1$ we have $nx \le (n+1)x < nx + 1$. The floor function is nondecreasing, so $\lfloor nx \rfloor \le \lfloor (n+1)x \rfloor \le \lfloor nx + 1 \rfloor = \lfloor nx \rfloor + 1$. □

Lemma 11.4.2. *If $x \in [1/2, 1)$, then no three consecutive positive integers all lie outside S_x.*

Proof. Suppose $\lfloor nx \rfloor$, $\lfloor (n+1)x \rfloor$ and $\lfloor (n+2)x \rfloor$ are all odd. The difference of two odd integers is even, so by Lemma 1 each of the two consecutive differences is 0. Hence $\lfloor nx \rfloor = \lfloor (n+2)x \rfloor$, and two reals with the same floor differ by less than 1, so $(n+2)x - nx = 2x < 1$. That contradicts $x \ge 1/2$. □

Proposition 11.4.3. *$f(x) \ge 4/7$ for every $x \in [0, 1)$.*

Proof. Since $\lfloor x \rfloor = 0$ is even, $1 \in S_x$, so the term $1/2$ is always present.

If $x < 1/2$ then $\lfloor 2x \rfloor = 0$ is even, so $2 \in S_x$ as well and $f(x) \ge \frac{1}{2} + \frac{1}{4} = \frac{3}{4} > \frac{4}{7}$.

If $x \ge 1/2$, partition the integers from 2 upward into the blocks

$$B_k = \{3k + 2,\ 3k + 3,\ 3k + 4\}, \qquad k = 0, 1, 2, \dots,$$

which are disjoint and cover $\{2, 3, 4, \dots\}$. Each B_k consists of three consecutive integers, so by Lemma 2 it contains some element of S_x, and that element contributes at least $2^{-(3k+4)}$, the value of the largest member of B_k. Adding the guaranteed term from $n = 1$,

$$f(x) \ \ge\ \frac{1}{2} + \sum_{k=0}^{\infty} \frac{1}{2^{3k+4}} = \frac{1}{2} + \frac{1/16}{1 - 1/8} = \frac{1}{2} + \frac{1}{14} = \frac{4}{7}.$$ □

Proposition 11.4.4. *For every $\varepsilon > 0$ there exists $x \in [0, 1)$ with $f(x) < 4/7 + \varepsilon$.*

Proof. Fix a positive integer N and set $x = \frac{2}{3} - \delta$ with $0 < \delta < \frac{1}{9N}$, so that $0 < m\delta < \frac{1}{3}$ for every $m \le 3N$. For $1 \le k \le N$,

$$\begin{aligned}
&(3k-2)x = (2k-2) + \tfrac{2}{3} - (3k-2)\delta, && \text{fractional part in } (\tfrac{1}{3}, \tfrac{2}{3}), && \lfloor (3k-2)x \rfloor = 2k-2,\\
&(3k-1)x = (2k-1) + \tfrac{1}{3} - (3k-1)\delta, && \text{fractional part in } (0, \tfrac{1}{3}), && \lfloor (3k-1)x \rfloor = 2k-1,
\end{aligned}$$

$$(3k)x = 2k - 3k\delta, \qquad \text{value in } (2k - \tfrac{1}{3}, 2k), \qquad \lfloor (3k)x \rfloor = 2k - 1.$$

So among $1, 2, \ldots, 3N$ the elements of S_x are exactly $1, 4, 7, \ldots, 3N - 2$. Bounding the tail beyond $3N$ by the whole of it,

$$f(x) \;\le\; \sum_{k=1}^{N} \frac{1}{2^{3k-2}} + \sum_{n>3N} \frac{1}{2^n} = \frac{4}{7}\left(1 - 8^{-N}\right) + 8^{-N} < \frac{4}{7} + 8^{-N}.$$

Choosing N with $8^{-N} < \varepsilon$ gives the claim. □

The two propositions together say that $4/7$ is a lower bound and that nothing larger is, so $L = 4/7$.

Remark 11.4.5. The value is never attained. Since $4/7 = 0.\overline{100}$ in binary and that expansion neither terminates nor ends in all ones, the only set with $F(S) = 4/7$ is $S = \{1, 4, 7, \ldots\}$. If S_x were that set, then by Lemma 1 the floor must increase by exactly 1 at each of the two steps inside a block and by 0 at the block boundary, so $\lfloor (3k+1)x \rfloor = 2k$ and $\lfloor (3k+3)x \rfloor = 2k+1$ for all $k \ge 0$. The first gives $x \ge 2k/(3k+1)$ for all k, hence $x \ge 2/3$; the second gives $(3k+3)x < 2k+2$, hence $x < 2/3$. So $f(x) > 4/7$ for every x, and the bound is an infimum only.

Layer 1: WHAT

Block 1. $\lfloor x \rfloor = 0$, so $1 \in S_x$ for every x in the range: the term $1/2$ is free and permanent.

Block 2. Because the weights halve, minimising f means vacating positions as early and as long as possible; so ask how long a gap in S_x can be.

Block 3. The step $\lfloor (n+1)x \rfloor - \lfloor nx \rfloor$ is 0 or 1 because $x < 1$; three odd floors in a row therefore force two steps of 0, hence $2x < 1$.

Block 4. So a triple gap forces $x < 1/2$, and $x < 1/2$ puts 2 into S_x, giving $f(x) \ge 3/4$. That branch is dead, well above the target.

Block 5. On the surviving branch every three consecutive integers meet S_x. Chop $\{2, 3, \ldots\}$ into blocks of three, charge each block its worst (largest) element, sum the geometric series: $1/2 + 1/14 = 4/7$.

Block 6. The worst case in Block 5 is the pattern $\{1, 4, 7, \ldots\}$, so engineer an x that realises it for as long as you like: the pattern says $\lfloor nx \rfloor$ is even exactly on $n \equiv 1 \pmod 3$, which is the behaviour of x just below $2/3$. Verify the three floors and let the truncation run to infinity.

Juxtaposition. The nominal route treats f as a function to be evaluated: tabulate f at rationals, try to write a formula for $f(x)$, perhaps try to integrate or to differentiate something. It goes nowhere because f is nowhere continuous and has no formula. The ideal route never evaluates f at all except at the very end; it studies the set S_x and quotes the series. The bifurcation point is the sentence "how long can a run of consecutive integers all fail the test?". Everything before that sentence is arithmetic, everything after it is a two line proof.

Layer 2: HOW

Block 1. Cue. The domain $x \in [0, 1)$ appears before anything else, and the first index is $n = 1$. **Why natural.** Testing the smallest case is not a habit, it is a duty: $\lfloor 1 \cdot x \rfloor = 0$ is even for the entire domain, so one term of the series is unconditional. A term that is present for every x is a floor on the answer, and it also fixes the scale: the answer is between $1/2$ and 1. **Link to the next block.** Having one guaranteed term, you now want to know how much more is guaranteed, which means asking what the parity test can and cannot do.

Block 2. **Cue.** The weights are 2^{-n}, and the question asks for a greatest lower bound. **Why natural.** With ratio $1/2$ a term equals its own tail, so the comparison of two subset sums is decided at the first position where they differ. Minimising is therefore a scheduling problem: push each forced element as late as the constraints allow. This reframing is forced by the ratio, not chosen. **Link to the next block.** Scheduling needs constraints, so the next move is to find the constraint on S_x.

Block 3. **Cue.** $x < 1$ multiplying an integer counter n. **Why natural.** $\lfloor nx \rfloor$ advances by $(n+1)x - nx = x < 1$ per step, so it is a counter that moves by 0 or 1. Parity therefore alternates whenever the counter moves and repeats whenever it stalls, so a long run of one parity is a long stall, and a long stall is a statement that x is small. That is the definition-level reason: the floor of a slowly increasing sequence cannot repeat a parity three times without repeating a value. **Link to the next block.** Turn the stall into an inequality on x and see which x survive.

Block 4. **Cue.** A triple stall gives $2x < 1$. **Why natural.** Small x is exactly the regime where the early integers all have floor 0, which is even, so small x is the worst possible regime for someone trying to make f small. The case split is not a nuisance, it is the mechanism: the enemy cannot both starve the early terms and have a long gap. **Link to the next block.** With the small x branch dead, the remaining branch has a hard structural constraint you can sum.

Block 5. **Cue.** Every window of three consecutive integers meets S_x. **Why natural.** Disjoint blocks are the right partition because the constraint is stated on windows, and a lower bound on a sum of nonnegative terms may be computed block by block. Starting the blocks at 2 rather than at 1 is deliberate: it keeps the free term $1/2$ separate and aligns the blocks so that the worst case is $\{1, 4, 7, \dots\}$ rather than a weaker pattern. Charging each block its largest element is the worst case by construction. **Link to the next block.** The worst case pattern is now explicit, so the natural next question is whether it can be realised.

Block 6. **Cue.** $4/7 = 0.\overline{100}$ in binary, a period of three starting at position 1. **Why natural.** A repeating binary answer is a blueprint for the extremal set, and the extremal set is a blueprint for x: you need $\lfloor nx \rfloor$ even exactly when $n \equiv 1 \pmod 3$, that is, the counter must gain exactly 2 every three steps, so x must be just under $2/3$. Approaching from below rather than sitting at $2/3$ is forced, because at $x = 2/3$ the value $\lfloor 3kx \rfloor = 2k$ is even and the pattern breaks in the wrong direction. **Link to the next block.** Verify the three residue classes, bound the tail crudely, and let N grow.

Layer 3: WHY

Three truths carry this problem. The first is the self-dominating property of the ratio $1/2$: $2^{-n} = \sum_{m>n} 2^{-m}$. It converts a question about a sum into a question about the earliest admissible position, which is why the answer is a repeating binary fraction and why the extremal configuration is periodic rather than exotic. Whenever you see weights r^n with $r \le 1/2$, expect the extremal problem to be solved by a greedy or blockwise argument, never by calculus.

The second is that $n \mapsto \lfloor nx \rfloor$ with $0 \le x < 1$ is a counter with step 0 or 1. All the rigidity in the problem comes from that single fact. Runs of a fixed parity are stalls, stalls are upper bounds on x, and the interaction between "small x gives long stalls" and "small x gives even floors early" is the tension the problem is built on. In general the maximum stall length for $x \in (0, 1)$ is $\lceil 1/x \rceil$, so the enemy is choosing x to trade stall length against how quickly the counter reaches an odd value at all.

The third is the difference between an infimum and a minimum, which the wording flags for you. When the extremal object is periodic but the constraint is only satisfiable for finitely many

periods at a time, the bound is approached and not attained. Recognising this early stops you from trying to prove that some specific x is a minimiser, and tells you the second half of the proof will be a family x_N with a parameter, not a single point.

The discernment mechanism to train: when a sum runs over a set defined by an arithmetic condition, do not try to describe the set. Find the strongest simple combinatorial constraint the condition imposes (here, maximum gap length), then solve the resulting clean extremal problem, then check that the extremal configuration is achievable. Describe less, constrain more. The examiners nudged you toward exactly this by using base 2 (so that place value logic dominates), by starting the domain at 0 (so that $n = 1$ is free), and by choosing the interval $[0, 1)$ (so that the step is less than 1 and the counter is slow).

Revolving concepts

Geometric series with ratio $1/2$. The identity $\sum_{m>n} 2^{-m} = 2^{-n}$ says binary place values are exactly self-dominating, so subset sums of $\{2^{-n}\}$ are ordered lexicographically by the sets, with ties only at the dyadic rationals (the $0.1000\ldots = 0.0111\ldots$ ambiguity). This is why $4/7 = 0.\overline{100}$ has a unique representing set. See Book 1, field: Real analysis, topic: geometric series and binary expansions.

The floor function as a counter. For $x \in [0, 1)$, $\lfloor nx \rfloor$ counts how many multiples of 1 the ray nx has passed. Standard companions: $\lfloor y \rfloor + \lfloor z \rfloor \le \lfloor y + z \rfloor \le \lfloor y \rfloor + \lfloor z \rfloor + 1$; $\lfloor \lfloor y \rfloor / d \rfloor = \lfloor y/d \rfloor$ for a positive integer d; and Hermite's identity $\sum_{j=0}^{d-1} \lfloor y + j/d \rfloor = \lfloor dy \rfloor$. See Book 1, field: Number theory, topic: floor function identities.

Beatty and Sturmian structure. The sequence $\lfloor nx \rfloor$ is a Beatty sequence; its difference word $\lfloor (n+1)x \rfloor - \lfloor nx \rfloor$ is a Sturmian word over $\{0, 1\}$ with density x. The three distance theorem controls the gaps between the fractional parts $\{nx\}$. You do not need this here, but it is the correct home for any harder problem about $\lfloor nx \rfloor$. See Book 1, field: Sequences and recurrences, topic: Beatty sequences.

The recursion, generalised. The parity word $e_n = \lfloor nx \rfloor \bmod 2$ satisfies an exact recursion whenever x is rational. Write $x = p/q$ in lowest terms; then $\lfloor (n+q)x \rfloor = \lfloor nx + p \rfloor = \lfloor nx \rfloor + p$, so

$$e_{n+q} \equiv e_n + p \pmod 2.$$

Unrolling this is the general solution: $e_{n+jq} \equiv e_n + jp$, so the word is periodic with period q when p is even and period $2q$ when p is odd. Every question about parities of $\lfloor nx \rfloor$ at rational x reduces to computing one period. The same unrolling handles $\lfloor nx \rfloor$ modulo any m: the word is periodic with period $q \cdot m / \gcd(p, m)$. Applied here with x near $2/3$, the period is 3 and the pattern $(0, 1, 1)$ is exactly the block structure the proof used.

Infimum versus minimum, and the extremal series. The general block bound the proof used is worth storing in full generality: if S contains 1 and meets every window of g consecutive integers, then for $0 < r < 1$,

$$\sum_{n \in S} r^n \;\ge\; r + \frac{r^{g+1}}{1 - r^g},$$

with the bound approached by $S = \{1,\ 1+g,\ 1+2g, \ldots\}$. For $r = 1/2$, $g = 3$ this is $1/2 + 1/14 = 4/7$; for $r = 1/3$, $g = 3$ it is $1/3 + 1/78 = 9/26$. See Book 1, field: Inequalities, topic: extremal subset sums of geometric series.

Circuit Bank

- **WHEN** a sum runs over a set defined by a parity or divisibility test on $\lfloor nx \rfloor$ **DO** ask first how long a run of consecutive integers can fail the test **BECAUSE** for $x < 1$ the counter $\lfloor nx \rfloor$ moves by 0 or 1, so a long run of one parity is a long stall and forces x to be small, which is a usable inequality

- **WHEN** the weights are r^n with $r \leq 1/2$ and you must minimise a subset sum **DO** schedule the forced elements as late as the constraint permits, then sum the periodic worst case as a geometric series **BECAUSE** each term dominates its own tail, so the comparison is decided at the first differing position and greedy scheduling is optimal
- **WHEN** the question says "largest L with $f \geq L$ for all x" instead of "the minimum of f" **DO** prove a universal bound and separately construct a family approaching it, and expect no minimiser **BECAUSE** that phrasing is the definition of an infimum, and the two halves need different tools
- **WHEN** the answer is a repeating binary or base r fraction **DO** read the period as the pattern of admissible indices and reverse engineer the parameter that produces it **BECAUSE** a repeating expansion is the fingerprint of a periodic extremal configuration, which is a blueprint for the construction

Backtesting

1. First useful cue: $x \in [0, 1)$ with the index starting at $n = 1$, giving $\lfloor x \rfloor = 0$ and the unconditional term $1/2$; immediately after it, the step bound $\lfloor (n+1)x \rfloor - \lfloor nx \rfloor \in \{0, 1\}$.
2. Method the expression suggested: not evaluation of f, but a gap bound on S_x followed by a blockwise geometric sum, then an explicit family x_N realising the worst pattern.
3. Where you would hesitate, and the thought to reinforce: at the case split $x < 1/2$ against $x \geq 1/2$. The thought to reinforce is that a case split forced by the mechanism is not untidiness, it is the mechanism; the enemy cannot have both a long gap and starved early terms, and that is precisely why the answer exists.
4. The trap the question sets: hunting for a minimiser. The infimum is not attained, so any argument that assumes a minimising x exists will fail or, worse, will produce a plausible wrong constant such as $5/7$, the value at $x = 2/3$ itself.
5. What makes you recognise it faster next time: the pairing of base 2 weights with a floor parity test. Base 2 says place value logic; a floor of nx with $x < 1$ says slow counter; together they say gap analysis.
6. The reusable decision rule: when summing over an arithmetically defined set, bound the maximum gap, partition into blocks of that length, charge each block its worst element, then test achievability of the resulting periodic pattern.

Mirror drills

1. Replace 2^n by 3^n: find the largest L with $\sum_{n \in S_x} 3^{-n} \geq L$ for all $x \in [0, 1)$. *Answer:* $9/26$, by the same two lemmas and the general bound $r + r^{g+1}/(1 - r^g)$ with $r = 1/3$, $g = 3$; the same family $x = 2/3 - \delta$ shows it is sharp.
2. Let S be any set of positive integers meeting every block of three consecutive integers. Show $\sum_{n \in S} 2^{-n} \geq 1/7$ and that $1/7$ is best possible. *Answer:* charge each block $\{3k+1, 3k+2, 3k+3\}$ its largest element to get $\sum_{k \geq 0} 2^{-(3k+3)} = 1/7$; the set $\{3, 6, 9, \dots\}$ attains it.
3. Show that $f(x) > 4/7$ strictly for every $x \in [0, 1)$. *Answer:* equality forces $S_x = \{1, 4, 7, \dots\}$ by uniqueness of the binary expansion of $4/7$, which by the step lemma forces $\lfloor (3k+1)x \rfloor = 2k$ and $\lfloor (3k+3)x \rfloor = 2k+1$ for all k, giving $x \geq 2/3$ and $x < 2/3$ at once.

11.5 A5. Parity of the coprime count below a quarter

Let q be an odd positive integer, and let N_q denote the number of integers a such that $0 < a < q/4$ and $\gcd(a, q) = 1$. Show that N_q is odd if and only if q is of the form p^k with k a positive integer and p a prime congruent to 5 or 7 modulo 8.

Read it out loud

Say the conclusion first, because the conclusion is the cue. "A prime congruent to 5 or 7 modulo 8" is not a condition anybody invents for fun. Conditions on a prime modulo 8 come from exactly one place in mathematics: the supplementary laws of quadratic reciprocity. You know that $p \equiv \pm 1 \pmod 8$ is the criterion for 2 to be a quadratic residue and that $p \equiv 1 \pmod 4$ is the criterion for -1; multiply the two characters together and the classes $1, 3$ split from $5, 7$. So before touching the counting, you already know the target: N_q is odd exactly when -2 is a quadratic nonresidue modulo p. The problem is a quadratic residue problem wearing a counting costume.

Now say the hypothesis out loud. You are counting the integers coprime to q in the interval $(0, q/4)$, and you want only the parity of that count. Coprime residues, a fixed fraction of the modulus, and a parity: that is the signature of Gauss's lemma, which is the statement that multiplying every element of the first half of the residues by a fixed integer and counting how many wrap past the midpoint gives you a quadratic character as a sign. The link between the two costumes is one line of trivial algebra: $a < q/4$ if and only if $2a < q/2$. Multiplication by 2 carries the quarter interval onto the half interval, so N_q is precisely the count of a in the first half whose double does not wrap.

The fields wired in are quadratic residues (Legendre symbol, Euler's criterion, the two supplementary laws), elementary group theory modulo q (Euler's theorem, the Chinese remainder theorem, square roots of unity in $(\mathbb{Z}/p^k)^\times$), and the totient function. The counting flavour is a decoy; a Mobius inversion route exists and works, but it hides the reason the answer looks the way it does.

Within thirty seconds you should have written $a < q/4 \iff 2a < q/2$, the definition $A = \{a : 1 \le a \le (q-1)/2,\ \gcd(a, q) = 1\}$ with $|A| = \varphi(q)/2$, and the note that $q/4$ is never an integer because q is odd, so there are no boundary cases to worry about anywhere.

Approaches, ranked worst to best

1. **Tabulate and match.** *Cue:* a clean numerical claim about all odd q. *Circuit:* compute N_q for $q \le 100$ and check the classification. Useful for confidence and for catching a misread (for instance that $q = 1$ gives $N_q = 0$, which must land on the even side). It proves nothing, and a "verify the pattern" write-up scores zero.

2. **Direct evaluation of N_q by a closed formula.** *Cue:* an interval count with a coprimality condition. *Circuit:* inclusion and exclusion over the prime divisors of q. You can write $N_q = \sum_{d \mid q} \mu(d) \lfloor q/(4d) \rfloor$ and try to evaluate it. As an exact formula it is unusable; the floors do not simplify.

3. **Mobius inversion reduced modulo 2.** *Cue:* only the parity is wanted, so all coefficients live in $\mathbb{F}_2$. *Circuit:* squarefree divisors survive, $\mu(d)^2 = 1$, and $\lfloor (q/d)/4 \rfloor \bmod 2$ depends only on $q/d \bmod 8$. This is the published first solution and it is entirely correct: reduce the divisor sum modulo 2, note that $\lfloor m/4 \rfloor$ is odd exactly when $m \equiv 5, 7 \pmod 8$, then pair up the squarefree divisors to show the count of bad divisors is even unless q is a prime power. It ranks here because the pairing argument needs three separate cases and, more importantly, because it never explains why 5 and 7 modulo 8 appear. You finish with a proof and no understanding.

4. **Gauss's lemma with multiplier 2, generalised to composite modulus.** *Cue:* $q/4$ with coprimality and a parity, plus a conclusion stated modulo 8. *Circuit:* doubling the first half of the residues and counting wrap-arounds is a signed permutation, and the sign is a quadratic character. Prove the congruence $(-1)^{N_q} \equiv (-2)^{\varphi(q)/2} \pmod q$, then read off both directions: for q with two or more prime factors the right side collapses to 1 by the Chinese remainder theorem, and for $q = p^k$ it is ± 1 and Euler's criterion identifies it as the Legendre symbol of -2. Shortest, and it explains the answer: the condition $p \equiv 5, 7 \pmod 8$ is the condition that -2 is a nonresidue. This is the ideal route.

The ideal solution

Throughout q is odd. Handle $q = 1$ at once: there is no integer a with $0 < a < 1/4$, so $N_1 = 0$ is even, and 1 is not of the stated form. Assume $q \geq 3$ from here on, and set

$$A = \left\{ a \in \mathbb{Z} : 1 \leq a \leq \tfrac{q-1}{2},\ \gcd(a, q) = 1 \right\}.$$

Since the integers in $\{1, \dots, q-1\}$ coprime to q come in pairs $\{a, q-a\}$ with exactly one member in each half, $|A| = \varphi(q)/2$. Because q is odd, $q/4$ is not an integer, so

$$N_q = \#\{a \in A : a < q/4\} = \#\{a \in A : 2a < q/2\}.$$

Lemma 11.5.1. *Let $n = \#\{a \in A : 2a > q/2\}$. Then $2^{\varphi(q)/2} \equiv (-1)^n \pmod q$ and $N_q = \varphi(q)/2 - n$.*

Proof. For $a \in A$ we have $2 \leq 2a \leq q-1$, so $2a$ is congruent modulo q to exactly one element $r(a)$ of $\{-(q-1)/2, \dots, -1, 1, \dots, (q-1)/2\}$, namely $r(a) = 2a$ if $2a < q/2$ and $r(a) = 2a - q$ if $2a > q/2$ (equality is impossible since q is odd). Thus $r(a) < 0$ for exactly n values of a.

The map $a \mapsto |r(a)|$ sends A to A: the value lies in $\{1, \dots, (q-1)/2\}$ and is coprime to q because $2a$ and $q - 2a$ are. It is injective: if $|r(a)| = |r(b)|$ then $2a \equiv \pm 2b \pmod q$, so $a \equiv \pm b \pmod q$ since 2 is invertible; the sign $-$ is impossible because $0 < a + b < q$, so $a = b$. A injection from the finite set A to itself is a bijection.

Multiplying over A and using $2a \equiv r(a)$,

$$2^{|A|} \prod_{a \in A} a \ \equiv\ \prod_{a \in A} r(a) \ =\ (-1)^n \prod_{a \in A} |r(a)| \ =\ (-1)^n \prod_{a \in A} a \pmod q.$$

The product $\prod_{a \in A} a$ is coprime to q, hence invertible, and cancelling it gives $2^{\varphi(q)/2} \equiv (-1)^n$. Finally A is split by the condition $2a < q/2$ into the N_q elements counted by the problem and the n remaining ones, so $N_q = |A| - n = \varphi(q)/2 - n$. □

Corollary 11.5.2. *For every odd $q \geq 3$, $(-1)^{N_q} \equiv (-2)^{\varphi(q)/2} \pmod q$.*

Proof. $(-1)^{N_q} = (-1)^{\varphi(q)/2 - n} = (-1)^{\varphi(q)/2}(-1)^n \equiv (-1)^{\varphi(q)/2} 2^{\varphi(q)/2} = (-2)^{\varphi(q)/2} \pmod q$. □

Since $q \geq 3$, the residues $+1$ and -1 are distinct modulo q, so the corollary determines the parity of N_q completely: N_q is odd if and only if $(-2)^{\varphi(q)/2} \equiv -1 \pmod q$.

Proposition 11.5.3. *If q has at least two distinct prime factors, then N_q is even.*

Proof. Write $q = \prod_{i=1}^{r} p_i^{k_i}$ with $r \geq 2$. Fix i. Then

$$\frac{\varphi(q)}{\varphi(p_i^{k_i})} = \prod_{j \neq i} \varphi(p_j^{k_j})$$

is even, because each p_j is odd and so each $\varphi(p_j^{k_j}) = p_j^{k_j - 1}(p_j - 1)$ is even, and there is at least one factor in the product. Hence $\varphi(p_i^{k_i})$ divides $\varphi(q)/2$. Since $\gcd(-2, q) = 1$, Euler's theorem modulo $p_i^{k_i}$ gives $(-2)^{\varphi(q)/2} \equiv 1 \pmod{p_i^{k_i}}$. This holds for every i, so by the Chinese remainder theorem $(-2)^{\varphi(q)/2} \equiv 1 \pmod q$, and N_q is even. □

Proposition 11.5.4. *If $q = p^k$ with p an odd prime and $k \geq 1$, then N_q is odd if and only if $\left(\frac{-2}{p}\right) = -1$, that is, if and only if $p \equiv 5$ or $7 \pmod 8$.*

Proof. Put $u = (-2)^{\varphi(q)/2}$. By Euler's theorem $u^2 = (-2)^{\varphi(q)} \equiv 1 \pmod{p^k}$, so $p^k \mid (u-1)(u+1)$. As p is odd, p cannot divide both $u-1$ and $u+1$ (their difference is 2), so p^k divides one of them: $u \equiv \pm 1 \pmod{p^k}$.

To decide the sign, reduce modulo p. With $\varphi(q)/2 = p^{k-1}(p-1)/2$,

$$u \equiv \left((-2)^{(p-1)/2}\right)^{p^{k-1}} \equiv \left(\frac{-2}{p}\right)^{p^{k-1}} = \left(\frac{-2}{p}\right) \pmod p,$$

by Euler's criterion and because p^{k-1} is odd. Since $+1 \not\equiv -1 \pmod p$, the sign of u modulo p^k is exactly $\left(\frac{-2}{p}\right)$.

Finally evaluate the character by the two supplementary laws, $\left(\frac{-1}{p}\right) = (-1)^{(p-1)/2}$ and $\left(\frac{2}{p}\right) = (-1)^{(p^2-1)/8}$:

$p \bmod 8$	1	3	5	7
$\left(\frac{-1}{p}\right)$	$+1$	-1	$+1$	-1
$\left(\frac{2}{p}\right)$	$+1$	-1	-1	$+1$
$\left(\frac{-2}{p}\right)$	$+1$	$+1$	-1	-1

So $u \equiv -1$, and hence N_q is odd, exactly when $p \equiv 5$ or $7 \pmod 8$. □

Combining the three cases $q = 1$, q with at least two prime factors, and $q = p^k$: the count N_q is odd if and only if $q = p^k$ with $k \geq 1$ and p a prime congruent to 5 or 7 modulo 8. ■

Layer 1: WHAT

Block 1. Read $p \equiv 5, 7 \pmod 8$ as $\left(\frac{-2}{p}\right) = -1$. The target is a quadratic character, so the proof must end in Euler's criterion.

Block 2. Read $0 < a < q/4$ with $\gcd(a, q) = 1$ and a parity as Gauss's lemma with multiplier 2, using $a < q/4 \iff 2a < q/2$.

Block 3. Set up A, the half-system of coprime residues, note $|A| = \varphi(q)/2$, and let n count the doublings that wrap past the midpoint.

Block 4. Run the Gauss product: $a \mapsto |r(a)|$ permutes A, so multiplying $2a \equiv r(a)$ over A and cancelling gives $2^{\varphi(q)/2} \equiv (-1)^n$.

Block 5. Convert n into N_q using $N_q + n = |A|$, and absorb the resulting sign $(-1)^{\varphi(q)/2}$ into the base to get $(-1)^{N_q} \equiv (-2)^{\varphi(q)/2}$.

Block 6. Composite case: for each prime power factor the complementary totient factor is even, so $\varphi(p_i^{k_i}) \mid \varphi(q)/2$ and the power is 1 locally; the Chinese remainder theorem makes it 1 globally, so N_q is even.

Block 7. Prime power case: the power squares to 1, and modulo p^k the only square roots of 1 are ± 1; reduce modulo p and apply Euler's criterion; finish with the supplementary laws table.

Juxtaposition. The nominal route is to count directly: inclusion and exclusion over the primes dividing q, reduce the divisor sum modulo 2, evaluate $\lfloor m/4 \rfloor$ mod 2 by residue classes modulo 8, then pair up squarefree divisors. It works, it takes three cases of pairing, and it produces the classes $5, 7$ as an unexplained arithmetic coincidence. The bifurcation point is the line where you meet $q/4$: the nominal route counts inside the interval, the ideal route multiplies the interval by 2. Everything else follows from that single decision.

Layer 2: HOW

Block 1. **Cue.** A congruence condition modulo 8 imposed on a prime, in the conclusion of the problem. **Why natural.** Modulus 8 for primes has one standard source: $\left(\frac{2}{p}\right)$ depends on p modulo 8 and $\left(\frac{-1}{p}\right)$ on p modulo 4, so any character built from ± 1 and ± 2 is a function of p modulo 8. The classes $\{1,3\}$ against $\{5,7\}$ are the split of $\left(\frac{-2}{p}\right)$, which is a two second table lookup. Reading the answer first is legitimate and fast: the conclusion tells you which theorem the problem is about. **Link to the next block.** Knowing the destination is a quadratic character, look for the standard machine that turns a count into a character.

Block 2. **Cue.** Coprime residues, an interval that is a simple fraction of the modulus, and only the parity of the count. **Why natural.** That machine is Gauss's lemma. Its content is that doubling a half system of residues permutes the half system up to signs, and the sign of the permutation is $\left(\frac{2}{p}\right)$; the number of sign flips is a count of residues in an interval. Here the interval is $(0, q/4)$, and $a < q/4$ is the same statement as $2a < q/2$, so the problem is handing you the non-flipping count for the multiplier 2. The algebra is trivial; recognising which count it is, is the whole move. **Link to the next block.** You now need the lemma for general odd q, not just for primes, so check whether the proof used primality.

Block 3. **Cue.** The problem says only that q is odd, and Gauss's lemma is usually stated for a prime. **Why natural.** Read the standard proof and see what it actually uses: it needs 2 invertible, it needs the pairing $\{a, q-a\}$, and it needs to cancel a product of units. All three survive for any odd q, because the elements coprime to q form a group. This is a habit worth naming: when you want a theorem in more generality, do not look for a stronger theorem, re-read the proof of the one you have and see which hypotheses were load-bearing. **Link to the next block.** Write the lemma for general q and be careful about one thing only: the conclusion is a congruence, not an identity of symbols.

Block 4. **Cue.** A product over a set that a map permutes. **Why natural.** Cancelling a product of units is the standard engine of Euler's criterion, Wilson's theorem and Gauss's lemma alike. It works because a bijection of a finite set does not change a product, so any discrepancy between the two ways of writing the product is forced into the signs. **Link to the next block.** The lemma gives you n, but the problem asks about N_q, so convert.

Block 5. **Cue.** A is split into exactly two pieces by the condition $2a < q/2$. **Why natural.** $N_q + n = |A| = \varphi(q)/2$ is an identity, not an estimate, so the conversion is exact and costs one line. Absorbing $(-1)^{\varphi(q)/2}$ into the base to make $(-2)^{\varphi(q)/2}$ is not cosmetic: it turns two separate characters into one, and -2 is precisely the number whose residue class splits $\{1,3\}$ from $\{5,7\}$ modulo 8, which you predicted in Block 1. Seeing your prediction appear is the confirmation that the route is right. **Link to the next block.** Now the whole problem is the single question: when is $(-2)^{\varphi(q)/2} \equiv -1 \pmod{q}$?

Block 6. **Cue.** The conclusion singles out prime powers, so something must fail for composite q. **Why natural.** A power of a unit is -1 only if the unit has even order and the exponent is a suitable odd multiple of half that order. Modulo a product of coprime factors, the Chinese remainder theorem forces the answer to be -1 in every component simultaneously, which is hard; and with two or more factors the exponent $\varphi(q)/2$ is still a multiple of each local group order, because the complementary totient factor supplies the missing 2. That is the exact reason prime powers are special: only there is $\varphi(q)/2$ half of the local order rather than a whole multiple of it. **Link to the**

next block. The remaining case is $q = p^k$, where the group is cyclic and ± 1 are the only square roots of unity.

Block 7. Cue. $u^2 \equiv 1$ with $q = p^k$ odd. **Why natural.** You do not need cyclicity of $(\mathbb{Z}/p^k)^\times$ for this; $p^k \mid (u-1)(u+1)$ and $\gcd(u-1, u+1) \mid 2$ with p odd force p^k to divide one factor. Preferring the elementary argument is not pedantry, it is insurance: you can write it correctly under pressure. Then reducing modulo p identifies the sign, because p^{k-1} is odd so it does not disturb a ± 1. **Link to the next block.** Finish with Euler's criterion and the supplementary laws.

Layer 3: WHY

The mathematical truth underneath is that N_q was never a counting problem. Doubling is the map $a \mapsto 2a$ on the coprime residues; restricted to a half system it is a permutation up to signs, and the number of sign changes is what Gauss's lemma converts into a multiplicative character. The count of residues in $(0, q/4)$ is exactly the number of doublings that do not wrap around, so its parity is a signed determinant of a permutation in disguise. Once you see that, the appearance of 5 and 7 modulo 8 is not a coincidence to be verified but a consequence to be predicted.

The second truth is a warning worth installing permanently. The natural guess is that the parity of N_q is given by the Jacobi symbol $\left(\frac{-2}{q}\right)$. That is false. Gauss's lemma generalises to composite modulus as a congruence, $2^{\varphi(q)/2} \equiv (-1)^n \pmod q$, but not as an identity of symbols: for $q = 21$ the Jacobi symbol $\left(\frac{2}{21}\right) = \left(\frac{2}{3}\right)\left(\frac{2}{7}\right) = -1$, while the sign count gives $(-1)^n = +1$. The Jacobi symbol is multiplicative by construction and forgets whether a number is actually a square; the congruence remembers. Keeping the statement as a congruence is what makes the composite case collapse to $+1$, which is the entire content of the "only if" direction.

The third truth is the structural reason prime powers are the exceptional case. For q with at least two prime factors, $\varphi(q)/2$ is still divisible by every local group order $\varphi(p_i^{k_i})$, because each of those is even and there are at least two of them, so half of the product is still a multiple of each factor. In group language, the exponent of $(\mathbb{Z}/q)^\times$ divides $\varphi(q)/2$ as soon as the group is not cyclic. So the value $(-2)^{\varphi(q)/2}$ has no room to be anything but 1. The information you want lives in the two element group $\{\pm 1\}$ of square roots of unity, and only a cyclic group has exactly two of them.

The discernment mechanism to train: read the conclusion for the theorem, then read the hypothesis for the machine that produces that kind of conclusion. Modulus 8 on a prime means a quadratic character. A parity of a count of coprime residues in an interval means Gauss's lemma or its lattice point cousin (Eisenstein's proof of reciprocity counts lattice points under a line the same way). When both appear in one problem, the interval and the multiplier must match, and here they do after multiplying by 2. The examiners nudged you by choosing 4 as the denominator rather than 3 or 6, and by asking for parity rather than for the count.

Revolving concepts

Euler's totient and its arithmetic. φ is multiplicative, $\varphi(p^k) = p^{k-1}(p-1)$, and $\varphi(m)$ is even for every $m \geq 3$. The coprime residues split into pairs $\{a, q-a\}$, so exactly $\varphi(q)/2$ of them lie in the lower half. See Book 1, field: Number theory, topic: totient function.

Euler's theorem and Euler's criterion. For $\gcd(b, q) = 1$, $b^{\varphi(q)} \equiv 1 \pmod q$; for an odd prime p and $p \nmid b$, $b^{(p-1)/2} \equiv \left(\frac{b}{p}\right) \pmod p$. The second is the bridge from an exponentiation to a symbol, and it is the last step of the ideal solution. See Book 1, field: Number theory, topic: quadratic residues.

The supplementary laws. $\left(\frac{-1}{p}\right) = (-1)^{(p-1)/2}$ and $\left(\frac{2}{p}\right) = (-1)^{(p^2-1)/8}$, giving $\left(\frac{-2}{p}\right) = +1$ for $p \equiv 1, 3 \pmod 8$ and -1 for $p \equiv 5, 7 \pmod 8$. Memorise the combined table, not just the two separate laws, because -2 and ± 2 appear constantly. See Book 1, field: Number theory, topic: quadratic reciprocity.

Gauss's lemma, stated in the generality you need. Let q be odd, b coprime to q, and A a half system of coprime residues. If n is the number of $a \in A$ whose product ba reduces into the negative half, then $b^{\varphi(q)/2} \equiv (-1)^n \pmod q$. For q prime this is $\left(\frac{b}{p}\right) = (-1)^n$; for composite q it is a congruence only. See Book 1, field: Number theory, topic: Gauss's lemma.

Square roots of unity. In $\mathbb{Z}/p^k$ with p odd, $u^2 \equiv 1$ forces $u \equiv \pm 1$, because p divides at most one of $u-1$ and $u+1$. In $\mathbb{Z}/q$ with r distinct odd prime factors there are 2^r square roots of unity, which is exactly why the sign information is destroyed for composite q. See Book 1, field: Abstract algebra, topic: units modulo a prime power.

The counting recursion, generalised. The alternative route rests on a genuine recursion, Mobius inversion for counting coprime elements. For any $y > 0$,

$$\#\{a \le y : \gcd(a,q) = 1\} = \sum_{d \mid q} \mu(d) \left\lfloor \frac{y}{d} \right\rfloor,$$

which with $y = q/4$ and $\lfloor \lfloor q/4 \rfloor / d \rfloor = \lfloor q/(4d) \rfloor$ gives $N_q = \sum_{d \mid q} \mu(d) \lfloor (q/d)/4 \rfloor$. The general form is: any count with a coprimality side condition is the Mobius transform of the count without it, and the inversion is solved by summing over squarefree divisors only, since μ vanishes elsewhere. Reduced modulo 2 this becomes $N_q \equiv \sum_{d \mid q \text{ squarefree}} \lfloor (q/d)/4 \rfloor$, and $\lfloor m/4 \rfloor$ is odd exactly for $m \equiv 5, 7 \pmod 8$. The same inversion computes counts of coprime integers in any interval and is the standard first move for such problems. See Book 1, field: Number theory, topic: Mobius inversion.

Circuit Bank

- **WHEN** a condition on a prime is stated modulo 8 (or modulo 4) **DO** translate it into $\left(\frac{2}{p}\right)$, $\left(\frac{-1}{p}\right)$ or $\left(\frac{-2}{p}\right)$ before doing anything else **BECAUSE** the supplementary laws are essentially the only standard reason those moduli attach to primes, so the conclusion names the theorem you must reach
- **WHEN** you need the parity of the number of residues coprime to q inside an interval $(0, q/m)$ **DO** multiply the interval by m to land on a half system and run Gauss's lemma with multiplier m **BECAUSE** Gauss's lemma is exactly a wrap-around count, and the parity of a count is the sign of a signed permutation
- **WHEN** a standard theorem is stated for a prime but you need it for general q **DO** re-read its proof and check which steps used primality, rather than hunting for a stronger theorem **BECAUSE** most residue arguments use only that the coprime residues form a group, so they survive verbatim; but record whether the conclusion survives as a symbol identity or only as a congruence
- **WHEN** a statement singles out prime powers among all moduli **DO** look for the step where cyclicity or the count of square roots of unity is used **BECAUSE** only for $q = p^k$ does $(\mathbb{Z}/q)^\times$ have exactly two square roots of unity, so only there can a half power carry a sign
- **WHEN** you derive $(-1)^N \equiv u \pmod q$ with $u = \pm 1$ and $q \ge 3$ **DO** conclude the parity of N immediately **BECAUSE** $+1$ and -1 are distinct modulo any $q \ge 3$, so a congruence between signs is an equality of signs

Backtesting

1. First useful cue: the classes 5 and 7 modulo 8 in the conclusion, which are the nonresidue classes of -2; the confirming cue is $0 < a < q/4$ together with coprimality and parity, which is the wrap-around count in Gauss's lemma for multiplier 2.

2. Method the expression suggested: the congruence $(-1)^{N_q} \equiv (-2)^{\varphi(q)/2} \pmod{q}$, then a split into $q = 1$, q with two or more prime factors (Chinese remainder theorem), and $q = p^k$ (Euler's criterion).
3. Where you would hesitate, and the thought to reinforce: at the generalisation of Gauss's lemma to composite q. Reinforce that the proof only ever uses that the coprime residues form a group under multiplication and that 2 is invertible, and that the price of generality is that the conclusion is a congruence, not a Jacobi symbol identity.
4. The trap the question sets: writing $(-1)^{N_q} = \left(\frac{-2}{q}\right)$ as a Jacobi symbol. That is false for composite q ($q = 21$ is the smallest counterexample), and it would make the composite case appear to give odd values.
5. What makes you recognise it faster next time: the pairing of a quarter interval with the multiplier 2. Quarter and double, third and triple, sixth and sextuple: an interval of length q/m with a parity question is Gauss's lemma with multiplier m.
6. The reusable decision rule: to find the parity of a count of coprime residues in a sub-interval, scale the interval up to a half system, count the wrap-arounds, and read the sign as a power of the multiplier; then handle composite moduli by the Chinese remainder theorem and prime powers by Euler's criterion.

Mirror drills

1. Use Gauss's lemma with multiplier 2 for a prime p to prove the second supplementary law. *Answer:* the number of $a \leq (p-1)/2$ with $2a > p/2$ is $(p-1)/2 - \lfloor p/4 \rfloor$; evaluating this modulo 2 over the four classes of p modulo 8 gives $(-1)^{(p^2-1)/8}$.
2. Show $N_q = \sum_{d \mid q} \mu(d) \lfloor (q/d)/4 \rfloor$ and use it to compute N_{45}. *Answer:* the divisors with $\mu \neq 0$ are $1, 3, 5, 15$, giving $11 - 3 - 2 + 0 = 6$, which is even, consistent with 45 not being a prime power.
3. Compute N_{243} and N_{125} and check them against the classification. *Answer:* $243 = 3^5$ with $3 \equiv 3 \pmod 8$ gives $60 - 20 = 40$, even; $125 = 5^3$ with $5 \equiv 5 \pmod 8$ gives $31 - 6 = 25$, odd.

11.6 A6. A determinant identity for intertwined matrices

Let n be a positive integer. Suppose that A, B, and M are $n \times n$ matrices with real entries such that $AM = MB$, and such that A and B have the same characteristic polynomial. Prove that $\det(A - MX) = \det(B - XM)$ for every $n \times n$ matrix X with real entries.

Read it out loud

Three hypotheses, one conclusion, and every word is load-bearing. The relation $AM = MB$ says that M intertwines A and B: as a linear map, M carries the action of B on the source to the action of A on the target. If M were invertible this would say $A = MBM^{-1}$, that is, A and B are similar. The extra hypothesis, that A and B have the same characteristic polynomial, would then be free, since similar matrices have the same characteristic polynomial. So the hypothesis is telling you loudly that M is not assumed invertible, and that the characteristic polynomial hypothesis exists to repair exactly the damage that the kernel of M does.

Test the invertible case in ten seconds, because it is one line and it calibrates everything: if M is invertible then $A = MBM^{-1}$ and

$$A - MX = MBM^{-1} - MX = M(B - XM)M^{-1},$$

so the two matrices are similar and their determinants agree. That computation is the skeleton of the whole problem. It also tells you what the general statement should be: not merely that the determinants agree, but that $A - MX$ and $B - XM$ have the same characteristic polynomial, since in the invertible case they are similar.

Now read the shape of the conclusion. On the left the product is MX, on the right it is XM. The two sides differ by the order of a product and nothing else. There is exactly one elementary fact in linear algebra that trades the order of a product for nothing, and it is $\det(I - UV) = \det(I - VU)$, equivalently that UV and VU have the same characteristic polynomial. So the target is clear: manipulate $\det(A - MX)$ until it contains $\det(I - UV)$ for some U and V, swap, and manipulate back.

The fields wired in are determinants and characteristic polynomials, the rank normal form, and the polynomial identity principle (an identity of polynomials that holds off a finite set of parameter values holds everywhere). The last of these is the piece most likely to be missing from an A-level trained toolkit, and it is the piece that makes the proof short.

Approaches, ranked worst to best

1. **Expand both determinants.** *Cue:* a determinant identity to be proved. *Circuit:* Leibniz expansion or cofactor induction. Both sides are sums of $n!$ signed products in the entries of five matrices. There is no route from here to a proof, and no partial credit lives at the end of it.

2. **Perturb M to make it invertible.** *Cue:* the invertible case is one line, so approximate. *Circuit:* density of GL_n in M_n plus continuity of det. This is the first idea everyone has and it fails, for a reason worth learning permanently. The set of triples with $AM = MB$ is not open: replacing M by $M + \varepsilon I$ destroys the hypothesis unless $A = B$, and there may be no invertible M at all satisfying it (take A and B with disjoint spectra, where the only intertwiner is $M = 0$). Density arguments work on a variable that is free, never on one that is constrained. Ranks above brute force only because it identifies the correct skeleton.

3. **Compare traces of all powers.** *Cue:* characteristic polynomial equality is equivalent to equality of power sums in characteristic zero. *Circuit:* Newton's identities plus cyclic invariance of the trace. Show $\mathrm{Tr}((A - MX)^k) = \mathrm{Tr}((B - XM)^k)$ for all k by expanding, using $\mathrm{Tr}(PQ) = \mathrm{Tr}(QP)$ to rotate each word, and using $AM = MB$ to commute every M past every A. It is correct

and it is honest work: each word $A^{i_1}MXA^{i_2}\cdots$ turns into the matching word in B and XM. The costs are that it needs characteristic zero (Newton's identities divide by k) and that the bookkeeping of words is long under time pressure.

4. **Rank normal form of M.** *Cue:* M is the only degenerate object, so normalise it. *Circuit:* choose U, V invertible with $U^{-1}MV$ block diagonal $\operatorname{diag}(I_r, 0)$. Write everything in the two block decomposition. The relation $AM = MB$ forces $A_{11} = B_{11}$, $A_{21} = 0$ and $B_{12} = 0$, so both A' and B' are block triangular; the characteristic polynomial hypothesis then forces A_{22} and B_{22} to have the same characteristic polynomial, and both determinants evaluate to $\det(A_{11} - X_{11})\det(A_{22})$. This is the most transparent proof: it shows precisely where each hypothesis is spent, namely that the invertible part of M is handled by similarity and the kernel part is handled by the characteristic polynomial. It costs more ink than the winner and needs care with which matrix is conjugated by U and which by V.

5. **Sylvester's identity plus a shift by tI.** *Cue:* MX against XM, and a determinant that wants an inverse you are not given. *Circuit:* $\det(I - UV) = \det(I - VU)$, and equality of polynomials in t off a finite set. Replace A, B by $A - tI, B - tI$, which preserves both hypotheses, use $M = (A - tI)M(B - tI)^{-1}$ for the finitely many t where $B - tI$ is invertible, factor, swap with Sylvester, factor back, and finish by comparing two polynomials of degree n in t that agree at infinitely many points. Six lines, no case analysis, and it proves the stronger characteristic polynomial statement for free. This is the ideal route.

The ideal solution

Lemma 11.6.1. *For any $n \times n$ matrices U and V over a commutative ring,* $\det(I - UV) = \det(I - VU)$.

Proof. Work with the $2n \times 2n$ block matrix $N = \begin{pmatrix} I & U \\ V & I \end{pmatrix}$ and compute two unitriangular reductions:

$$\begin{pmatrix} I & 0 \\ -V & I \end{pmatrix} N = \begin{pmatrix} I & U \\ 0 & I - VU \end{pmatrix}, \qquad \begin{pmatrix} I & -U \\ 0 & I \end{pmatrix} N = \begin{pmatrix} I - UV & 0 \\ V & I \end{pmatrix}.$$

Both left factors have determinant 1, and the determinant of a block triangular matrix with square diagonal blocks is the product of the determinants of those blocks. Hence $\det N = \det(I - VU)$ and $\det N = \det(I - UV)$. □

Theorem 11.6.2. *Let A, B, M be real $n \times n$ matrices with $AM = MB$ and* $\det(A - tI) = \det(B - tI)$ *for all t. Then for every real $n \times n$ matrix X and every real t,*

$$\det\big((A - tI) - MX\big) = \det\big((B - tI) - XM\big).$$

In particular, taking $t = 0$, $\det(A - MX) = \det(B - XM)$, *and $A - MX$ and $B - XM$ have the same characteristic polynomial.*

Proof. Fix X and write $A_t = A - tI$ and $B_t = B - tI$. Define

$$p(t) = \det(A_t - MX), \qquad r(t) = \det(B_t - XM).$$

Each entry of $A_t - MX$ is a polynomial in t of degree at most 1, so p is a polynomial in t of degree at most n; likewise r. It therefore suffices to prove $p(t) = r(t)$ for all but finitely many real t, since then $p - r$ is a polynomial of degree at most n with infinitely many roots and so is identically zero.

The polynomial $\det(B - tI)$ is not identically zero (it has degree n with leading coefficient $(-1)^n$), so B_t is invertible for all but at most n values of t. Fix such a t.

From $AM = MB$ we get $A_tM = AM - tM = MB - tM = MB_t$, and therefore

$$M = A_tMB_t^{-1}.$$

Substituting this occurrence of M and factoring A_t out on the left,

$$\det(A_t - MX) = \det\left(A_t - A_t M B_t^{-1} X\right) = \det(A_t)\det\left(I - (MB_t^{-1})X\right).$$

Apply the lemma with $U = MB_t^{-1}$ and $V = X$, then factor B_t^{-1} out on the right:

$$\det\left(I - (MB_t^{-1})X\right) = \det\left(I - X(MB_t^{-1})\right) = \det\left((B_t - XM)B_t^{-1}\right) = \frac{\det(B_t - XM)}{\det(B_t)}.$$

The hypothesis that A and B have the same characteristic polynomial says exactly that $\det(A_t) = \det(B_t)$ for every t. Combining the two displays,

$$p(t) = \det(A_t - MX) = \frac{\det(A_t)}{\det(B_t)}\det(B_t - XM) = \det(B_t - XM) = r(t).$$

This holds for all but at most n values of t, hence for all t, and $t = 0$ gives the required identity. Since $p(t) = (-1)^n$ times the characteristic polynomial of $A - MX$ evaluated at t, and similarly for r, the two matrices have the same characteristic polynomial. □

Remark 11.6.3. Both hypotheses are sharp. Equality of determinants alone does not suffice: take

$$A = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}, \quad B = \begin{pmatrix} 0 & 0 \\ 0 & 2 \end{pmatrix}, \quad M = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \quad X = \begin{pmatrix} 3 & 0 \\ 0 & 1 \end{pmatrix}.$$

Then $AM = MB = 0$ and $\det A = \det B = 0$, but $\det(A - MX) = -3$ while $\det(B - XM) = -6$. The characteristic polynomials $t^2 - t$ and $t^2 - 2t$ differ, which is precisely what the proof needed. Note also that A and B need not be similar: with $A = \left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$, $B = 0$ and $M = \left(\begin{smallmatrix} 1 & 0 \\ 0 & 0 \end{smallmatrix}\right)$ the hypotheses hold and A is not similar to B.

Layer 1: WHAT

Block 1. Test M invertible: $A - MX = M(B - XM)M^{-1}$, so the statement is a similarity statement in disguise, and the degenerate M is the entire difficulty.

Block 2. Name the shape: the two sides differ only in the order of a product, so the target identity is $\det(I - UV) = \det(I - VU)$.

Block 3. To factor A out of $A - MX$ you need M written with a factor of A on the left. The relation $AM = MB$ gives exactly that, $M = AMB^{-1}$, provided B is invertible.

Block 4. B need not be invertible, so shift: replace A, B by $A - tI, B - tI$. This is the unique perturbation that preserves both hypotheses, since $A_t M = MB_t$ follows from $AM = MB$ and $\det A_t = \det B_t$ is the characteristic polynomial hypothesis itself.

Block 5. Run the chain: factor A_t out, swap with Sylvester, factor B_t^{-1} out, cancel $\det A_t$ against $\det B_t$.

Block 6. Finish by degree counting: both sides are polynomials of degree at most n in t agreeing off a finite set, so they agree everywhere; set $t = 0$.

Juxtaposition. The nominal route is to try to prove that $A - MX$ and $B - XM$ are similar, which is what the invertible case suggests, and to reach for a density argument in M when that fails. It fails twice: the matrices need not be similar, and M cannot be perturbed without destroying $AM = MB$. The bifurcation point is the sentence "B_t must be invertible for this step". The zombie response is to abandon the step. The trained response is to notice that invertibility is a generic property, to add the parameter t that makes it generic, and to check that the added parameter respects the hypotheses. Choosing the perturbation that preserves the hypotheses, rather than the one that makes the matrix you want invertible, is the whole discipline of this problem.

Layer 2: HOW

Block 1. **Cue.** M appears on the left in one determinant and on the right in the other, with no invertibility assumed anywhere. **Why natural.** Testing the invertible case is not optimism, it is measurement: it tells you what the statement means, it gives you the algebraic identity $A - MX = M(B - XM)M^{-1}$ to imitate, and it tells you which hypothesis is doing which job. Since the characteristic polynomial hypothesis is redundant when M is invertible, it must be there for the singular case only. **Link to the next block.** Knowing the target is a similarity-like identity, look for the standard fact that swaps the order of a product.

Block 2. **Cue.** MX against XM. **Why natural.** $\det(I - UV) = \det(I - VU)$ is the unique elementary statement that exchanges the order of a matrix product without cost, and it holds even when neither factor is invertible. Recognising it is a pattern match on the shape of the expression, not an insight. Its cousins are worth holding in the same slot: UV and VU have the same characteristic polynomial, and for rectangular U, V the nonzero eigenvalues match. **Link to the next block.** To reach the form $I - UV$ you must factor something out of $A - MX$, so ask what can be factored.

Block 3. **Cue.** The only relation available is $AM = MB$, and it has M on both sides. **Why natural.** If you want A to come out as a left factor of MX, you must rewrite M so that it starts with A; the relation rearranges to $M = AMB^{-1}$ and that is the only rearrangement it offers. Notice how the hypothesis is used: not as a symmetry, but as a substitution rule that inserts A where you need it. That is the standard way an intertwining relation is spent. **Link to the next block.** The rearrangement requires B^{-1}, which you have not been given, so the next move must manufacture invertibility.

Block 4. **Cue.** A required inverse that the hypotheses do not supply. **Why natural.** Invertibility is generic: $\det(B - tI)$ is a nonzero polynomial in t, so all but finitely many shifts of B are invertible. The reason to shift by tI specifically, rather than by anything else, is that this is the one perturbation under which both hypotheses survive: $A_t M = MB_t$ is immediate, and $\det A_t = \det B_t$ is a restatement of the characteristic polynomial hypothesis. In other words, the hypothesis you were given is precisely a licence to shift. When a hypothesis is stated for all t in disguise, the intended proof uses all t. **Link to the next block.** With B_t invertible, run the algebra.

Block 5. **Cue.** A product of three determinants with $\det A_t$ and $\det B_t$ at the two ends. **Why natural.** The cancellation $\det A_t / \det B_t = 1$ is where the characteristic polynomial hypothesis is spent, and it is spent exactly once. That is a good sign in a proof: each hypothesis should have a visible point of consumption. If a hypothesis is never consumed, either the proof is wrong or the statement is stronger than claimed. **Link to the next block.** You now have the identity for all but finitely many t, so upgrade.

Block 6. **Cue.** An identity proved off a finite exceptional set, with both sides polynomial. **Why natural.** Two polynomials of degree at most n that agree at more than n points are equal. Degree counting is the cheapest form of the polynomial identity principle and it avoids any appeal to topology or to Zariski density, so it costs one sentence and cannot be challenged by a grader. State the degree bound explicitly, because a grader will look for it. **Link to the next block.** Set $t = 0$ and observe that you have in fact proved the stronger characteristic polynomial statement.

Layer 3: WHY

The mathematics underneath is the theory of UV against VU. Sylvester's identity $\det(I - UV) = \det(I - VU)$ says that the two products have the same nonzero spectrum, and the block proof

shows why: the matrix $\left(\begin{smallmatrix} I & U \\ V & I \end{smallmatrix}\right)$ can be cleared in two directions, and the leftover block is $I - UV$ or $I - VU$ depending on which direction you clear. Every identity in which the order of a product flips is ultimately this statement, and it is why the problem is solvable at all: the conclusion is not an accident of determinants, it is a shadow of the fact that MX and XM are spectrally almost the same.

The second truth is the polynomial identity principle. A polynomial identity in several variables that holds on a set which is large in each variable holds identically. The cheap version, used here, is that a polynomial in one variable of degree at most n with more than n roots is zero. The general version, that a polynomial vanishing on a nonempty open subset of $\mathbb{R}^N$ is zero, is what lets you assume genericity in any variable that is free. The discipline is to identify which variables are free. Here t and X are free and M is constrained, which is the exact reason the perturbation must be applied to the shift and not to M.

The third truth is structural and is best seen through the rank normal form route. Write $M = U \left(\begin{smallmatrix} I_r & 0 \\ 0 & 0 \end{smallmatrix}\right) V^{-1}$. In these coordinates the relation $AM = MB$ forces both A and B into block triangular form with a shared top left block, and the two determinants both collapse to $\det(A_{11} - X_{11}) \det(A_{22})$ against $\det(B_{11} - X_{11}) \det(B_{22})$. The first factors agree because M acts invertibly there, so similarity does the work; the second factors agree only because A_{22} and B_{22} inherit the same characteristic polynomial, and X has disappeared from them entirely. So the honest content of the theorem is: on the part of the space where M is invertible, the identity is similarity; on the part killed by M, the variable X cannot reach and only the spectral data matter. Knowing that, you understand why the hypothesis could not be weakened to $\det A = \det B$, and the two by two example in the remark is the smallest witness.

The discernment mechanism to train: when a proof stalls on a missing invertibility, do not abandon the step and do not perturb blindly. Ask which perturbations preserve every hypothesis. Usually there is exactly one natural family, and the hypotheses themselves tell you which, because a hypothesis stated as an equality of characteristic polynomials is an equality for all t, and an equality for all t is an invitation to use t. The examiners nudged you toward this by stating the hypothesis as "the same characteristic polynomial" rather than the more natural sounding "the same eigenvalues with multiplicity"; the polynomial phrasing is the hint.

Revolving concepts

Characteristic polynomial. $\chi_C(t) = \det(tI - C)$, monic of degree n; its coefficients are the elementary symmetric functions of the eigenvalues, with $\operatorname{Tr}(C)$ and $\det(C)$ as the two extremes. Similar matrices have the same characteristic polynomial; the converse is false (a nonzero nilpotent Jordan block against the zero matrix). Cayley and Hamilton gives $\chi_C(C) = 0$. See Book 1, field: Linear algebra, topic: characteristic polynomial and similarity.

Sylvester's determinant identity. $\det(I_m - UV) = \det(I_n - VU)$ for U of size $m \times n$ and V of size $n \times m$; for square U, V this says $\chi_{UV} = \chi_{VU}$. Proof by clearing the block matrix $\left(\begin{smallmatrix} I & U \\ V & I \end{smallmatrix}\right)$ in two directions. Consequences worth storing: $\det(I + uv^T) = 1 + v^T u$ for column vectors, and the matrix determinant lemma $\det(C + uv^T) = \det(C)(1 + v^T C^{-1} u)$. See Book 1, field: Matrices and determinants, topic: Sylvester identity.

Intertwiners. $AM = MB$ says M is a homomorphism of $\mathbb{R}[x]$ modules from $(\mathbb{R}^n, B)$ to $(\mathbb{R}^n, A)$, so M maps generalised eigenspaces of B into generalised eigenspaces of A for the same eigenvalue; in particular if A and B have disjoint spectra then $M = 0$. This is the reason a perturbation of M is illegal: the solution set of $AM = MB$ in M is a linear subspace determined by the spectra, and it may miss GL_n entirely. See Book 1, field: Linear algebra, topic: Sylvester equation and intertwiners.

Rank normal form and block determinants. Every M of rank r factors as $U \left(\begin{smallmatrix} I_r & 0 \\ 0 & 0 \end{smallmatrix}\right) V^{-1}$ with U, V invertible; and $\det \left(\begin{smallmatrix} P & Q \\ 0 & S \end{smallmatrix}\right) = \det P \det S$ for square diagonal blocks. These two facts together are the whole of the alternative proof. See Book 1, field: Matrices and determinants, topic: block determinants.

The polynomial identity principle. A polynomial of degree at most d in one variable with more than d roots is identically zero; consequently an identity between polynomial expressions that holds for all but finitely many values of a parameter holds for all values, and one that holds on a nonempty open subset of $\mathbb{R}^N$ holds identically. This is how "assume the generic case" is made rigorous. See Book 1, field: Polynomials, topic: identity principle and genericity.

The recursion behind the trace route, generalised. The third published route needs that the traces of all powers determine the characteristic polynomial, which is Newton's identities: with $p_k = \operatorname{Tr}(C^k)$ and e_i the elementary symmetric functions of the eigenvalues,

$$p_k - e_1 p_{k-1} + e_2 p_{k-2} - \cdots + (-1)^{k-1} e_{k-1} p_1 + (-1)^k k\, e_k = 0,$$

a recursion which determines $e_1, \ldots, e_n$ from $p_1, \ldots, p_n$ one at a time. Its closed form is the generating function identity

$$\det(I - tC) = \exp\left(- \sum_{k \geq 1} \frac{\operatorname{Tr}(C^k)}{k} t^k \right),$$

obtained by taking logarithms of $\prod_i (1 - \lambda_i t)$. The generalisation to record: any symmetric function of eigenvalues can be computed from power sums by this recursion, and the division by k is exactly why the trace route needs characteristic zero (or characteristic exceeding n). The same recursion is the standard tool whenever a problem gives you $\operatorname{Tr}(C^k)$ for all k and asks for eigenvalues. See Book 1, field: Polynomials, topic: Newton identities and power sums.

Circuit Bank

- **WHEN** one side of an identity has UV and the other has VU **DO** reach for $\det(I - UV) = \det(I - VU)$ and reshape both sides into that form **BECAUSE** the only structural difference is the order of a product, and that identity is the elementary fact which trades order for nothing, valid without any invertibility
- **WHEN** a step needs an inverse the hypotheses do not provide **DO** shift by tI, prove the identity for the all but finitely many t where the inverse exists, then compare polynomials of degree at most n in t **BECAUSE** invertibility is generic, and equality of two degree n polynomials at more than n points is equality
- **WHEN** you must choose which object to perturb **DO** perturb only a free variable, never one constrained by a hypothesis, and prefer the perturbation under which every hypothesis is stable **BECAUSE** the solution set of a constraint like $AM = MB$ need not meet the good set at all, so a perturbation that breaks a hypothesis proves nothing
- **WHEN** a hypothesis looks stronger than the conclusion seems to need **DO** find the single line where it is consumed, and build a small counterexample to the weaker version **BECAUSE** every hypothesis in a well posed problem has exactly one point of consumption; if you cannot find it, you have either misused it or proved something stronger
- **WHEN** a matrix in the problem is the only object not assumed invertible **DO** try its rank normal form $\operatorname{diag}(I_r, 0)$ and read what the other hypotheses force on the blocks **BECAUSE** the rank normal form separates the part where the map is an isomorphism, handled by similarity, from the kernel, where only spectral data survive

Backtesting

1. First useful cue: MX on one side against XM on the other, which names Sylvester's identity; the confirming cue is that M is never assumed invertible while the one line invertible case is trivial, which locates the difficulty and explains why the characteristic polynomial hypothesis exists.

2. Method the expression suggested: substitute $M = A_t M B_t^{-1}$ from the shifted intertwining relation, factor, swap orders by Sylvester, factor back, cancel $\det A_t$ against $\det B_t$, and conclude by degree counting in t.
3. Where you would hesitate, and the thought to reinforce: at the demand for B_t^{-1}. Reinforce that invertibility is generic and that the correct perturbation is the one preserving both hypotheses, which the phrase "the same characteristic polynomial" is quietly recommending, since it is an equality for every t.
4. The trap the question sets: perturbing M towards invertibility. It is the first idea, it feels like the standard density argument, and it is illegal because $AM = MB$ is a constraint on M; worse, there are instances (disjoint spectra) where $M = 0$ is the only intertwiner.
5. What makes you recognise it faster next time: the pairing of an intertwining relation with a determinant whose two sides differ by the order of a product. Intertwining relations are substitution rules; order flips are Sylvester.
6. The reusable decision rule: when a determinant identity needs an inverse you do not have, introduce a spectral parameter t that makes the inverse generic, check the hypotheses survive the shift, prove the identity generically, and finish by comparing polynomials in t of bounded degree.

Mirror drills

1. Prove $\det(I_m - UV) = \det(I_n - VU)$ for rectangular U ($m \times n$) and V ($n \times m$), and deduce that UV and VU have the same nonzero eigenvalues with multiplicity. *Answer:* clear $\left(\begin{smallmatrix} I_m & U \\ V & I_n \end{smallmatrix}\right)$ in both directions using unitriangular factors of determinant 1; the eigenvalue statement follows by applying the identity with U replaced by U/t.
2. With $AM = MB$ and M invertible, show $A - MX$ and $B - XM$ are similar for every X. *Answer:* $A = MBM^{-1}$, so $A - MX = M(B - XM)M^{-1}$.
3. Produce A, B, M, X with $AM = MB$ and $\det A = \det B$ but $\det(A - MX) \neq \det(B - XM)$, and say which step of the proof breaks. *Answer:* $A = \operatorname{diag}(0,1)$, $B = \operatorname{diag}(0,2)$, $M = \operatorname{diag}(1,0)$, $X = \operatorname{diag}(3,1)$ give -3 against -6; the cancellation $\det A_t = \det B_t$ fails for $t \neq 0$.

11.7 B1. a perfect cube hides an integrating factor

Let f be a three times differentiable function (defined on $\mathbb{R}$ and real valued) such that f has at least five distinct real zeros. Prove that $f + 6f' + 12f'' + 8f'''$ has at least two distinct real zeros.

Read it out loud

This is a zero counting question dressed as a differential expression. You are given a hypothesis about zeros of f, nothing about a formula for f, and asked for a conclusion about zeros of a fixed combination of f and its first three derivatives. The only elementary tool that turns "many zeros of h" into "one fewer zero of h'" is Rolle's theorem, so the moment "distinct real zeros" is attached to a statement about derivatives, the reaction circuit fires: count with Rolle, do not compute with formulas, and do not look for an explicit f.

The second thing to read out loud is the coefficient string $1, 6, 12, 8$ attached to f, f', f'', f''' in ascending order of derivative. Four numbers on a degree three combination, in the ratio $1 : 6 : 12 : 8$, which is Pascal's row for degree three scaled by powers of two ($1, 3, 3, 1$ against $1, 2, 4, 8$ gives $1, 6, 12, 8$). That is the guiding light: the combination is not an arbitrary cubic in the derivative, it is the binomial expansion of a single linear term cubed, and a perfect power sitting inside a linear combination of derivatives is exactly the signal to reach for an integrating factor, because an integrating factor is the device that turns $h' + ch$ into a bare derivative of a product.

Within thirty seconds you should have $8t^3 + 12t^2 + 6t + 1 = (2t + 1)^3$ written on your paper, because that identity is the whole problem.

Approaches, ranked worst to best

1. **direct estimation of the combination.** *Cue:* a five zero hypothesis and a two zero conclusion, no formula in sight. *Circuit:* none, this is zombie mathematics. Trying to bound $f + 6f' + 12f'' + 8f'''$ with generic inequalities relating a function to its derivatives, with no use of the specific coefficients. This is the wrong kind of tool for the claim: existence of a zero is a qualitative statement, and it stalls immediately because there is no bound to write down without more information about f.

2. **apply Rolle separately to f, f', f'', f'''.** *Cue:* four objects, four zero counts $5, 4, 3, 2$. *Circuit:* Rolle's theorem, used without a target function. Rolle alone gives f' at least four zeros, f'' at least three, f''' at least two. The zero counts match the problem's numbers, which is exactly why this route is tempting, but it is a dead end: the zeros of f, f', f'', f''' are four different sets of points, and knowing each function vanishes somewhere says nothing about where the specific combination $f + 6f' + 12f'' + 8f'''$ vanishes. This ranks above the first approach because it finds the right theorem, but it never bundles the four pieces into one function, which is the actual content of the problem.

3. **integrating factor $e^{x/2}$ collapsing the cubic operator.** *Cue:* $1, 6, 12, 8$ factor as $(2t + 1)^3$. *Circuit:* product rule plus Rolle, chained three times on one function. Since $8t^3 + 12t^2 + 6t + 1 = (2t + 1)^3$ is a perfect cube, differentiating $e^{x/2}f$ three times reproduces the target combination exactly, up to a nonvanishing factor, in one substitution with no bookkeeping of several exponentials. This is the ideal route: minimal ink, every step forced once the factorisation is seen.

The ideal solution

Since $8t^3 + 12t^2 + 6t + 1 = (2t + 1)^3$, the target expression is 8 times $(2D + 1)^3$ applied to f, where $D = d/dx$; equivalently it is 64 times $(D + \frac{1}{2})^3 f$.

Let $g(x) = e^{x/2}f(x)$. Since $e^{x/2} > 0$ for every real x, g vanishes exactly where f vanishes, so g has at least five distinct real zeros.

Because f is three times differentiable, so is g, being a product of f with a smooth exponential; hence g, g', g'' are each differentiable and therefore continuous on all of $\mathbb{R}$. This is exactly what Rolle's theorem needs, so it applies at every stage below without any extra hypothesis being smuggled in.

Differentiate once:

$$g'(x) = e^{x/2}\left(\tfrac{1}{2}f(x) + f'(x)\right).$$

Let $x_1 < x_2 < \cdots < x_5$ be five of the zeros of g. Rolle's theorem supplies a zero of g' in each open interval (x_i, x_{i+1}), $i = 1, \ldots, 4$. These four intervals are pairwise disjoint, so the four zeros of g' they produce are pairwise distinct. Hence g' has at least four distinct real zeros.

Differentiate again:

$$g''(x) = e^{x/2}\left(\tfrac{1}{4}f(x) + f'(x) + f''(x)\right).$$

By the same argument, applied to the at least four zeros of g', g'' has at least three distinct real zeros.

Differentiate a third time:

$$g'''(x) = e^{x/2}\left(\tfrac{1}{8}f(x) + \tfrac{3}{4}f'(x) + \tfrac{3}{2}f''(x) + f'''(x)\right) = \tfrac{1}{8}e^{x/2}\big(f(x) + 6f'(x) + 12f''(x) + 8f'''(x)\big).$$

By Rolle applied once more to the at least three zeros of g'', g''' has at least two distinct real zeros.

Since $e^{x/2}$ never vanishes, $g'''(x) = 0$ exactly when $f(x) + 6f'(x) + 12f''(x) + 8f'''(x) = 0$. Therefore $f + 6f' + 12f'' + 8f'''$ has at least two distinct real zeros, as required.

Layer 1: WHAT

Block 1: read the coefficients $1, 6, 12, 8$ as $(2t+1)^3$, converting an opaque fourth order combination into a labelled operator $(2D+1)^3$. Block 2: set $g = e^{x/2}f$, so that multiplying by a never vanishing exponential preserves the zero set of f exactly. Block 3: differentiate g once and see that this reproduces $(D + \frac{1}{2})$ acting on f inside the exponential wrapper. Block 4: apply Rolle three times in a row, from g to g' to g'' to g''', since differentiating three times is exactly cubing the operator. Block 5: read off that g''' is, up to the nonvanishing factor $\frac{1}{8}e^{x/2}$, precisely the target combination, so its zero count transfers unchanged.

Juxtaposition: the nominal route (approach two above) also reaches "two zeros" through three applications of Rolle, but on the wrong function; it differentiates f itself and hopes the four resulting zero sets recombine at the end. The bifurcation point is the choice of what to differentiate. The zombie route starts differentiating before deciding what object it is building. The ideal route multiplies by $e^{x/2}$ first and only then starts differentiating, so the recombination is automatic at every step instead of being wished for at the last one.

Layer 2: HOW

Block 1. **Cue.** The coefficients $1, 6, 12, 8$ attached to f, f', f'', f'''. **Why natural.** Four coefficients on a degree three combination is Pascal's row for $n = 3$ scaled geometrically; checking $8t^3 + 12t^2 + 6t + 1 = (2t+1)^3$ costs one line and shows the operator is a perfect cube of a first order operator, not an arbitrary cubic. **Link to the next block.** A perfect cube of $(D + \frac{1}{2})$ is exactly what three product rule differentiations naturally produce, so the next move is to build the function that differentiates into that operator.

Block 2. **Cue.** The identity $\frac{d}{dx}\big(e^{cx}h(x)\big) = e^{cx}\big(h'(x) + ch(x)\big)$. **Why natural.** This is the only way, up to a scalar, to turn $h' + ch$ into a bare derivative, because $u' = cu$ forces u to be exponential; choosing $c = \frac{1}{2}$ matches the root found in Block 1 exactly. **Link to the next block.** Setting $g = e^{x/2}f$ makes the next differentiation reproduce $(D + \frac{1}{2})f$ automatically, and since $e^{x/2} > 0$ everywhere, g starts with the same five zeros as f for free.

Block 3. **Cue.** g has at least five distinct zeros, and Rolle's theorem is available because g is differentiable everywhere. **Why natural.** Between any two consecutive zeros of a differentiable function the derivative must vanish at least once; four disjoint intervals from five zeros force four distinct zeros of g'. **Link to the next block.** The identical argument applies to g' (three more zeros for g'') and then to g'' (two more zeros for g'''), because nothing in the argument used any property of g beyond differentiability and having several zeros.

Block 4. **Cue.** g''' has been computed explicitly and factors as $\frac{1}{8}e^{x/2}$ times the target expression. **Why natural.** $e^{x/2}$ never vanishes, so multiplying or dividing by it rescales a function without moving or removing any zero. **Link to the next block.** The two zeros of g''' transfer without loss to $f + 6f' + 12f'' + 8f'''$, which is exactly the claim to be proved, and the chain closes.

Layer 3: WHY

The truth underneath this problem is that a linear differential operator with constant coefficients and only real roots can always be realised, up to multiplication by a never vanishing exponential, as a pure iterated derivative, and Rolle's theorem is blind to such multiplication because it only cares about the location of zeros, never their size. So any statement of the shape "f has m zeros, show $L(D)f$ has at least $m - n$ zeros" for a real rooted degree n polynomial L reduces to the same three ingredients: factor L, peel off one root at a time with an exponential, apply Rolle once per root.

The discernment mechanism is algebraic and happens before any calculus: look at the coefficients and ask whether they belong to a polynomial with only real roots, here visibly a perfect cube. If they do not, this route is unavailable, because Rolle's theorem is a statement about real valued functions of a real variable with no direct analogue for a genuinely complex exponential factor; that signals a different problem entirely, not a harder version of this one.

The examiners nudged you toward the route by choosing $1, 6, 12, 8$ rather than an arbitrary quadruple. A solver who expands $(2t + 1)^3$ on seeing four coefficients on a third order combination finds the route in under a minute; a solver who treats the four terms as unrelated spends the full time on the second approach above and never closes the argument. Training this discernment means building the habit of factoring every coefficient list met in a differential context before touching a derivative, the same reflex as factoring a quadratic before completing the square.

Revolving concepts

Rolle's theorem: if h is continuous on $[a, b]$, differentiable on (a, b), and $h(a) = h(b)$, some $c \in (a, b)$ has $h'(c) = 0$. The corollary used three times above, that at least k distinct zeros of h force at least $k - 1$ distinct zeros of h' strictly between consecutive pairs, is the workhorse of every zero counting problem on the Putnam.

Integrating factors: for constant c, e^{cx} is the unique function u (up to a nonzero scalar) with $u' = cu$, and $\frac{d}{dx}(uh) = u(D + c)h$ for such u. This is the same device used to solve first order linear differential equations $y' + cy = Q(x)$; here it certifies a zero count instead of solving an equation.

Generalised recursion (the repeated structure in this problem): let $L(t) = \sum_{k=0}^{n} c_k t^k$ have real roots $r_1, \ldots, r_n$ counted with multiplicity. Multiplying by $e^{-r_1 x}$ and differentiating once realises $(D - r_1)f$ up to that exponential; rescaling by $e^{(r_1 - r_2)x}$ and differentiating again realises $(D - r_2)(D - r_1)f$; continuing for all n roots realises $L(D)f$, up to a leading coefficient and a nonvanishing exponential, after exactly n differentiations. Each differentiation costs exactly one zero via Rolle, so if f has $m > n$ distinct real zeros, $L(D)f$ has at least $m - n$ distinct real zeros. When the roots coincide, as here with $r_1 = r_2 = r_3 = -\frac{1}{2}$, every rescaling factor between steps is trivially 1, and the whole chain collapses to differentiating a single $e^{-r_1 x} f$ repeatedly, which is why this problem admits the one substitution shortcut; distinct real roots still work, but need a genuinely different exponential bridging each pair of steps.

Binomial coefficients as a diagnostic: recognising $1, 6, 12, 8$ as the expansion of $(2t+1)^3$ is the same pattern matching used whenever a coefficient list should be tested against $(at+b)^n$ before any calculus is attempted on it.

Circuit Bank

- **WHEN** a fixed linear combination of f and several derivatives sits between a zero count hypothesis and a zero count conclusion **DO** write the coefficients as a polynomial $L(t)$ in the operator $D = d/dx$ and check whether L has only real roots **BECAUSE** Rolle's theorem is the only elementary tool linking zero counts across a derivative, and it only reaches the target expression once that expression is exhibited as a pure derivative
- **WHEN** $L(D)$ factors with a single repeated real root r **DO** multiply f by one exponential e^{-rx} and differentiate that one product the full number of times, instead of juggling several exponentials **BECAUSE** a repeated root makes every intermediate rescaling factor between steps trivial, so one substitution absorbs the whole chain
- **WHEN** $L(D)$ factors with distinct real roots $r_1, \ldots, r_n$ **DO** peel off one root at a time: multiply by $e^{-r_1 x}$, differentiate, rescale by $e^{(r_1-r_2)x}$, differentiate again, and so on **BECAUSE** each factor of L needs its own matching exponential, and only the most recent derivative, not the original function, may be rescaled between steps
- **WHEN** a hypothesis gives m distinct zeros and a conclusion asks for exactly $m-n$ zeros where n is the order of the combination **DO** expect the proof to consist of exactly n applications of Rolle's theorem, no more and no fewer **BECAUSE** each application of Rolle costs exactly one zero, so the arithmetic $m \to m-n$ is the proof's structure, not a coincidence to verify separately

Backtesting

1. First useful cue: the coefficient string $1, 6, 12, 8$ on a third order combination.
2. Method the expression suggested: factor as a perfect cube $(2t+1)^3$, then peel it off with a single exponential integrating factor.
3. Where you would hesitate, and the thought to reinforce: whether multiplying by $e^{x/2}$ changes the zero count of f; reinforce that any strictly positive factor preserves a zero set exactly, so this step needs only a one line justification.
4. The trap the question sets: applying Rolle three times to f itself, getting the numerically satisfying chain $5 \to 4 \to 3 \to 2$ on four different functions, and mistaking that coincidence of arithmetic for a proof.
5. What makes you recognise it faster next time: any problem of the shape "f has m zeros, prove a linear combination of f and its derivatives has $m-n$ zeros" should trigger a check of the coefficients against $(at+b)^n$ before a single derivative is written.
6. The reusable decision rule: factor the coefficient polynomial in D first, choose the integrating factor matching its root or roots second, differentiate and apply Rolle third.

Mirror drills

1. If f is differentiable with at least two distinct real zeros, show $f + f'$ has at least one real zero. *Answer:* let $g = e^x f$; then $g' = e^x(f + f')$, and g has two zeros so g' has one by Rolle.

2. If f is twice differentiable with at least four distinct real zeros, show $f + 4f' + 4f''$ has at least two real zeros. *Answer:* $4t^2 + 4t + 1 = (2t+1)^2$, so with $g = e^{x/2}f$, $g'' = \frac{1}{4}e^{x/2}(f + 4f' + 4f'')$, and g has four zeros so g'' has two.
3. If f is twice differentiable with at least three distinct real zeros, show $f'' - 3f' + 2f$ has at least one real zero. *Answer:* $t^2 - 3t + 2 = (t-1)(t-2)$ has distinct real roots; chain two exponentials (multiply by e^{-x}, differentiate, rescale by e^{-x} again, differentiate) applying Rolle after each derivative to go from three zeros of f down to one.

11.8 B2. crossing off triples and their sums

Given the list of positive integers $1, 2, 3, 4, \ldots$, *take the first three numbers* $1, 2, 3$ *and their sum* 6, *and cross all four numbers off the list. Repeat with the three smallest remaining numbers* $4, 5, 7$ *and their sum* 16, *crossing all four off the list. Continue in this way, at each stage crossing off the three smallest remaining numbers together with their sum, and consider the sequence of sums produced:* $6, 16, 27, 36, \ldots$. *Prove or disprove that some number in this sequence has base ten representation ending in* 2015.

Read it out loud

Strip away the story and this is an operationally defined sequence: you are not handed a formula for s_n, you are handed a rule (take three, append the sum, delete four) and asked a question about the residue of s_n modulo 10^4 for some n. That mismatch, a rule with no formula set against a question purely about digits, is itself the command term. Whenever a Putnam problem defines a sequence procedurally and then asks about its behaviour modulo a power of ten, it is never inviting you to run the procedure until you get lucky. It is inviting you to prove the procedure is eventually periodic, or periodic enough to steer, and then to solve a small congruence.

Read "prove or disprove" for what it is here: exam theatre. An ending-digit claim about an infinite sequence is almost always provable by exhibiting one term, and disproving it would need a genuine obstruction, some invariant forbidding the digits 2015 forever, which is a much harder thing to manufacture for a sieve this loosely constrained. Default to "prove", and go looking for a construction, not a proof of impossibility.

The first useful move costs thirty seconds and no insight at all: extend the given data by hand. Continuing past 36: $11, 12, 13 \to 36$ (given), then $14, 15, 17 \to 46$ (note 16 is already gone, it was a sum), then $18, 19, 20 \to 57$, then $21, 22, 23 \to 66$, then $24, 25, 26 \to 75$. Write the differences $s_{n+1} - s_n$: $10, 11, 9, 10, 11, 9, \ldots$. That is the guiding light. The sums are not exactly arithmetic, but they wobble around an arithmetic trend with period 3, and a wobble of period 3 riding on a step size close to 10 is exactly the fingerprint of a self-referential block structure. This sentence, three steps remove twelve numbers of data but a block of ten integers only has ten slots, has to be self-generated the moment you see it, in the arena, with nothing but this differenced data in front of you.

Fields embedded: Sequences and recurrences dressed in a combinatorics costume. The real content being tested is whether you can turn an operational rule into a provable block invariant by strong induction, and whether "ends in 2015" becomes, in your hands, a congruence you can actually solve.

Approaches, ranked worst to best

1. **brute simulation to the target.** *Cue:* the specific four digit tail in "prove or disprove". *Circuit:* none, this is zombie maths. it costs unbounded ink: the first term that ends in 2015 turns out to be $s_{1201} = 12015$, well over a thousand steps of hand simulation before any hit. Even granting a correct answer, this route earns no marks for insight and is not finishable in the arena.

2. **spot the pattern, state it, skip the proof.** *Cue:* the visibly near-arithmetic differences $10, 11, 9, 10, 11, 9, \ldots$. *Circuit:* pattern recognition with no induction behind it. this finds the right idea fast but leaves every claim about s_n for large n unjustified. A grader has no reason to believe a guessed formula holds at $n = 4201$ just because it held for $n \leq 8$; this loses most of the marks despite having the right instinct.

3. **strong induction on blocks of three steps proving a self-referential decade lemma, then a linear congruence.** *Cue:* the period-3 wobble riding on a step size of 10. *Circuit:* the block

invariant is exactly the periodicity the rule was begging you to find. the ideal solution. It proves the pattern in one clean induction and needs only ONE controllable sub-case of the wobble, not a full classification, because the problem only demands existence.

The ideal solution

Index the steps from 0: at step n let $a_n < b_n < c_n$ be the three numbers removed and $s_n = a_n + b_n + c_n$ the accompanying sum, so $s_0 = 6$, $s_1 = 16$, $s_2 = 27$, $s_3 = 36, \ldots$ exactly as given. Group steps into blocks of three indexed by $q = 0, 1, 2, \ldots$, block q consisting of steps $3q, 3q+1, 3q+2$.

Claim 11.8.1. *For every integer $q \geq 0$:*

(i) $a_{3q} = 10q + 1$, $b_{3q} = 10q + 2$, $c_{3q} = 10q + 3$, *so* $s_{3q} = 30q + 6$;

(ii) $s_q = 10q + h_q$ *for some* $h_q \in \{5, 6, 7\}$, *and* $\{a_{3q+1}, b_{3q+1}, c_{3q+1}\} = \{10q + 4, 10q + 5, 10q + 6, 10q + 7\} \setminus \{s_q\}$, *so* $s_{3q+1} = 40q + 22 - s_q$, *equal to* $30q + 17$, $30q + 16$, $30q + 15$ *according as* $h_q = 5, 6, 7$;

(iii) $a_{3q+2} = 10q + 8$, $b_{3q+2} = 10q + 9$, $c_{3q+2} = 10q + 10$, *so* $s_{3q+2} = 30q + 27$.

Proof. Strong induction on q. For $q = 0$, steps $0, 1, 2$ are given directly: $1, 2, 3 \to 6$ (so $h_0 = 6$), $4, 5, 7 \to 16$, $8, 9, 10 \to 27$, matching (i) to (iii).

Fix $q \geq 1$ and assume the Claim for every $q' < q$. Two consequences follow.

First, every number removed during steps $0, \ldots, 3q - 1$ lies in $\{1, \ldots, 10q\}$, and all $10q$ of them are removed. Each earlier block $q' < q$ removes nine numbers directly, $\{10q' + 1, \ldots, 10q' + 10\} \setminus \{s_{q'}\}$ by (i) to (iii), and by (ii) at index q' the missing tenth number $s_{q'}$ also lies inside that same decade. So decade q' is entirely crossed off by the end of block q', for every $q' < q$, giving $\{1, \ldots, 10q\}$ fully crossed off after step $3q - 1$. It is worth repeating why nothing else interferes: any sum $s_{q'}$ with $q \leq q' \leq 3q - 1$ already computed lies, by (ii), in the later decade $\{10q' + 1, \ldots, 10q' + 10\}$ with $q' \geq q$, hence strictly above $10q + 3$, and cannot masquerade as one of the next three integers. So the three smallest survivors at the start of step $3q$ are exactly $10q + 1, 10q + 2, 10q + 3$, proving (i) and giving $s_{3q} = 30q + 6$.

Second, since $q \geq 1$ we have $q < 3q$, so step q has already run by step $3q$; step q belongs to block $\lfloor q/3 \rfloor < q$, covered by the hypothesis, so s_q already has a fixed value $10q + h_q$ with $h_q \in \{5, 6, 7\}$. After step $3q$ removes $10q + 1, 10q + 2, 10q + 3$, the candidates $10q + 4, 10q + 5, 10q + 6, 10q + 7$ have exactly one entry, s_q, already crossed off (no other sum can land here, by the same decade-disjointness argument). So step $3q + 1$ removes the remaining three of these four, giving $s_{3q+1} = 40q + 22 - s_q$, proving (ii). In every case the untouched top of the decade, $10q + 8, 10q + 9, 10q + 10$, is now the full set of survivors, so step $3q + 2$ removes them, proving (iii). This closes the induction. □

The Claim answers everything. Parts (i) and (iii) fix the units digits of s_{3q} and s_{3q+2} at 6 and 7, so only s_{3q+1} can ever end in the digit 5 that 2015 needs, and it does so exactly when $h_q = 7$. Part (iii) supplies an unconditional witness for this: $s_{3q'+2} = 30q' + 27 = 10(3q' + 2) + 7$, so $h_{3q'+2} = 7$ automatically, for every q', with no dependence on deeper history. Choosing $q \equiv 2 \pmod 3$ therefore guarantees $h_q = 7$ and $s_{3q+1} = 30q + 15$, at no extra cost.

Solve the tail: $30q + 15 \equiv 2015 \pmod{10^4} \iff 3q \equiv 200 \pmod{1000}$. Since $3 \times 667 \equiv 1 \pmod{1000}$, this gives $q \equiv 200 \times 667 \equiv 400 \pmod{1000}$. Combined with $q \equiv 2 \pmod 3$ (moduli coprime, so the Chinese remainder theorem applies): write $q = 1000j + 400$; since $1000 \equiv 1$ and $400 \equiv 1 \pmod 3$, this needs $j + 1 \equiv 2 \pmod 3$, i.e. $j \equiv 1 \pmod 3$. Take $j = 1$, giving $q = 1400$, and indeed $1400 \equiv 2 \pmod 3$.

With $q = 1400$: $N = 3q + 1 = 4201$ and

$$s_{4201} = 30(1400) + 15 = 42015,$$

whose base ten representation ends in 2015. The statement is proved, not disproved: $\boxed{42015}$ is an explicit term of the sequence with this property.

Layer 1: WHAT

Block 1: define a_n, b_n, c_n, s_n and group steps into blocks of three indexed by q. Block 2: extend the given data by hand to expose the near-arithmetic wobble $10, 11, 9, 10, 11, 9, \ldots$. Block 3: recognise the wobble as a decade colliding with itself, one number in each block of ten was already used up earlier as a sum. Block 4: prove the decade lemma by strong induction, tracking carefully why no stray sum can interfere. Block 5: read off that only the middle sub-case of each block can end in the digit 5, and that one sub-case, $h_q = 7$, is available unconditionally. Block 6: turn "ends in 2015" into a pair of congruences and solve them by the Chinese remainder theorem to name an explicit witness, 42015.

Juxtapose against the nominal route: the zombie approach simulates the sieve term by term, hunting for a hit that does not arrive until $s_{1201} = 12015$, well past a thousand steps, with no argument for why it must arrive at all. The bifurcation point is Block 3: the instant you stop asking what the next term is and start asking why the differenced pattern has period exactly 3, you have left brute force behind for good.

Layer 2: HOW

Block 1. **Cue.** The problem hands you a rule, not a formula, and asks a question purely about digits. **Why natural.** An operational definition plus a digit-ending question is the standard signature of "find the eventual period, then solve a congruence"; no other tool turns a rule into digits. **Link to the next block.** Naming a_n, b_n, c_n, s_n turns a story into an object you can induct on.

Block 2. **Cue.** The given data already shows four terms, too few to trust, just enough to suggest. **Why natural.** Extending by hand costs a few lines and either kills a wrong guess immediately or hands you the exact period to prove. **Link to the next block.** The difference sequence $10, 11, 9, 10, 11, 9$ has period 3, and three steps removing four numbers of data against a block of ten is a ratio worth interrogating, not admiring.

Block 3. **Cue.** Each block of three steps produces twelve numbers of data, but a decade has only ten slots. **Why natural.** Two of those twelve are sums, and sums are large; if a sum from one decade happens to have a value landing inside a later decade, it pre-empties a slot there before that decade is ever reached directly. **Link to the next block.** The quantum leap is naming the self-reference precisely: block q's missing tenth number should be s_q itself, computed earlier, or in the same breath when $q = 0$.

Block 4. **Cue.** A claim depending on every smaller index and on the current index itself is a strong induction with a lookahead. **Why natural.** The base case is forced by direct computation; the step needs the decade fact for all $q' < q$ to clear the ground below $10q$, and the value fact for q itself, legitimate precisely because $q < 3q$ once $q \geq 1$. **Link to the next block.** Once proved, every s_n is known up to the single unresolved bit $h_q \in \{5, 6, 7\}$.

Block 5. **Cue.** The question only asks for existence, not a full description of the sequence. **Why natural.** Chasing the general rule for h_q when $q \equiv 1 \pmod 3$ would need one more layer of recursion, extra ink this problem never asked for; the $q \equiv 2 \pmod 3$ sub-case is unconditional and free, predicated on nothing but part (iii) of the Claim. **Link to the next block.** Fix attention on $s_{3q+1} = 30q + 15$, valid whenever $q \equiv 2 \pmod 3$.

Block 6. **Cue.** "Ends in 2015" is a statement about residues modulo 10^4. **Why natural.** A linear congruence in q modulo 1000, intersected via the Chinese remainder theorem with $q \equiv 2 \pmod 3$,

is guaranteed a solution because the moduli are coprime. **Link to the next block.** Solve, substitute, exhibit $s_{4201} = 42015$, done.

Layer 3: WHY

The truth underneath this problem is a resonance. The rule consumes three integers and manufactures one new one, their sum, every step, so across m steps roughly $3m$ integers are consumed directly while the m sums produced grow roughly linearly at a rate close to the consumption rate. When the output stream's growth rate is close to a whole multiple of the input rate, here a block of three steps growing sums by about 30 while consuming a decade of 10, the outputs and the frontier of unconsumed integers are forced to interleave in a fixed, periodic way. This is the same phenomenon behind Beatty sequences, three-distance theorems, and other greedy constructions on $\mathbb{N}$: whenever removal and reinsertion rates are commensurate, the long-run behaviour collapses onto a finite set of local pictures.

The discernment mechanism: when a sequence is defined by an operation rather than a formula, and the question concerns residues, compute enough terms to see whether the process is nearly arithmetic; if it is, suspect the near-arithmetic behaviour is exact modulo the deviation's own period, then hunt for the reason using the resonance above. Train this by deliberately extending any "sequence defined by an operation" problem by at least six terms before attempting a formula, purely to expose the period, the way $6, 16, 27, 36$ was extended to $46, 57, 66, 75$ here.

What the examiners were nudging toward: giving exactly four terms, no more, is a dare. Four terms is too few to trust a period-3 phenomenon by eye alone, on purpose, so a candidate who only pattern-matches without proving anything is exposed, while a candidate willing to extend the data and then prove the extension earns the full ten marks.

Revolving concepts

Strong induction with a lookahead: ordinary induction assumes the statement at $n-1$ to get n; here the step at block q needs the statement at every $q' < q$, to clear ground, and separately the value fact at index q itself, legitimate because $q < 3q$ for $q \geq 1$ means index q has already been resolved by an earlier block. See Book 1, field: Sequences and recurrences, topic: strong induction. Whenever a recursively defined object at position N needs information from a position that is a function of N itself, check that the referenced position is provably earlier in the construction order before invoking it; that check is the entire content of the induction.

Digit-ending conditions as congruences: the base ten representation of x ends in the digit string D exactly when $x \equiv D \pmod{10^{(\text{digits in } D)}}$, together with $x \geq D$. See Book 1, field: Number theory, topic: congruences and modular arithmetic. Solving $aq \equiv b \pmod{m}$ with $\gcd(a, m) = 1$ is done by multiplying through by the inverse of a modulo m, found by the extended Euclidean algorithm; combining two congruences with coprime moduli is the Chinese remainder theorem, which guarantees a solution unique modulo the product of the moduli.

Greedy self-consuming sequences: any process shaped like "remove the k smallest surviving elements of $\mathbb{N}$, adjoin a new element built from them, remove that too, repeat" is a recognisable Putnam genre. If the adjoined element's typical size grows linearly in the step count at a rate commensurate with $k+1$, the process is eventually periodic when viewed in blocks of the right length, and the correct method is always the same two moves used here: extend by hand to expose the period, then prove a block invariant by strong induction.

Circuit Bank

- **WHEN** a sequence is defined operationally and the question asks about residues or ending digits **DO** extend the data by hand for at least six terms and difference it, looking for a periodic

wobble around an arithmetic trend **BECAUSE** a periodic wobble is provable by a block-level strong induction, and only the induction, not the raw terms, can be trusted at the scale the question demands

- **WHEN** a "prove or disprove" question concerns whether some residue or digit pattern occurs, ever, in a loosely constrained integer process **DO** default to assuming it is true and hunt for one explicit witness **BECAUSE** disproving requires a genuine obstruction, rare and hard to manufacture for sieves this free, while proving needs only one construction
- **WHEN** an inductive step needs a fact about an index that looks earlier but is really tied to the current one, such as s_q needing to be known while proving something about block q **DO** check explicitly that the referenced index is resolved strictly before the point of use, here $q < 3q$ for $q \geq 1$, and treat equality as the base case **BECAUSE** skipping this check is the single most common way this style of induction silently becomes circular
- **WHEN** a problem only asks for existence of one witness, not a full classification **DO** solve only the branch of any case split that is easiest to pin down unconditionally, and ignore the rest **BECAUSE** full classification costs ink the problem is not paying for, and the discarded branches, here h_q for $q \equiv 0, 1 \pmod 3$, are never needed for an existence claim

Backtesting

1. First useful cue: an operationally defined sequence paired with a question purely about the last four digits.
2. Method the expression suggested: extend the given terms by hand and difference them to expose a periodic wobble.
3. Where you would hesitate, and the thought to reinforce: trusting the pattern without proof; the thought is that a strong induction with a lookahead is available precisely because the referenced index q always sits inside an earlier block once $q \geq 1$.
4. The trap the question sets: giving only four terms, too few to responsibly pattern match, to punish anyone who does not extend the data and prove the extension.
5. What makes you recognise it faster next time: noticing the consumption rate, three per step, and the decade size, ten, are close multiples, the numeric fingerprint of a resonant, eventually periodic sieve.
6. The reusable decision rule: when a rule-defined sequence is asked about modulo a power of ten, extend by hand, find the period by differencing, prove a block invariant by strong induction, then solve the resulting congruence for a single witness.

Mirror drills

1. Starting from $1, 2, 3, 4, \ldots$, repeatedly cross off the two smallest remaining numbers and their sum, three numbers per step. Show the resulting sequence of sums is eventually periodic modulo a suitable power of ten. *Answer:* each step removes three numbers and each sum lands inside a block of size close to a small multiple of the step count; the same block invariant technique applies, with the block length worked out by matching removal rate to sum size.
2. A sequence is defined by $t_0 = 1$ and $t_{n+1} = t_n + (\text{digit sum of } t_n)$. Does some t_n end in the digits 2026? *Answer:* this process is not obviously periodic, digit sum is not linear in t_n, so the resonance argument above does not transfer directly; flag this as a structurally different, harder genre rather than forcing the same technique.

3. Solve $17q \equiv 5 \pmod{2015}$ for all integer q, then combine with $q \equiv 1 \pmod{4}$ by the Chinese remainder theorem to give the general solution modulo 4×2015. *Answer:* $\gcd(17, 2015) = 1$ gives a unique inverse of 17 mod 2015, found by the extended Euclidean algorithm, then combine exactly as in the main solution.

11.9 B3. which arithmetic progression matrices have AP powers

Let S be the set of all 2×2 real matrices

$$M = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$$

whose entries a, b, c, d, in that order, form an arithmetic progression. Find all matrices M in S for which there is some integer $k > 1$ such that M^k is also in S.

Read it out loud

Four unknowns, tied together by "in arithmetic progression, in that order." Structurally that is two linear equations in four unknowns, dressed up as a combinatorial condition so it does not look like one at first glance. The first useful move, available within thirty seconds, is to write a, b, c, d as $a, a+t, a+2t, a+3t$: the sentence handed you this substitution for free, and it collapses four unknowns to two.

The second cue sits in "there is some integer $k > 1$ such that M^k is also in S": you are being asked whether a HIGH power of a matrix lands back inside a thin, linearly defined slice of the space of 2×2 matrices. Computing M^k symbolically by repeated multiplication is exactly the situation the trace and determinant quadratic identity exists to shortcut: every 2×2 matrix satisfies $M^2 = \tau M - \delta I$ with $\tau = \operatorname{tr} M$, $\delta = \det M$, which turns an exponentially growing computation into a two-term linear recursion before a single eigenvector is ever written down.

Fields embedded: Matrices and determinants on the surface, Linear algebra and Sequences and recurrences underneath. What is really being tested is whether you reach for trace and determinant before reaching for diagonalisation, and whether you can test membership in a linearly defined set by evaluating its defining equations rather than rebuilding a basis for it.

Approaches, ranked worst to best

1. **symbolic brute force.** *Cue:* "is some power in S". *Circuit:* none, pure computation. compute $M^2, M^3, \ldots$ directly in a, t and impose the arithmetic-progression conditions on raw entries at each step. The algebra explodes well before $k = 5$ and gives no reason to stop looking, since a negative result at small k proves nothing about all k.

2. **explicit diagonalisation.** *Cue:* a 2×2 real matrix, powers wanted. *Circuit:* eigenvalues and a change of basis. find M's eigenvalues and eigenvectors, write $M = PDP^{-1}$, compute $M^k = PD^kP^{-1}$ explicitly, then impose the arithmetic-progression condition on the result. This is correct and is essentially the official first solution's route; it works, but it drags an explicit $\sqrt{\tau^2 + 8t^2}$ and a recursively defined auxiliary sequence through the entire rest of the argument, costing more ink than the problem needs.

3. **trace/determinant reduction plus a functional-evaluation test for membership.** *Cue:* $M^2 = \tau M - \delta I$ holding for every 2×2 matrix, and S being linearly defined. *Circuit:* no eigenvector is ever computed; only the sign and magnitude of the eigenvalues matter, never their exact values. the ideal solution: every power collapses to $t_k M + u_k I$, and S-membership collapses to the single condition $u_k = 0$ by evaluating S's defining equations at the identity matrix.

The ideal solution

Write the entries as $a, a+t, a+2t, a+3t$ for real a, t, forced directly by "in arithmetic progression, in that order." Then

$$\tau := \operatorname{tr} M = a + d = 2a + 3t, \qquad \delta := \det M = ad - bc = a(a+3t) - (a+t)(a+2t) = -2t^2.$$

For any 2×2 matrix $M = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$, direct expansion gives $M^2 = \begin{pmatrix} a^2+bc & b(a+d) \\ c(a+d) & d^2+bc \end{pmatrix}$, which equals $\tau M - \delta I = \begin{pmatrix} (a+d)a-(ad-bc) & (a+d)b \\ (a+d)c & (a+d)d-(ad-bc) \end{pmatrix}$ entrywise, since $(a+d)a-(ad-bc) = a^2+bc$ and likewise for the last entry. So

$$M^2 = \tau M - \delta I$$

for every 2×2 matrix, with no special property of M required.

Case $t = 0$**.** Then $a = b = c = d$ and $M = aJ$ where $J = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$ satisfies $J^2 = 2J$, so $J^k = 2^{k-1}J$ for all $k \geq 1$ by induction, giving $M^k = a^k 2^{k-1} J$: a matrix with all four entries equal, trivially an arithmetic progression with common difference 0. So every $M = aJ$, $a \in \mathbb{R}$, works for every $k \geq 2$.

Case $t \neq 0$**.** Then $\delta = -2t^2 \neq 0$, so M is invertible, and $b = a + t \neq a$ means M is not a scalar matrix, so $\{I, M\}$ is linearly independent. Repeated use of $M^2 = \tau M - \delta I$ gives, for every $k \geq 1$,

$$M^k = t_k M + u_k I, \qquad t_1 = 1,\ u_1 = 0, \qquad t_{k+1} = \tau t_k + u_k, \quad u_{k+1} = -\delta t_k,$$

so $u_k = -\delta t_{k-1} = 2t^2 t_{k-1}$ for $k \geq 2$.

Characterise S by its defining equations directly. Writing a general matrix as $N = \begin{pmatrix} p & q \\ u & v \end{pmatrix}$, "$p, q, u, v$ in arithmetic progression" means $q - p = u - q = v - u$, i.e.

$$L_1(N) := p - 2q + u = 0, \qquad L_2(N) := q - 2u + v = 0.$$

These are linear functionals; $M \in S$ gives $L_1(M) = L_2(M) = 0$, and direct evaluation on the identity gives $L_1(I) = 1 - 0 + 0 = 1$ and $L_2(I) = 0 - 0 + 1 = 1$. So for any scalars x, y,

$$L_i(xM + yI) = xL_i(M) + yL_i(I) = y \qquad (i = 1, 2).$$

Both equations return the same number, 1, when evaluated at I: I's entries $1, 0, 0, 1$ read the same forwards and backwards, and that palindromic symmetry is exactly why both differences see the same value. Applying this with $x = t_k$, $y = u_k$: $M^k \in S \iff u_k = 0$. Membership collapses from two conditions to one, because they coincide on I.

So, for $k \geq 2$, $M^k \in S \iff t_{k-1} = 0$. The sequence t_j obeys $t_{j+1} = \tau t_j + 2t^2 t_{j-1}$, whose characteristic equation $x^2 - \tau x - 2t^2 = 0$ is exactly M's own characteristic equation, with roots

$$\lambda_{1,2} = \frac{\tau \pm \sqrt{\tau^2 + 8t^2}}{2},$$

real and distinct (discriminant $\tau^2 + 8t^2 > 0$ automatically, since $t \neq 0$), with $\lambda_1 \lambda_2 = -2t^2 < 0$: the eigenvalues of M always have opposite sign, whatever τ is. Since $t_1 = 1$, $t_2 = \tau = \lambda_1 + \lambda_2$ match the standard closed form for this recursion, $t_j = \dfrac{\lambda_1^j - \lambda_2^j}{\lambda_1 - \lambda_2}$ for every $j \geq 1$.

So $t_{k-1} = 0 \iff \lambda_1^{k-1} = \lambda_2^{k-1}$. Taking absolute values, $|\lambda_1|^{k-1} = |\lambda_2|^{k-1}$; since $x \mapsto x^{k-1}$ is injective on $[0, \infty)$ for $k - 1 \geq 1$, this forces $|\lambda_1| = |\lambda_2|$, which combined with $\lambda_1 \lambda_2 < 0$ forces $\lambda_2 = -\lambda_1$, i.e. $\tau = 0$. Conversely, if $\tau = 0$ then $\lambda_2 = -\lambda_1$ and $\lambda_1^{k-1} = \lambda_2^{k-1} = (-1)^{k-1} \lambda_1^{k-1}$ holds, as $\lambda_1 \neq 0$, exactly when $k - 1$ is even, i.e. k is odd.

So, for $t \neq 0$: some $k > 1$ works if and only if $\tau = 0$, and then every odd $k \geq 3$ works. $\tau = 2a + 3t = 0$ gives $a = -\frac{3t}{2}$, so the entries are $-\frac{3t}{2}, -\frac{t}{2}, \frac{t}{2}, \frac{3t}{2}$, i.e. $M = \frac{t}{2} \begin{pmatrix} -3 & -1 \\ 1 & 3 \end{pmatrix}$ for $t \neq 0$; taking $t = 0$ here only reproduces the zero matrix, already covered by the first family.

Combining both cases, with $B = \begin{pmatrix} -3 & -1 \\ 1 & 3 \end{pmatrix}$:

$$\boxed{M \in \left\{ \lambda \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} : \lambda \in \mathbb{R} \right\} \cup \{\mu B : \mu \in \mathbb{R}\}}$$

are exactly the matrices of S with $M^k \in S$ for some integer $k > 1$.

Layer 1: WHAT

Block 1: collapse a, b, c, d to (a, t) via the arithmetic-progression substitution. Block 2: derive τ, δ and the universal identity $M^2 = \tau M - \delta I$. Block 3: split into $t = 0$, trivial and always valid, and $t \neq 0$, the real content. Block 4: characterise S by its two linear equations and notice both agree on I, collapsing membership to $u_k = 0$. Block 5: solve $t_{k-1} = 0$ via the eigenvalues' sign and magnitude alone, never their exact values. Block 6: translate $\tau = 0$ back into matrix form and state the union of two families.

Juxtapose against the nominal route: diagonalise M explicitly and carry $\sqrt{\tau^2 + 8t^2}$ through every subsequent line, as the official first solution does. The bifurcation point is Block 4: the decision to test membership by evaluating S's own defining equations at I, rather than re-deriving an explicit basis for S and arguing linear independence against it.

Layer 2: HOW

Block 1. **Cue.** Four unknowns tied together by "in arithmetic progression, in that order." **Why natural.** That phrase is exactly two linear equations in four unknowns; the natural response is to substitute the general term of an arithmetic progression directly and cut the unknowns to two. **Link to the next block.** Every entry is now written in a and t alone, so trace and determinant are the next natural objects.

Block 2. **Cue.** A 2×2 matrix and a question about its powers. **Why natural.** Every 2×2 matrix obeys $M^2 = \tau M - \delta I$, a one-line consequence of expanding both sides; there is no reason to reach for eigenvectors before checking whether this alone is enough. **Link to the next block.** Repeated multiplication turns this into a two-term linear recursion for the coefficients of $M^k = t_k M + u_k I$.

Block 3. **Cue.** $t = 0$ makes M a scalar multiple of the all-ones matrix, a degenerate case worth clearing first. **Why natural.** Degenerate cases often satisfy a target condition trivially and for a different reason than the generic case; separating them stops one proof doing two jobs at once. **Link to the next block.** With $t = 0$ disposed of, the whole remaining question is about $t \neq 0$, where M is invertible and non-scalar.

Block 4. **Cue.** S itself is defined by two linear equations, and M^k always lives in $\operatorname{span}\{M, I\}$. **Why natural.** Testing whether a vector in a known two-dimensional space lies in a subspace defined by linear equations is a direct evaluation, not a search; evaluating both equations at I is the cheapest possible test. **Link to the next block.** Both equations return the same constant 1 on I, so membership collapses to the single condition $u_k = 0$.

Block 5. **Cue.** $u_k = 0$ for $k \geq 2$ is the same as $t_{k-1} = 0$, a statement about a linear recursion's closed form. **Why natural.** The recursion's characteristic roots are M's own eigenvalues, always real, discriminant automatically positive, and of opposite sign, product $= \delta < 0$; equal powers of opposite-signed reals is a magnitude-then-sign argument, not a computation. **Link to the next block.** $t_{k-1} = 0$ happens exactly when $\tau = 0$ and k is odd, translating a matrix-power question into one clean scalar condition.

Block 6. Cue. $\tau = 0$ is one linear equation in a, t. **Why natural.** Substituting back converts the abstract condition into an explicit one-parameter family of matrices, matching the concrete $t = 0$ family already found. **Link to the next block.** Union the two families for the final answer.

Layer 3: WHY

The truth underneath: any 2×2 real matrix obeys a two-term linear recursion for its powers, immediate from the trace/determinant quadratic and needing no eigenvector, so M^k always has the shape $t_k M + u_k I$. A codimension-two condition like "lies in S", restricted to this two-dimensional slice, can be at most a two-equation linear system in (t_k, u_k); here it degenerates to one equation because S's two defining functionals coincide on I. That coincidence is predicated on nothing more exotic than I's entries reading the same forwards and backwards, $1, 0, 0, 1$, which is exactly the symmetry "arithmetic progression" itself respects: reversing a, b, c, d to d, c, b, a negates the common difference but preserves the progression.

The discernment mechanism: when a problem restricts to a linear subspace of matrices and asks about powers staying inside it, look first for the smallest invariant subspace containing the powers you care about, here $\operatorname{span}\{M, I\}$, forced by the degree two trace/determinant identity, then test the original subspace's defining equations on a convenient spanning set of that invariant subspace rather than rebuilding a basis for it. Train this by reaching for trace and determinant, or the minimal polynomial in general, before reaching for eigenvectors, whenever "matrix power stays in a linearly defined set" appears.

What the examiners were nudging toward: phrasing the constraint as entries "in arithmetic progression, in that order" rather than stating the equations outright is a small act of misdirection, reading like a combinatorial condition and tempting a search for integer patterns, when the intended reduction is purely linear algebraic, two equations, four unknowns, straight down to two free parameters, available in the arena without ever factoring $\tau^2 + 8t^2$.

Revolving concepts

The 2×2 trace/determinant quadratic $M^2 = \tau M - \delta I$: every 2×2 real matrix satisfies its own characteristic equation, checkable by direct expansion in one line. See Book 1, field: Matrices and determinants, topic: characteristic polynomial. This is a genuine recursion once multiplied through by M^{k-1}, giving $M^{k+1} = \tau M^k - \delta M^{k-1}$, and it generalises to $n \times n$ matrices via the degree n characteristic polynomial, giving a length n linear recursion for the coefficients of M^k in the basis $I, M, \ldots, M^{n-1}$.

Linear functionals cutting out a subspace, evaluated at a fixed vector: if $V = \{N : L_1(N) = \cdots = L_r(N) = 0\}$ and $x \in V$, then for fixed y, $sx + ty \in V \iff t \cdot L_i(y) = 0$ for every i; when several $L_i(y)$ coincide, membership collapses to fewer independent conditions. See Book 1, field: Linear algebra, topic: subspaces and dual functionals.

Closed forms for order two linear recurrences via characteristic roots: $x_{j+1} = px_j + qx_{j-1}$ with distinct roots λ_1, λ_2 of $z^2 - pz - q = 0$ gives $x_j = A\lambda_1^j + B\lambda_2^j$, fit from the first two terms; here it produces $t_j = (\lambda_1^j - \lambda_2^j)/(\lambda_1 - \lambda_2)$. See Book 1, field: Sequences and recurrences, topic: auxiliary equation method. A repeated root λ gives $x_j = (A + Bj)\lambda^j$; complex conjugate roots give a modulus times a cosine or sine envelope; the same machinery computes ordinary Fibonacci-type sequences and any linear recursion met on the Putnam, this problem's t_k, u_k included.

Sign and reality of eigenvalues from the determinant alone: a real 2×2 matrix with negative determinant has two real eigenvalues of strictly opposite sign, since the discriminant $\tau^2 - 4\delta$ is then automatically positive and the product of the roots equals $\delta < 0$. See Book 1, field: Matrices and determinants, topic: eigenvalues of 2×2 matrices. This single sign fact, not the eigenvalues' exact values, is what closes the problem.

Circuit Bank

- **WHEN** a matrix's entries obey a single linear constraint, arithmetic progression, equal entries, trace zero, and a question asks about powers staying inside that constraint **DO** reduce to the trace/determinant recursion $M^k = t_k M + u_k I$ before touching the specific constraint **BECAUSE** this shrinks the entire power sequence to two scalar sequences that any linear condition can then be tested against directly
- **WHEN** a target subspace S is defined by linear equations L_i **DO** test membership of $tM + uI$ by evaluating each L_i at I directly **BECAUSE** $L_i(tM + uI) = tL_i(M) + uL_i(I) = uL_i(I)$ whenever $M \in S$, collapsing the whole question to the sign of u against the known constants $L_i(I)$
- **WHEN** two real numbers raised to the same positive integer power are claimed equal **DO** split the claim into equal magnitude, injective on $[0, \infty)$, and compatible sign, treated separately **BECAUSE** odd and even powers treat sign differently, and merging the two steps is where errors hide
- **WHEN** a 2×2 real matrix has negative determinant **DO** conclude immediately, with no computation, that its eigenvalues are real and of opposite sign **BECAUSE** the discriminant $\tau^2 - 4\delta$ is then automatically positive and the product of the roots is $\delta < 0$

Backtesting

1. First useful cue: "in arithmetic progression, in that order" applied to four matrix entries, a linear constraint dressed as a combinatorial one.
2. Method the expression suggested: substitute $b, c, d = a + t, a + 2t, a + 3t$, cutting to two free parameters, then reach for trace and determinant rather than eigenvectors.
3. Where you would hesitate, and the thought to reinforce: wanting to diagonalise M because that is how powers are usually computed; the thought is that the trace/determinant recursion already gives every power in $\text{span}\{M, I\}$ without naming an eigenvector.
4. The trap the question sets: "there is some integer $k > 1$" invites chasing specific small k by direct computation, which finds $k = 3$ for one family quickly but gives no reason no other k, or no other matrix, works; only the sign and magnitude argument on the eigenvalues closes the case fully.
5. What makes you recognise it faster next time: seeing a linear constraint on matrix entries, together with a "does some power stay in the constraint" question, as asking you to find the invariant two-dimensional slice $\{tM + uI\}$ and test the constraint's defining equations on I alone.
6. The reusable decision rule: reduce matrix powers via trace and determinant before anything else, characterise the target set by its defining linear equations, evaluate those equations at the identity, and resolve the resulting scalar recursion by the sign and magnitude of the characteristic roots rather than their exact values.

Mirror drills

1. Let $N = \begin{pmatrix} a & b \\ c & d \end{pmatrix}$ be real with $a + d = 0$. Show N^2 is always a scalar multiple of I. *Answer:* immediate from $N^2 = \tau N - \delta I$ with $\tau = 0$, so $N^2 = -\delta I$.
2. Let T be the set of 2×2 real matrices with $a = d$, equal diagonal entries. For which $M \in T$ does $M^k \in T$ for some $k > 1$? *Answer:* the defining equation is $L(N) = p - v = 0$ and

$L(I) = 1 - 1 = 0$, so every power of every $M \in T$ automatically stays in T; a degenerate case worth noting precisely because it contrasts with B3, where $L_i(I) \neq 0$ did the work.

3. For real $t \neq 0$, does $\begin{pmatrix} 0 & t \\ -t & 0 \end{pmatrix}$ have some power equal to a real scalar multiple of $\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$? *Answer:* its eigenvalues are $\pm it$, not real, so the opposite-sign-real-eigenvalue argument breaks down entirely; check directly that every power is a scalar multiple of I or of the original matrix, never of the all-ones matrix.

11.10 B4. Ravi substitution decouples a triangle sum

Let T be the set of all triples (a, b, c) of positive integers for which there exist triangles with side lengths a, b, c. Express

$$\sum_{(a,b,c)\in T} \frac{2^a}{3^b 5^c}$$

as a rational number in lowest terms.

Read it out loud

This is a three variable geometric sum taken not over a box but over the integer points of an open cone: the summand $2^a 3^{-b} 5^{-c}$ is completely separable in a, b, c, and every ounce of difficulty has been pushed into the index set. Say that out loud, because it decides everything. If the index set were $a, b, c \geq 1$ with no further condition, you would write the answer in one line as a product of three geometric series. So the whole problem is: change coordinates until the index set becomes a product again.

The fields wired into the question are tiny in number and that is the tell. Geometry supplies exactly one fact, the triangle inequality. Analysis supplies exactly one fact, that a sum of nonnegative terms may be regrouped and reordered at will. Everything else is the geometric series. The examiners are not testing whether you can sum $\sum r^n$; they are testing whether, on being handed a constraint, you reroute into coordinates in which the constraint dissolves.

The first useful cue is the phrase "for which there exist triangles with side lengths a, b, c". That is the command term. It does not say $a < b + c$; it says triangle. A triangle is the object whose defining data is three positive side lengths satisfying three strict inequalities, and the canonical way to store those three inequalities without carrying them around is to name their slacks. Within thirty seconds you should have written

$$x = b + c - a, \qquad y = c + a - b, \qquad z = a + b - c,$$

and underneath it, "$x, y, z > 0$, integers, and $y + z = 2a$, $z + x = 2b$, $x + y = 2c$". That last line is where the whole solution lives, and it also contains the one trap: over the integers the correspondence is not onto, because x, y, z must all have the same parity.

The second cue is the specific bases $2, 3, 5$ with 2 upstairs and $3, 5$ downstairs. That asymmetry is deliberate. It is there so that the answer is not symmetric and so that you cannot fudge the bookkeeping; it also guarantees convergence, because the constraint $a < b + c$ is exactly what keeps 2^a from beating $3^b 5^c$.

Approaches, ranked worst to best

1. **Slice by perimeter.** *Cue:* "triples of positive integers", a Diophantine flavour. *Circuit:* count lattice points level by level, then sum the counting function. You set $a + b + c = N$, count the triangles of perimeter N (Alcuin's sequence, nearest integer to $N^2/48$ or $(N + 3)^2/48$), and try to reassemble. It fails instantly because the summand is not a function of N: $2^a 3^{-b} 5^{-c}$ separates the variables, so slicing by their sum is exactly the wrong slice. Maximum ink, zero progress.

2. **Fix a first.** *Cue:* a is the only exponent in the numerator. *Circuit:* innermost sum over the variable that looks most special. For fixed a the pairs (b, c) must satisfy $b + c > a$ and $|b - c| < a$, which is a wedge intersected with a half plane. You end up splitting the (b, c) quadrant into three regions and summing a two dimensional geometric series over each. It works, but you will write four times as much as you need and each region is an index error waiting to happen.

3. **Fix b and c, geometric in a.** *Cue:* for fixed b, c the legal a form a contiguous interval $|b-c| < a < b+c$. *Circuit:* when one variable ranges over an interval of consecutive integers, do that sum first. This is the honest workhorse and it is the official first solution. You get

$$S = \sum_{b,c \geq 1} \frac{2^{b+c} - 2^{|b-c|+1}}{3^b 5^c},$$

then you must split on the sign of $b-c$ to remove the modulus, giving $S_1 = 85/231$ over $b \leq c$ and $S_2 = 34/77$ over $b > c$, and $S_1 + S_2 = 17/21$. Correct, fully rigorous, and it costs four geometric series plus two reindexings. It ranks below the ideal because the modulus was never necessary: it is an artefact of refusing to change coordinates.

4. **Ravi substitution.** *Cue:* "there exist triangles with side lengths". *Circuit:* name the slacks of the constraining inequalities and use them as coordinates. The three inequalities become $x, y, z > 0$; the summand becomes a product of powers of $1/15$, $2/5$, $2/3$; the only residue of the integrality is a parity condition which splits the sum into two copies of the same product. Three geometric series, one factor of $17/2$, done.

5. **Cone decomposition.** *Cue:* the index set is the set of lattice points of a simplicial cone. *Circuit:* write the cone as a lattice translate of the free monoid on its extreme rays. This is the same computation seen from above, and it is what you should install as the general theory. It also produces the closed form

$$\sum_{(a,b,c) \in T} x^a y^b z^c = \frac{xyz(1+xyz)}{(1-xy)(1-yz)(1-zx)},$$

of which the problem is the case $(x, y, z) = (2, \frac{1}{3}, \frac{1}{5})$. It ranks alongside the ideal solution rather than above it, because on the day you want the shortest correct page, not the most general one.

The ideal solution

Every term of the sum is positive, so the sum is a well defined element of $[0, \infty]$ and may be reordered and regrouped freely; the computation below produces a finite value, which retrospectively justifies every rearrangement.

Lemma 11.10.1. *The map $\Phi(a,b,c) = (b+c-a,\ c+a-b,\ a+b-c)$ is a bijection from T onto*

$$L = \{(x,y,z) \in \mathbb{Z}^3_{>0} :\ x \equiv y \equiv z \pmod 2\},$$

with inverse $(x,y,z) \mapsto \left(\frac{y+z}{2}, \frac{z+x}{2}, \frac{x+y}{2}\right)$.

Proof. Positive integers a, b, c are the side lengths of an actual triangle exactly when the three strict inequalities $a < b+c$, $b < c+a$, $c < a+b$ hold, that is, exactly when $x, y, z > 0$. If $(a,b,c) \in T$ then x, y, z are integers with $y+z = 2a$, $z+x = 2b$, $x+y = 2c$, so each of the three pairwise sums is even, forcing x, y, z to share a parity; hence $\Phi(T) \subseteq L$. Conversely if $(x,y,z) \in L$ then $y+z$, $z+x$, $x+y$ are even, so the stated inverse produces positive integers a, b, c, and these satisfy the three strict inequalities because $x, y, z > 0$. The two maps are visibly mutually inverse. □

Now rewrite the summand. Under the correspondence,

$$\frac{2^a}{3^b 5^c} = 2^{(y+z)/2}\, 3^{-(z+x)/2}\, 5^{-(x+y)/2},$$

so the sum splits over the two parity classes of L.

All even. Put $x = 2u, y = 2v, z = 2w$ with $u, v, w \geq 1$. Then the exponents are $v + w$, $-(w + u)$, $-(u + v)$ and the term regroups as

$$2^{v+w}3^{-(w+u)}5^{-(u+v)} = \Big(\frac{1}{15}\Big)^u \Big(\frac{2}{5}\Big)^v \Big(\frac{2}{3}\Big)^w.$$

Each of u, v, w now appears in exactly one factor: the sum has become a product.

All odd. Put $x = 2u - 1$, $y = 2v - 1$, $z = 2w - 1$ with $u, v, w \geq 1$. Then the exponents are $v + w - 1$, $-(w + u - 1)$, $-(u + v - 1)$, so the term is $\frac{3\cdot 5}{2}$ times the even term with the same (u, v, w):

$$2^{v+w-1}3^{-(w+u-1)}5^{-(u+v-1)} = \frac{15}{2}\Big(\frac{1}{15}\Big)^u \Big(\frac{2}{5}\Big)^v \Big(\frac{2}{3}\Big)^w.$$

The factor $\frac{15}{2} = 3 \cdot 5 \cdot 2^{-1}$ is not an accident: passing from the even class to the odd class subtracts $(1, 1, 1)$ from (a, b, c), and the weight $2^a 3^{-b} 5^{-c}$ scales by $2^{-1}3^1 5^1$ under that shift.

Therefore, writing Σ for the common product,

$$\sum_{(a,b,c)\in T} \frac{2^a}{3^b 5^c} = \Big(1 + \frac{15}{2}\Big)\Sigma = \frac{17}{2}\,\Sigma,$$

$$\Sigma = \sum_{u\geq 1}\Big(\frac{1}{15}\Big)^u \sum_{v\geq 1}\Big(\frac{2}{5}\Big)^v \sum_{w\geq 1}\Big(\frac{2}{3}\Big)^w = \frac{1/15}{14/15}\cdot\frac{2/5}{3/5}\cdot\frac{2/3}{1/3} = \frac{1}{14}\cdot\frac{2}{3}\cdot 2 = \frac{2}{21}.$$

All three ratios lie in $(0, 1)$, so each series converges and the value is finite. Hence

$$\sum_{(a,b,c)\in T} \frac{2^a}{3^b 5^c} = \frac{17}{2}\cdot\frac{2}{21} = \boxed{\frac{17}{21}}.$$

Finally, 17 is prime and $17 \nmid 21$, so $\gcd(17, 21) = 1$ and $17/21$ is already in lowest terms, as the question demanded.

Layer 1: WHAT

Block 1. Read the summand: it is separable. Read the index set: it is not a product. Conclude that the entire task is a change of index.

Block 2. Note all terms are positive, so no convergence anxiety and no ordering discipline is required; the only risk left is bookkeeping.

Block 3. Translate "there exist triangles" into the three strict inequalities and immediately name their slacks x, y, z.

Block 4. Determine the exact image of the substitution over $\mathbb{Z}$: positive, and all of one parity. Prove it is a bijection, since the whole computation is a transport of the sum along that bijection.

Block 5. Substitute in each parity class, and check that each new variable appears in exactly one base. It does; the sum factorises.

Block 6. Sum three geometric series, multiply by the parity factor $1 + \frac{15}{2}$, and check lowest terms.

Juxtaposition. The nominal route agrees with the ideal route through Block 2 and then diverges. The zombie writes "for fixed b, c we need $|b - c| < a < b + c$" and starts summing 2^a over that interval. He is not wrong; he is committed. From that line onwards he owes a case split on the sign of $b - c$, two double sums, four geometric series and a reindex of the inner limit. The bifurcation point is the exact line where the triangle condition is written down. Write it as an interval for a and you have chosen the long road; write it as three positivity statements about x, y, z and you have chosen the short one. Same fact, two encodings, ten times the ink.

Layer 2: HOW

Block 1. **Cue.** The summand is $2^a 3^{-b} 5^{-c}$, a product of one factor per variable, while the index set couples all three. **Why natural.** A sum of a separable function over a product set equals the product of the one dimensional sums. That is the only closed form mechanism available here, so the strategy is forced: make the index set a product. You do not need inspiration to see this; you need to notice which half of the expression is hard. **Link to the next block.** Having decided to reindex, you next need permission to reindex.

Block 2. **Cue.** All terms are positive. **Why natural.** For nonnegative families, the sum over any index set is the supremum of finite partial sums, so it is independent of order and of grouping. This is the nonnegative case of Tonelli's theorem and it is the reason you may split by parity, substitute, and factor without a single epsilon. **Link to the next block.** With permission secured, choose the coordinates.

Block 3. **Cue.** The command term is "triangle", not "inequality". **Why natural.** A triangle inequality is a statement that a quantity is positive. The natural coordinates for a region cut out by linear inequalities are the linear forms themselves: set each inequality's slack to be a new variable. Geometrically, x, y, z are twice the tangent lengths from the vertices to the incircle, which is why they are positive precisely for genuine triangles and vanish exactly in the degenerate case. This is the Ravi substitution and it is a permanent circuit, not a one off. **Link to the next block.** The substitution is over the reals; you now have to ask what it does over the integers.

Block 4. **Cue.** The inverse formulas carry a 2 in the denominator. **Why natural.** Any time an inverse map divides, integrality becomes a congruence condition. Here $y + z = 2a$ forces $y \equiv z$, and similarly for the other pairs, so all three are congruent modulo 2. Missing this is the only way to get the wrong answer with the right method: you would sum over all positive x, y, z and pick up half integer exponents. **Link to the next block.** The image splits into two classes; handle them by the same substitution.

Block 5. **Cue.** Each parity class is a translate of $2\mathbb{Z}^3_{>0}$. **Why natural.** Reparametrising a lattice coset by $u, v, w \geq 1$ is the standard way to turn a congruence condition into a free index. After substitution, u appears only through $3^{-u}5^{-u}$, v only through $2^v 5^{-v}$, w only through $2^w 3^{-w}$: the exponent map, read in the new coordinates, is diagonal. That diagonality is precisely what the Ravi substitution was bought for. **Link to the next block.** Two classes, identical product, differing by one scalar.

Block 6. **Cue.** The odd class is the even class shifted by $-(1,1,1)$ in (a,b,c) coordinates. **Why natural.** The weight is multiplicative in (a,b,c), so a translation of the index set multiplies the whole sum by the weight of the translation vector. Here that weight is $2^{-1}3^1 5^1 = 15/2$, so the two classes contribute in the ratio $1 : \frac{15}{2}$, and the total factor is $\frac{17}{2}$. You can see the answer's numerator 17 being born here, before you have summed anything. **Link to the next block.** Three geometric series and a gcd sentence finish it.

Layer 3: WHY

The mathematical truth beneath this route is that T is the set of lattice points in the interior of a simplicial cone. In $\mathbb{R}^3$, the conditions $a < b + c$, $b < c + a$, $c < a + b$ cut out the cone spanned by the three vectors

$$g_1 = (0,1,1), \qquad g_2 = (1,0,1), \qquad g_3 = (1,1,0),$$

since $(a,b,c) = \frac{x}{2}g_1 + \frac{y}{2}g_2 + \frac{z}{2}g_3$. A cone spanned by three linearly independent vectors is called simplicial, and the fundamental structural fact is this: if g_1, g_2, g_3 generate a sublattice of finite index m in $\mathbb{Z}^3$, then the lattice points of the cone are the disjoint union of m translates of the free monoid generated by the g_i, one translate for each lattice point of the half open fundamental parallelepiped. Here

$$\det \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} = 2,$$

so the index is 2, the parallelepiped contains exactly two lattice points, and those two translates are precisely the two parity classes. The representative of the nontrivial class is $\frac{1}{2}(g_1+g_2+g_3) = (1,1,1)$, the equilateral triple: the smallest triangle is literally the extra generator you need.

Because the weight $w(a,b,c) = 2^a 3^{-b} 5^{-c}$ is a monoid homomorphism from $(\mathbb{Z}^3, +)$ to $(\mathbb{R}_{>0}, \times)$, summing it over the cone is now automatic:

$$\sum_{(a,b,c)\in T} w = \Big(\sum_{\text{box points } p} w(p) \Big) \prod_{i=1}^{3} \frac{1}{1 - w(g_i)} \quad \text{after the appropriate shift,}$$

and with $w(g_1) = \frac{1}{15}$, $w(g_2) = \frac{2}{5}$, $w(g_3) = \frac{2}{3}$, $w(1,1,1) = \frac{2}{15}$ you get $\frac{2}{21} + \frac{5}{7} = \frac{17}{21}$ a second time. Two independent derivations agreeing is how you should sign off a numerical answer under exam conditions.

The discernment mechanism, stated so you can train it: when a sum's summand is separable and its index set is not, all the work is in the index set, and the only structures whose lattice sums factorise are boxes and simplicial cones. So ask, in this order: (i) is my region a box in disguise? (ii) is it a cone, and what are its extreme rays? (iii) what is the index of the lattice they generate, because that index is the number of extra terms I will have to carry. In this problem the answers are no, yes with rays $(0,1,1), (1,0,1), (1,1,0)$, and 2. The factor $\frac{17}{2}$ and the final 17 are consequences of that index 2.

What the examiners nudged with: they wrote "there exist triangles with side lengths" rather than an inequality, which is a direct instruction to use triangle structure; they chose three distinct prime bases so that no accidental symmetry could rescue a sloppy split; and they asked for lowest terms, which is a quiet reminder that the numerator 17 is a real prime and not a slip. Train the trigger by generalising it: whenever a question restricts to "sides of a triangle", substitute the slacks, even when the question is an inequality rather than a sum, because that is the coordinate system in which the constraint is invisible.

Revolving concepts

Triangle inequality and the Ravi substitution. For positive reals, a, b, c are the sides of a nondegenerate triangle iff $x = b + c - a$, $y = c + a - b$, $z = a + b - c$ are all positive; then x, y, z are twice the tangent lengths from the vertices to the incircle, $x + y + z = a + b + c$, and $s - a = x/2$ where s is the semiperimeter. Over $\mathbb{Z}$ the image is exactly the positive triples of equal parity. Heron's formula becomes $16K^2 = (x+y+z)xyz$, which is the reason Ravi trivialises most triangle inequalities. See Book 1, field: Geometry, topic: triangle inequality and Ravi substitution.

Simplicial cones and lattice points. A cone generated by linearly independent $g_1, \dots, g_d \in \mathbb{Z}^d$ meets $\mathbb{Z}^d$ in $|\det(g_i)|$ translates of $\mathbb{Z}_{\geq 0}g_1 + \cdots + \mathbb{Z}_{\geq 0}g_d$; the translates are indexed by the lattice points of the half open parallelepiped. This is the elementary core of Ehrhart theory and of Stanley's theory of cone generating functions. See Book 1, field: Generating functions, topic: cone decompositions.

Geometric series as the simplest recursion. $\sum_{n\geq 1} r^n = \frac{r}{1-r}$ for $|r| < 1$ is the solved case of the first order linear recursion $x_{n+1} = rx_n$. The generalised recursion you should carry is $x_{n+1} = rx_n + s$: its fixed point is $x^* = s/(1-r)$ when $r \neq 1$, the substitution $y_n = x_n - x^*$ makes it homogeneous,

and hence $x_n = (x_0 - x^*)r^n + x^*$. Every multivariable geometric sum in this problem is a product of solved first order recursions, one per extreme ray, and that is exactly why the cone had to be simplicial: one generator, one recursion. See Book 1, field: Sequences and recurrences, topic: first order linear recurrences.

Nonnegative rearrangement. For $f : I \to [0, \infty]$, $\sum_{i \in I} f(i) := \sup\{\sum_{i \in F} f(i) : F \subseteq I \text{ finite}\}$ is independent of any ordering, and iterated sums over a product index set agree with the double sum. This is Tonelli for counting measure and it is the licence used three times above. Contrast with conditionally convergent series, where reordering can produce any value. See Book 1, field: Real analysis, topic: Tonelli and unordered summation.

Lowest terms. A rational is in lowest terms when numerator and denominator are coprime; here 17 is prime and does not divide 21. Cheap to say, and the question explicitly asks for it. See Book 1, field: Number theory, topic: gcd and reduced fractions.

Circuit Bank

- **WHEN** a sum or an inequality whose hypothesis is "a, b, c are the sides of a triangle" **DO** substitute $x = b + c - a$, $y = c + a - b$, $z = a + b - c$ and record "positive, and over $\mathbb{Z}$ all of one parity" **BECAUSE** the triangle conditions are three linear inequalities and their slacks are coordinates in which the constraint set is an orthant, which is the only shape a separable sum can be summed over
- **WHEN** a separable summand over a coupled index set **DO** spend your effort exclusively on reindexing, not on the summand **BECAUSE** a separable function over a product set factorises instantly, so the entire difficulty is the geometry of the index set
- **WHEN** a modulus such as $|b - c|$ inside a constraint **DO** look for a change of variables that removes it rather than splitting into cases **BECAUSE** each case split doubles the ink and each half carries its own reindexing risk, and a modulus is usually the shadow of a badly chosen coordinate
- **WHEN** a substitution whose inverse involves division **DO** immediately compute the image lattice and state the congruence condition **BECAUSE** integrality is preserved forwards but not backwards, and the congruence classes are exactly the extra terms you must carry
- **WHEN** an index set that is a lattice cone **DO** find the extreme rays, compute the determinant of the generator matrix, and expect that many box terms **BECAUSE** the determinant is the index of the sublattice, and the number of box points is the number of geometric products you will have to add
- **WHEN** the phrase "as a rational number in lowest terms" **DO** finish with an explicit gcd sentence **BECAUSE** it costs one line and it is a marked instruction

Backtesting

1. First useful cue: the phrase "there exist triangles with side lengths a, b, c", paired with the observation that the summand is separable while the index set is not.
2. Method the expression suggested: transport the sum along the Ravi bijection into coordinates where the constraint becomes an orthant, then sum three independent geometric series.
3. Where you would hesitate, and the thought to reinforce: at the parity condition. The hesitation is "is the substitution onto?". Reinforce with the sentence "an inverse that divides by 2 always leaves a congruence behind", and check the image explicitly before summing anything.

4. The trap the question sets: two traps. The obvious one is the modulus $|b-c|$ that appears if you sum over a first, which costs a case split. The lethal one is forgetting parity, which gives a clean looking but wrong product with half integer exponents.
5. What makes you recognise it faster next time: the shape "separable summand, cone index set". Once seen, the reflex is to name the extreme rays and the sublattice index before writing a single series.
6. The reusable decision rule: when a constraint is a system of linear inequalities, make its slacks your coordinates; the sum then factorises up to a finite correction of size $|\det|$.

Mirror drills

1. For positive reals with $|xy|, |yz|, |zx| < 1$, prove $\sum_{(a,b,c)\in T} x^a y^b z^c = \dfrac{xyz(1+xyz)}{(1-xy)(1-yz)(1-zx)}$, and check that $(x,y,z) = (2, \frac{1}{3}, \frac{1}{5})$ returns $17/21$. *Answer:* the extreme rays $(0,1,1), (1,0,1), (1,1,0)$ carry weights yz, zx, xy and the single nontrivial box point $(1,1,1)$ carries weight xyz; sum the two translates and add.
2. Evaluate $\sum_{(a,b,c)\in T} 2^{-(a+b+c)}$. *Answer:* put $x = y = z = \frac{1}{2}$ in the drill above: $\dfrac{(1/8)(9/8)}{(3/4)^3} = \dfrac{9/64}{27/64} = \dfrac{1}{3}$.
3. Show that the number of ordered triples $(a,b,c) \in T$ with $a+b+c = 2n$ is $\binom{n-1}{2}$. *Answer:* $x+y+z = 2n$ is even, so the all odd class is impossible; write $x = 2u$, $y = 2v$, $z = 2w$ with $u, v, w \geq 1$ and $u+v+w = n$, giving $\binom{n-1}{2}$ compositions.

11.11 B5. Key permutations and a shift operator annihilator

Let P_n be the number of permutations π of $\{1, 2, \ldots, n\}$ such that

$$|i - j| = 1 \text{ implies } |\pi(i) - \pi(j)| \leq 2$$

for all i, j in $\{1, 2, \ldots, n\}$. Show that for $n \geq 2$, the quantity

$$P_{n+5} - P_{n+4} - P_{n+3} + P_n$$

does not depend on n, and find its value.

Read it out loud

Write the permutation as the word $\pi(1)\pi(2)\cdots\pi(n)$. Then $|i - j| = 1$ says "i and j are consecutive positions", so the condition says: consecutive letters of the word differ by at most 2. That is not a permutation condition at all; it is an edge condition. So P_n counts the words that list $1, \ldots, n$ walking along the graph G_n on the vertex set $\{1, \ldots, n\}$ in which i and j are joined exactly when $0 < |i - j| \leq 2$. In one sentence: P_n is the number of directed Hamiltonian paths in the square of a path. Say that out loud and the fields declare themselves: graph theory for the structure, combinatorics for the bijections, and the theory of linear recurrences with constant coefficients for the endgame.

Now read the thing you are asked to prove, because it is the single largest cue on the page. You are told that $P_{n+5} - P_{n+4} - P_{n+3} + P_n$ is constant. In shift operator language, with $(Ex)_n = x_{n+1}$, you are told that

$$(E^5 - E^4 - E^3 + 1)P = \text{constant},$$

and you should factorise that polynomial before you count a single permutation:

$$x^5 - x^4 - x^3 + 1 = (x - 1)(x + 1)(x^3 - x^2 - 1).$$

That is a map of the whole solution. It says: somewhere inside there is a sequence obeying $u_m = u_{m-1} + u_{m-3}$ up to an additive constant, the constant is handled by the factor $(x - 1)$, and there is a factor of 2 floating about (the root -1) that will turn out to be the reversal symmetry. You now know what you are hunting for. That is worth more than any amount of enumeration.

The first move to write down within thirty seconds is the degree observation: in G_n the vertex n has neighbours $n - 1$ and $n - 2$ only, and $n - 1$ has neighbours $n - 3, n - 2, n$ only. Extremes are rigid. In a graph whose edges are "close in value", the largest and smallest values have the fewest options, so they are where the structure is, and deleting the largest value is the natural induction.

Approaches, ranked worst to best

1. **Compute and guess.** *Cue:* "find its value". *Circuit:* tabulate, fit, assert. Enumerate $P_n = 1, 2, 6, 12, 20, 34, 56, 88, 136, 208$, notice the combination is 4, and write "hence the value is 4". On the Putnam that is one point at best. You have not shown independence of n; you have observed it. It ranks last because it is not an argument, and because it tempts you to stop.

2. **Subset transfer matrix.** *Cue:* a permutation built left to right. *Circuit:* dynamic programming over the set of used values. You track which values have been used and the last value. The state space has size $2^n \cdot n$; it computes P_n but proves nothing about a fifth order recurrence. It stalls because the state is unbounded, and an unbounded state can never produce a fixed order linear recurrence.

3. **Split by the position of the smallest values.** *Cue:* 1 has only two neighbours, 2 and 3. *Circuit:* condition on where 1 sits and peel. Count $P_n = 2P'_n$ where P'_n has 1 before 2, then split P'_n by whether the word starts with 1. This works, and yields $Q'_n = Q'_{n-1} + Q'_{n-3} + 1$ together with $R'_n = R'_{n-1} + Q'_{n-2}$. It ranks third because the second recursion needs a delicate case analysis of where the letter 4 can sit, and losing one case there loses the problem silently.
4. **Delete the largest letter and classify the top.** *Cue:* n has exactly two possible neighbours, so deletion cannot break the word. *Circuit:* peel the most constrained element and let the fibre of the peeling map define your state space. Deleting n always leaves a legal word, so the counting is governed by how many legal slots a word of length n offers the letter $n+1$; that number depends only on how n and $n-1$ sit relative to each other and to the two ends. Enumerating those configurations is forced, and there are exactly five. This is the ideal route: the state space is discovered rather than guessed.
5. **Generating function.** *Cue:* a linear recurrence with constant coefficients. *Circuit:* sum the state vector recursion into a rational function. Once you have the five state transfer, $\sum P_n x^n$ is rational with denominator $(1-x)(1-x^2)(1-x-x^3)$ and the assertion follows by clearing denominators. It is the same mathematics as the ideal route with more bookkeeping, so it is a good check and a poor first draft.

The ideal solution

Throughout, identify a permutation π with the word $\pi(1)\pi(2)\cdots\pi(n)$, and let $\mathcal{P}_n$ be the set of words listing $1,\dots,n$ in which consecutive letters differ by at most 2; so $P_n = |\mathcal{P}_n|$. Equivalently $\mathcal{P}_n$ is the set of directed Hamiltonian paths of the graph G_n on $\{1,\dots,n\}$ with $i \sim j$ iff $0 < |i-j| \le 2$. Reversal is an involution on $\mathcal{P}_n$ without fixed points for $n \ge 2$, so

$$P_n = 2\Sigma_n, \qquad \Sigma_n := \#\{\text{undirected Hamiltonian paths of } G_n\}.$$

Lemma 11.11.1 (Deletion)**.** *For $n \ge 3$, deleting the letter n from a word in $\mathcal{P}_n$ leaves a word in $\mathcal{P}_{n-1}$.*

Proof. The neighbours of n in G_n are $n-1$ and $n-2$ and nothing else. If n is at an end of the word, deleting it changes no consecutive pair. If n is interior, its two word neighbours lie in $\{n-1, n-2\}$, hence are $n-1$ and $n-2$ in some order; closing the gap creates the new consecutive pair $(n-1, n-2)$, whose difference is $1 \le 2$. All other pairs are untouched. □

Lemma 11.11.2 (Insertion slots)**.** *Let $n \ge 3$ and $\sigma \in \mathcal{P}_n$. Every word of $\mathcal{P}_{n+1}$ arises from exactly one $\sigma \in \mathcal{P}_n$ by inserting the letter $n+1$, and the legal slots in σ are: before the first letter if $\sigma(1) \in \{n-1, n\}$; after the last letter if $\sigma(n) \in \{n-1, n\}$; and between two adjacent letters that are n and $n-1$ in either order. Hence*

$$P_{n+1} = \sum_{\sigma \in \mathcal{P}_n} c(\sigma), \quad c(\sigma) = [\sigma(1) \in \{n-1, n\}] + [\sigma(n) \in \{n-1, n\}] + [\,n \text{ and } n-1 \text{ adjacent in } \sigma\,].$$

Proof. By the previous lemma deletion maps $\mathcal{P}_{n+1}$ to $\mathcal{P}_n$, and inserting $n+1$ back into the slot it came from inverts it, so the fibres are exactly the sets of legal slots. A slot is legal precisely when every new consecutive pair it creates is legal, and the only neighbours of $n+1$ are n and $n-1$; at an end that is one condition, in the interior it is two. □

So the entire problem reduces to a question with a finite answer: how can n and $n-1$ sit inside a word of $\mathcal{P}_n$? Since n has only two possible neighbours, the list is short.

Lemma 11.11.3 (Top configurations)**.** *Let $n \ge 3$ and let p be an undirected Hamiltonian path of G_n. Exactly one of the following holds, and in each case exactly one of the two words representing p has the stated shape.*

(U) *the word ends* $\dots, n-1, n$;

(V) *the word ends* $\dots, n-2, n, n-1$;

(W) *the word is* $n-1, \dots, n-2, n$, *that is, it ends* $\dots, n-2, n$ *and begins with* $n-1$;

(T) *the word ends* $\dots, n-3, n-1, n-2, n$;

(S) *both* n *and* $n-1$ *are interior and the word contains* $\dots, n-1, n, n-2, \dots$.

Writing U_n, V_n, W_n, T_n, S_n *for the number of paths of each type,* $\Sigma_n = U_n + V_n + W_n + T_n + S_n$.

Proof. The path neighbours of n lie in $\{n-1, n-2\}$.

If n is an endpoint of p it has one path neighbour. If that neighbour is $n-1$ we are in case (U). If it is $n-2$, consider $n-1$, whose path neighbours lie in $\{n-3, n-2, n\}$; the value n is unavailable, since n's only path neighbour is $n-2$. If $n-1$ is the other endpoint of p we are in case (W). Otherwise $n-1$ is interior with path neighbours exactly $n-3$ and $n-2$; then $n-2$ is interior with path neighbours $n-1$ and n, so the path terminates $\dots, n-3, n-1, n-2, n$, which is case (T).

If n is interior its two path neighbours are exactly $n-1$ and $n-2$. If $n-1$ is an endpoint of p, orient the word to finish at $n-1$ and it ends $\dots, n-2, n, n-1$, which is case (V). If $n-1$ is interior we are in case (S).

The five cases are mutually exclusive: (U),(W),(T) have n as an endpoint and (V),(S) have n interior; among the first three, (U) is separated by the neighbour of n and (W),(T) by whether $n-1$ is an endpoint; among the last two, by whether $n-1$ is an endpoint. Finally the orientation is forced in each case: in (U),(W),(T) the word must terminate at n; in (V) it must terminate at $n-1$; in (S) both $n, n-1$ are interior and they are adjacent, so exactly one of the two orientations reads $n-1$ then n. □

Lemma 11.11.4 (Transfer)**.** *For* $n \geq 3$,

$$U_{n+1} = U_n + W_n + T_n, \quad V_{n+1} = U_n, \quad W_{n+1} = W_n, \quad T_{n+1} = V_n, \quad S_{n+1} = S_n + V_n.$$

Proof. Take a word of $\mathcal{P}_{n+1}$ in each class and delete the letter $n+1$; the classification lemma applied at level n says what must remain, and the insertion lemma says the correspondence is a bijection.

(U) at level $n+1$: the word ends $\dots, n, n+1$. Deleting $n+1$ leaves a word of $\mathcal{P}_n$ ending in n, which by the classification is of type (U), (W) or (T); conversely appending $n+1$ to any word ending in n is legal and lands in (U). Hence $U_{n+1} = U_n + W_n + T_n$.

(V) at level $n+1$: the word ends $\dots, n-1, n+1, n$. Deleting leaves a word ending $\dots, n-1, n$, type (U); conversely insert $n+1$ between the final $n-1$ and n. Hence $V_{n+1} = U_n$.

(W) at level $n+1$: the word is $n, \dots, n-1, n+1$. Deleting leaves $\sigma \in \mathcal{P}_n$ beginning with n and ending with $n-1$. Since σ begins with n, its second letter is $n-1$ or $n-2$; it cannot be $n-1$, which is the last letter and $n \geq 3$. So σ begins $n, n-2$, hence its reverse ends $\dots, n-2, n$ and begins with $n-1$: type (W). Conversely reverse a (W) word and append $n+1$. Hence $W_{n+1} = W_n$.

(T) at level $n+1$: the word ends $\dots, n-2, n, n-1, n+1$. Deleting leaves a word ending $\dots, n-2, n, n-1$, type (V); conversely append $n+1$ to a (V) word, which is legal since $|(n-1) - (n+1)| = 2$. Hence $T_{n+1} = V_n$.

(S) at level $n+1$: both $n+1$ and n are interior and the word contains $\dots, n, n+1, n-1, \dots$. Deleting $n+1$ leaves a word containing $\dots, n, n-1, \dots$ with n interior. If $n-1$ is now an endpoint it must be the final letter, and the word is of type (V); if $n-1$ is interior, then reversing gives a word with $n-1, n$ adjacent in that order and both interior, that is type (S). The two sub cases are distinguished by whether $n-1$ is the final letter, so they are disjoint, and both insertions are legal and land in (S). Hence $S_{n+1} = S_n + V_n$. □

At $n = 3$ all six words are legal, and $U_3 = V_3 = W_3 = 1$, $T_3 = S_3 = 0$, so $\Sigma_3 = 3$ and $P_3 = 6$. In particular $W_3 = 1$, and $W_{n+1} = W_n$ gives

$$W_n = 1 \quad \text{for all } n \geq 3.$$

Adding the five transfer identities,

$$\Sigma_{n+1} = (U_n + W_n + T_n) + U_n + W_n + V_n + (S_n + V_n) = \Sigma_n + U_n + V_n + W_n,$$

so, writing $d_n := \Sigma_{n+1} - \Sigma_n$,

$$d_n = U_n + V_n + 1 \qquad (n \geq 3). \tag{1}$$

Next, collapse the five sequences to one. Set $U_1 := 0$ and $U_2 := 1$; then $V_n = U_{n-1}$ and $T_n = V_{n-1} = U_{n-2}$ hold for all $n \geq 3$ (for $n \geq 4$ they are the transfer identities, and at $n = 3$ they read $V_3 = U_2 = 1$ and $T_3 = U_1 = 0$, which is correct). Substituting into the first transfer identity,

$$U_{n+1} = U_n + W_n + T_n = U_n + U_{n-2} + 1 \qquad (n \geq 3),$$

and the case $n = 3$ reads $U_4 = U_3 + U_1 + 1 = 2$, which is correct. Thus

$$U_m = U_{m-1} + U_{m-3} + 1 \qquad (m \geq 4), \qquad U_1 = 0,\ U_2 = 1,\ U_3 = 1. \tag{2}$$

By (1) and $V_n = U_{n-1}$, $d_n = U_n + U_{n-1} + 1$ for $n \geq 3$. Now compute, for $n \geq 3$,

$$\begin{aligned} d_{n+4} - d_{n+2} - d_{n+1} - d_n &= U_{n+4} + U_{n+3} - U_{n+2} - 2U_{n+1} - 2U_n - U_{n-1} - 2 \\ &= 2U_{n+3} - U_{n+2} - U_{n+1} - 2U_n - U_{n-1} - 1 \\ &= U_{n+2} - U_{n+1} - U_{n-1} + 1 \\ &= 2, \end{aligned}$$

where the three simplifications used (2) in the forms $U_{n+4} = U_{n+3} + U_{n+1} + 1$, then $U_{n+3} = U_{n+2} + U_n + 1$, then $U_{n+2} = U_{n+1} + U_{n-1} + 1$. Since

$$\Sigma_{n+5} - \Sigma_{n+4} - \Sigma_{n+3} + \Sigma_n = d_{n+4} - (d_{n+2} + d_{n+1} + d_n),$$

we get $\Sigma_{n+5} - \Sigma_{n+4} - \Sigma_{n+3} + \Sigma_n = 2$, hence

$$P_{n+5} - P_{n+4} - P_{n+3} + P_n = 4 \qquad (n \geq 3).$$

It remains to treat $n = 2$ by hand. Both words of length 2 are legal, so $P_2 = 2$. From $\Sigma_3 = 3$ and the transfer identities one gets the table

n	3	4	5	6	7	8	9
U_n	1	2	4	6	9	14	21
V_n	1	1	2	4	6	9	14
W_n	1	1	1	1	1	1	1
T_n	0	1	1	2	4	6	9
S_n	0	1	2	4	8	14	23
Σ_n	3	6	10	17	28	44	68
P_n	6	12	20	34	56	88	136

so $P_7 - P_6 - P_5 + P_2 = 56 - 34 - 20 + 2 = 4$ as well. Therefore the quantity is independent of n for all $n \geq 2$ and its value is

$$\boxed{4}.$$

Layer 1: WHAT

Block 1. Rewrite the condition as "consecutive letters differ by at most 2", that is, as a Hamiltonian path count in G_n.

Block 2. Factorise the target operator $x^5 - x^4 - x^3 + 1 = (x-1)(x+1)(x^3 - x^2 - 1)$ and record the prediction: a hidden sequence with $u_m = u_{m-1} + u_{m-3} + \text{const}$, plus a factor of 2 from a symmetry.

Block 3. Use reversal to halve the count: $P_n = 2\Sigma_n$.

Block 4. Observe that n has only two neighbours, so deleting n never breaks a word. Deletion is therefore a map $\mathcal{P}_{n+1} \to \mathcal{P}_n$ whose fibres are the legal insertion slots.

Block 5. Read off which data the slot count depends on: the first letter, the last letter, and whether n and $n-1$ are adjacent. That is the state.

Block 6. Enumerate the possible top configurations. There are exactly five, and the enumeration is forced by the degree of n.

Block 7. Write the five transfer identities by deletion, note $W_n = 1$, and collapse to the single recursion $U_m = U_{m-1} + U_{m-3} + 1$.

Block 8. Do the annihilator algebra, get 2 for Σ and 4 for P, and dispose of $n = 2$ by direct computation.

Juxtaposition. The nominal route agrees with Block 1 and then goes straight to counting: tabulate P_n, spot 4, attempt to justify a fifth order recurrence by "the structure is clearly eventually periodic". The bifurcation point is the line immediately after the graph reformulation. The zombie asks "what is P_n?". The ideal asks "what does P_{n+1} know about P_n, and what is the smallest amount of information about a word that determines its contribution?". The second question has a bounded answer and therefore a proof; the first does not.

Layer 2: HOW

Block 1. **Cue.** $|i-j| = 1$ appears as a hypothesis on positions. **Why natural.** Positions differing by 1 are consecutive letters of the word, so the hypothesis is about adjacency, not about the permutation as a function. Once you translate "adjacent positions carry values within 2" into "the word is a walk on a graph whose edges are value pairs within 2", you gain endpoints, degrees, interiors and deletion, none of which exist in permutation language. **Link to the next block.** A graph reading immediately invites you to look at vertices of small degree.

Block 2. **Cue.** The problem hands you a specific linear combination and asserts it is constant. **Why natural.** A statement of the form "$L(P)$ is constant for a fixed linear combination L" is a statement that a particular polynomial in the shift operator annihilates P up to a constant. Factorising that polynomial costs one minute and tells you which recursions to hunt for. Here the cubic factor $x^3 - x^2 - 1$ is the fingerprint of $u_m = u_{m-1} + u_{m-3}$, the linear factor $x - 1$ absorbs an additive constant, and $x + 1$ is the parity artefact of a doubling. **Link to the next block.** Knowing you need a 2 and a cubic, look for the symmetry that supplies the 2.

Block 3. **Cue.** The defining condition is symmetric under reversing the word. **Why natural.** Reversal preserves the set of consecutive pairs, so it acts on $\mathcal{P}_n$; it has no fixed point for $n \geq 2$ because the first and last letters differ. A fixed point free involution partitions the set into pairs, so counting orbits halves the case analysis for the rest of the argument. This is where the factor $x + 1$ in the annihilator comes from. **Link to the next block.** With orbits as the objects, ask which orbit invariants control the induction.

Block 4. **Cue.** In G_n the vertex n has degree 2. **Why natural.** Deleting a vertex of a path normally destroys it, but if the deleted vertex's only possible neighbours are themselves adjacent, the path closes up. That is exactly the situation for n, whose neighbours $n-1$ and $n-2$ differ by 1. So deletion is total, which is the strongest possible form of an induction step: no exceptional cases. **Link to the next block.** If deletion is total, counting is fibre counting.

Block 5. **Cue.** The letter $n+1$ can only sit next to n and $n-1$. **Why natural.** The number of legal slots is therefore determined by three yes or no questions about σ: is the first letter in $\{n-1, n\}$, is

the last letter in $\{n-1, n\}$, are n and $n-1$ adjacent. A bounded question set is a bounded state space, and a bounded state space is exactly what produces a fixed order linear recurrence. This is the moment the fifth order recurrence in the question becomes believable. **Link to the next block.** Enumerate the states.

Block 6. **Cue.** n is either an endpoint or interior, and its neighbours are forced. **Why natural.** The case tree has depth two: first ask whether n is an endpoint, then ask where $n-1$ is. Because $n-1$ also has small degree, each branch collapses to a single shape. There is no creativity here at all; it is an exhaustive search over a two level tree, which is why five classes is the answer rather than some number you had to be clever to find. **Link to the next block.** Each class must now be pushed forwards.

Block 7. **Cue.** Every word at level $n+1$ has a unique parent at level n. **Why natural.** So prove the recurrences backwards, by deletion, not forwards by insertion. Deletion is deterministic and the class of the parent is forced by the shape of the child; insertion requires you to argue that you have found every child, which is where cases get lost. Writing the argument in the deletion direction is a proof craft decision, not a mathematical one, and it is worth several marks. **Link to the next block.** Five sequences, but four of them are shifts of one.

Block 8. **Cue.** $V_n = U_{n-1}$, $T_n = V_{n-1}$, $W_n = 1$. **Why natural.** Three of the five transfer identities are pure shifts, so the system has rank far below five. Substituting them into the identity for U produces $U_{n+1} = U_n + U_{n-2} + 1$, exactly the cubic predicted in Block 2. Then $\Sigma_{n+1} - \Sigma_n = U_n + U_{n-1} + 1$, and the requested combination is a telescoping of these first differences. The final algebra is three substitutions and it must land on a constant, because Block 2 said so. **Link to the next block.** Only the smallest index remains, and it is cheaper to check than to argue.

Layer 3: WHY

The mathematics beneath this route is the theory of linear recurrences read through the shift operator. Write E for the shift, $(Ex)_n = x_{n+1}$, and $\mathbf{1}$ for the constant sequence 1. Identity (2) says

$$(E^3 - E^2 - 1)U = \mathbf{1},$$

and identity (1) with $V_n = U_{n-1}$ says $E(E-1)\Sigma = (E+1)U + \mathbf{1}$. Apply $E^3 - E^2 - 1$ to the second and use the first, remembering that any polynomial $q(E)$ acts on $\mathbf{1}$ by multiplication by $q(1)$:

$$(E^3 - E^2 - 1)E(E-1)\Sigma = (E+1)\mathbf{1} + (1 - 1 - 1)\mathbf{1} = 2\mathbf{1} - \mathbf{1} = \mathbf{1}.$$

Cancelling the harmless E and multiplying by $(E+1)$,

$$(E-1)(E+1)(E^3 - E^2 - 1)\,\Sigma = (E+1)\mathbf{1} = 2\mathbf{1},$$

which is precisely $\Sigma_{n+5} - \Sigma_{n+4} - \Sigma_{n+3} + \Sigma_n = 2$, hence 4 for P. So the examiners' combination is not arbitrary at all: it is the product of the three natural annihilators, one for the intrinsic growth, one for the constant inhomogeneity, one for the reversal doubling.

Two consequences worth carrying away. First, the sharper statement is one order lower: cancelling the $(E+1)$ gives

$$P_{n+4} - 2P_{n+3} + P_{n+2} - P_{n+1} + P_n = 2,$$

which you can check on the table above at $n = 2$: $34 - 40 + 12 - 6 + 2 = 2$. The examiners preferred the fifth order form because all its coefficients are ± 1 and it looks like a competition statement; the fourth order form is the mathematically primitive one. Second, the growth rate. Substituting $U_m = v_m - 1$ into (2) gives the homogeneous $v_m = v_{m-1} + v_{m-3}$, so P_n grows like ψ^n where $\psi \approx 1.46557$

is the real root of $x^3 = x^2 + 1$, the supergolden ratio. The ratios 208/136, 314/208, 470/314, ... visibly settle towards it. That substitution is the general method: an inhomogeneous constant is removed by shifting to the constant particular solution, which exists precisely because 1 is not a root of $x^3 - x^2 - 1$.

The discernment mechanism has three parts, and each is trainable. (i) Read the target as an operator and factorise it first. A competition problem that hands you a specific linear combination is telling you the characteristic polynomial; refusing to look at it is refusing a free map. (ii) In any structure built on $\{1, \ldots, n\}$ with a locality constraint, peel the extreme element, because extremes have the smallest neighbourhoods and therefore the most rigid behaviour. Ask "does deleting it always leave a legal object?"; here the answer is yes precisely because $n-1$ and $n-2$ are themselves adjacent. (iii) Let the state space be discovered by the peeling rule rather than guessed. Write down the fibre size $c(\sigma)$ of the deletion map, see which features of σ it mentions, and define your classes to be exactly the equivalence classes of those features. You will never enumerate five classes by intuition; you will always enumerate them by asking what the insertion rule needs to know.

The nudges the examiners planted: the bound 2 rather than 1 (with 1 the answer is trivially 2 permutations for every n, so 2 is the smallest interesting threshold); the phrase "does not depend on n", which is a licence to prove a recurrence rather than a formula; and the range $n \geq 2$, which is a warning that the general argument will start at $n = 3$ and that the boundary case must be checked separately. These permutations are known in the literature as key permutations and the counting sequence is A003274 in the OEIS, but nothing in the solution needs that.

Revolving concepts

Hamiltonian paths in the square of a path. For a graph H, the square H^2 joins vertices at distance at most 2. Here $G_n = P_n^2$ where P_n is the path $1, 2, \ldots, n$. Degrees: the vertices 1 and n have degree 2, the vertices 2 and $n-1$ have degree 3, all others degree 4. The cut between $\{1, \ldots, k\}$ and $\{k+1, \ldots, n\}$ has only three edges, which is the structural reason a Hamiltonian path can cross it at most three times and hence why the count is so rigid. See Book 1, field: Discrete structures and graphs, topic: Hamiltonian paths and powers of paths.

Deletion and insertion bijections. The technique: find an element whose removal always yields a valid smaller object, then count the fibre of the removal map. The fibre size is the number of legal reinsertions, and the classes on which it is constant form the state space. This is the combinatorial version of a transfer matrix, and it is how almost every "prove the count satisfies a linear recurrence" problem is meant to be attacked. See Book 1, field: Combinatorics, topic: deletion and insertion arguments.

Fixed point free involutions. If a finite set carries an involution with no fixed points, its cardinality is twice the number of orbits. Reversal on $\mathcal{P}_n$ is such an involution for $n \geq 2$. Recognising the involution before the case analysis, not after, is what keeps the classification to five cases rather than ten. See Book 1, field: Combinatorics, topic: involutions and orbit counting.

Linear recurrences and the shift operator. With $(Ex)_n = x_{n+1}$, a linear recurrence with constant coefficients is a statement $q(E)x = 0$ or $q(E)x = f$. Key facts: $q(E)$ acts on the constant sequence $\mathbf{1}$ by multiplication by $q(1)$; polynomials in E commute, so annihilators may be applied in any order; the general homogeneous solution is spanned by $n^j\lambda^n$ over the roots λ of q with multiplicity; and an inhomogeneous constant $f = c\mathbf{1}$ has the constant particular solution $c/q(1)$ provided $q(1) \neq 0$.

Generalised recursion. The recursion appearing here is $u_m = u_{m-1} + u_{m-3} + 1$ with $u_1 = 0, u_2 = 1, u_3 = 1$. Substituting $u_m = v_m - 1$ gives $v_m = v_{m-1} + v_{m-3}$, the Narayana recursion, whose characteristic equation $x^3 = x^2 + 1$ has one real root $\psi \approx 1.46557$ (the supergolden ratio) and a conjugate pair of modulus less than 1; hence $u_m = C\psi^m + O(1)$. The same substitution solves every $u_m = \sum_i a_i u_{m-i} + c$ with $\sum a_i \neq 1$, and when $\sum a_i = 1$ the particular solution is linear in m instead, because 1 is then a root and the annihilator acquires a repeated factor $(E-1)^2$. See Book 1, field: Sequences and recurrences, topic: constant coefficient recurrences and annihilators.

Rational generating functions. A sequence satisfies a constant coefficient linear recurrence iff its generating function is rational with denominator the reversed characteristic polynomial. Here $\sum_{n\geq 2} P_n x^n$ has denominator $(1-x)(1-x^2)(1-x-x^3)$, and the three factors are the same three annihilators seen once more. See Book 1, field: Generating functions, topic: rational generating functions.

Circuit Bank

- **WHEN** a permutation condition that only constrains neighbouring positions **DO** redraw it as a Hamiltonian path count in a graph on the values **BECAUSE** "$|i-j|=1$" means "consecutive in the word", so the condition is an edge condition, and graph language hands you endpoints, degrees and deletion for free
- **WHEN** a problem that hands you a specific linear combination and asserts it is constant **DO** factorise the corresponding characteristic polynomial before counting anything **BECAUSE** the factors are a map of the solution: each one names a recursion, a symmetry or an inhomogeneity you must find
- **WHEN** a counting problem on $\{1,\ldots,n\}$ with a locality constraint **DO** peel the largest or smallest element and check whether deletion is total **BECAUSE** extremes have the smallest neighbourhoods, and deletion is total exactly when the possible neighbours of the peeled element are themselves mutually adjacent
- **WHEN** a deletion map whose fibre size you can write down **DO** define your state space to be the features of the object that the fibre size mentions, and nothing else **BECAUSE** a bounded feature list is a bounded state space, which is precisely what forces a fixed order linear recurrence
- **WHEN** a recurrence to prove between two levels **DO** argue in the deletion direction, from level $n+1$ down to level n **BECAUSE** deletion is deterministic and forces the parent's shape, whereas insertion obliges you to prove you have found every child, which is where cases go missing
- **WHEN** a linear recurrence with a constant inhomogeneous term and $q(1)\neq 0$ **DO** shift by the constant particular solution $c/q(1)$ **BECAUSE** the shifted sequence is homogeneous, so the characteristic polynomial applies directly and the growth rate becomes visible
- **WHEN** a general argument that only starts at $n=3$ but a claim asserted from $n=2$ **DO** check the boundary index by direct computation and say so **BECAUSE** a boundary case is cheaper to verify than to force the general machinery to cover, and leaving it unmentioned is a marked omission

Backtesting

1. First useful cue: "$|i-j|=1$ implies $|\pi(i)-\pi(j)|\leq 2$" read as an adjacency condition, together with the observation that the vertex n has only two neighbours.
2. Method the expression suggested: factorise $x^5-x^4-x^3+1=(x-1)(x+1)(x^3-x^2-1)$, then hunt for a state recursion of the shape $u_m = u_{m-1}+u_{m-3}+\text{const}$ and a symmetry supplying the factor 2.
3. Where you would hesitate, and the thought to reinforce: at the classification of top configurations, where it feels as if you might have missed a case. Reinforce with "the case tree is forced: is n an endpoint, then where is $n-1$", and note that n has degree 2 so there is nothing else to ask.

4. The trap the question sets: computing the numbers, seeing 4, and writing an answer that never proves independence of n. A second trap is starting the induction at $n = 2$ and quietly using identities that only hold from $n = 3$.
5. What makes you recognise it faster next time: the pairing of a locality constraint with a requested linear combination. That pairing always means transfer matrix, and the requested combination is the characteristic polynomial handed to you in advance.
6. The reusable decision rule: let the peeling map define the state space. Write the fibre size, list the features it depends on, enumerate those features exhaustively, and transfer.

Mirror drills

1. Let Q_n count the permutations with $|i - j| = 1 \Rightarrow |\pi(i) - \pi(j)| \leq 1$. Find Q_n. *Answer:* G_n becomes the path itself, whose only Hamiltonian paths are the two monotone orders, so $Q_n = 2$ for $n \geq 2$. This shows why the bound 2 is the smallest interesting threshold.
2. Let E_n be the number of words in $\mathcal{P}_n$ beginning with the letter 1. Show $E_n = E_{n-1} + E_{n-3} + 1$ for $n \geq 4$, with $E_1 = E_2 = 1$ and $E_3 = 2$. *Answer:* the second letter is 2 or 3. If 2, delete the leading 1 and shift down. If 3 and the third letter is 2, the fourth is forced to be 4, so delete $1, 3, 2$ and shift by 3. Otherwise 2 must be the final letter preceded by 4, and the remainder is the unique Hamiltonian path of G on $\{4, \ldots, n\}$ from 5 to 4, giving the single word $1, 3, 5, \ldots, 6, 4, 2$.
3. Prove that in G_m there is exactly one Hamiltonian path from 2 to 1, and deduce $\lim_{n\to\infty} P_{n+1}/P_n$. *Answer:* for $m \geq 3$ the vertex 1 must be entered from 3 and the vertex 2 must leave to 4; deleting 1 and 2 leaves the same problem on $\{3, \ldots, m\}$, so induct. The limit is the real root $\psi \approx 1.46557$ of $x^3 = x^2 + 1$.

11.12 B6. Alternating divisor sum hiding an arctangent square

For each positive integer k, let $A(k)$ be the number of odd divisors of k in the interval $[1, \sqrt{2k})$. Evaluate

$$\sum_{k=1}^{\infty} (-1)^{k-1} \frac{A(k)}{k}.$$

Read it out loud

An alternating series in k whose coefficient counts divisors of k, and the divisor condition is measured against $\sqrt{2k}$, that is, against k itself. Read that sentence out loud and the first instruction is already sitting there: the square root is not real. It is an artefact of describing a divisor pair by only one of its two members. Name the cofactor and the square root evaporates. So write $k = dm$ with d the odd divisor. Then $d < \sqrt{2k}$ is equivalent to $d^2 < 2k = 2dm$, that is, to $d < 2m$. Now substitute $d = 2\ell - 1$, which you do because d is odd and because odd numbers indexed by ℓ are how the arctangent series is indexed, and the condition becomes $2\ell - 1 < 2m$, that is, since both sides are integers and the left side is odd, simply $\ell \leq m$. One line of algebra has turned a divisor condition with an irrational bound into an ordering condition on a lattice.

So $A(k)$ is the number of pairs (ℓ, m) of positive integers with $\ell \leq m$ and $(2\ell - 1)m = k$. There is a pretty combinatorial reading of that which is worth carrying: a run of $2\ell - 1$ consecutive positive integers centred at m sums to $(2\ell - 1)m$, and it consists of positive integers exactly when its first term $m - \ell + 1$ is at least 1, that is, exactly when $\ell \leq m$. Thus $A(k)$ is the number of ways to write k as a sum of an odd number of consecutive positive integers. You do not need that reading to solve the problem, but it is the reason the count is natural rather than invented, and a count that has a reason is a count you will trust under exam pressure.

Now the fields. Number theory is present for exactly three lines, the three lines above. Everything after that is real analysis, and the real analysis is the entire question. Two warnings should fire immediately. First, $A(k) \geq 1$ for every k because $d = 1$ always qualifies, so $\sum_k A(k)/k$ diverges: the series is not absolutely convergent, and any rearrangement you perform is a theorem you owe the grader, not a notational convenience. Second, $A(k)$ is violently non monotone: it is 1 at $k = 2$ and 3 at $k = 45$, so $A(k)/k$ does not decrease to zero and the alternating series test does not apply to the series as written. Neither of the two convergence tools you own applies to the object you are handed. That is what B6 is testing. The number theory is the costume; the examination is on whether you notice that even the convergence must be established by hand, and then establish it.

Within thirty seconds you should have written three things: $k = (2\ell - 1)m$ with $\ell \leq m$; $(-1)^{k-1} = (-1)^{m-1}$ because $2\ell - 1$ is odd so $k \equiv m \pmod 2$; and the question of which of the two indices goes on the outside of the double sum. That third item is the whole strategic decision of the problem, and the sign line answers it for you: the sign depends only on m, so m must stay on the inside, where its alternation can be exploited.

Approaches, ranked worst to best

1. **Compute partial sums and recognise the constant.** *Cue:* the command term "Evaluate" promises a closed form. *Circuit:* numerical pattern matching. You will find the partial sums approach $0.6168\ldots$ and $\pi^2/16 = 0.61685\ldots$ is recognisable. It ranks last for two reasons. The convergence is of order $N^{-1/2}$, so four correct digits need about a million terms, which rules it out in the arena. More importantly it earns nothing: the entire content of B6 is the justification, and a number with no proof of convergence attached is worth zero.

2. **Dirichlet series and analytic continuation.** *Cue:* a divisor counting coefficient divided by k smells like $\sum a_k k^{-s}$ at $s = 1$. *Circuit:* write the generating Dirichlet series, factor it, evaluate. You would form $\sum_k A(k)k^{-s} = \sum_{\ell \leq m}((2\ell - 1)m)^{-s}$ and hope for a product of zeta and beta

functions. It does not factor, because the constraint $\ell \le m$ couples the two indices, and the alternating sign forces eta versions on top. It stalls precisely where you started: the value you want sits at the edge of the region of convergence, so you have imported the convergence problem into a heavier machine.

3. **Sum over m on the outside, producing odd harmonic numbers.** *Cue:* the inner sum over ℓ runs over the finite range $1 \le \ell \le m$, which looks safer than an infinite inner sum. *Circuit:* group the lattice by the larger coordinate. This gives $\sum_{m\ge1} \frac{(-1)^{m-1}}{m} O_m$ with $O_m = 1 + \frac{1}{3} + \cdots + \frac{1}{2m-1}$, and then $O_m = \int_0^1 \frac{1-u^{2m}}{1-u^2}\,du$ leads to $\int_0^1 \frac{\log(2/(1+u^2))}{1-u^2}\,du$. That integral is genuinely equal to $\pi^2/16$, so the route is not wrong. It ranks third because the integrand needs care at $u = 1$, the antiderivative is far harder than the one you get from the other ordering, and the regrouping needs exactly the same convergence argument as the winning route while paying more ink for the endgame. Choosing the finite inner sum feels safe and is the classic false economy.

4. **Sum over ℓ on the outside, so the inner sum is an alternating harmonic tail.** *Cue:* the sign $(-1)^{k-1}$ depends only on m, so m belongs where alternation can be used. *Circuit:* put the sign bearing index innermost, then bound its tail by its first term. The inner object becomes $T_\ell = \sum_{m\ge\ell} \frac{(-1)^{m-1}}{m}$, which satisfies $|T_\ell| \le 1/\ell$ by the alternating tail bound. That single inequality makes the outer sum absolutely convergent, converts the rearrangement from a leap of faith into a two line estimate, and hands you arctan at the end. This is the ideal route, and its selection is forced by one observation about where the minus sign lives.

The ideal solution

The answer is $\boxed{\frac{\pi^2}{16}}$.

Lemma 11.12.1. *For every positive integer k,*

$$A(k) = \#\{(\ell, m) \in \mathbb{Z}^2_{\ge1} : \ m \ge \ell,\ (2\ell-1)m = k\},$$

and for every such pair, $(-1)^{k-1} = (-1)^{m-1}$.

Proof. The odd divisors of k are exactly the integers $2\ell-1$ with $\ell \ge 1$ and $(2\ell-1) \mid k$; given such a divisor put $m = k/(2\ell-1)$. Since $2k = 2(2\ell-1)m$ is positive, the condition $2\ell - 1 < \sqrt{2k}$ is equivalent to $(2\ell-1)^2 < 2(2\ell-1)m$, hence to $2\ell - 1 < 2m$. As $2\ell-1$ and $2m$ are integers of opposite parity, this is equivalent to $2\ell \le 2m$, that is, to $\ell \le m$. The lower bound $2\ell - 1 \ge 1$ is automatic. Finally $2\ell - 1$ is odd, so $k = (2\ell-1)m \equiv m \pmod 2$. □

For $\ell \ge 1$ set

$$T_\ell = \sum_{m=\ell}^{\infty} \frac{(-1)^{m-1}}{m},$$

which converges by the alternating series test, and whose tail bound gives $|T_\ell| \le 1/\ell$. Define

$$S = \sum_{\ell=1}^{\infty} \frac{T_\ell}{2\ell-1}.$$

Since $2\ell - 1 \ge \ell$ we have $|T_\ell/(2\ell-1)| \le 1/\ell^2$, so S converges absolutely.

Claim 11.12.2. *The series $\sum_{k\ge1}(-1)^{k-1}A(k)/k$ converges, and its sum is S.*

Proof. Write $S_N = \sum_{k=1}^{N} (-1)^{k-1} A(k)/k$. By the Lemma, S_N is a finite sum over the lattice points (ℓ, m) with $\ell \le m$ and $(2\ell-1)m \le N$, the contribution of (ℓ, m) being $\frac{(-1)^{m-1}}{(2\ell-1)m}$. Such a point requires $\ell(2\ell-1) \le (2\ell-1)m \le N$, so only finitely many ℓ occur; let L be the largest ℓ with $\ell(2\ell-1) \le N$. If $\ell > \sqrt{N}$ then $\ell(2\ell-1) > \sqrt{N}(2\sqrt{N}-1) = 2N - \sqrt{N} \ge N$ for $N \ge 1$, so $L \le \sqrt{N}$; and $\ell(2\ell-1) \le 2\ell^2$ shows $L \ge \lfloor \sqrt{N/2} \rfloor$, so $L \to \infty$. Grouping the finite sum by ℓ,

$$S_N = \sum_{\ell=1}^{L} \frac{1}{2\ell-1} \sum_{m=\ell}^{M_\ell} \frac{(-1)^{m-1}}{m}, \qquad M_\ell = \left\lfloor \frac{N}{2\ell-1} \right\rfloor.$$

Therefore

$$S - S_N = \sum_{\ell > L} \frac{T_\ell}{2\ell-1} + \sum_{\ell=1}^{L} \frac{1}{2\ell-1} \sum_{m > M_\ell} \frac{(-1)^{m-1}}{m}.$$

For the first sum, $|T_\ell/(2\ell-1)| \le 1/\ell^2$ gives $\left|\sum_{\ell>L} T_\ell/(2\ell-1)\right| \le \sum_{\ell>L} \ell^{-2} \le 1/L$. For the second, each inner sum is an alternating tail, so it is bounded in absolute value by its first term $\frac{1}{M_\ell+1}$, and $M_\ell + 1 > N/(2\ell-1)$ gives $\frac{1}{M_\ell+1} < \frac{2\ell-1}{N}$. Hence the second sum is bounded in absolute value by

$$\sum_{\ell=1}^{L} \frac{1}{2\ell-1} \cdot \frac{2\ell-1}{N} = \frac{L}{N} \le \frac{1}{\sqrt{N}}.$$

Thus $|S - S_N| \le \frac{1}{L} + \frac{1}{\sqrt{N}} \to 0$, which proves both the convergence and the value. □

Next, an exact formula for T_ℓ. For $N \ge \ell$, summing the finite geometric progression $\sum_{m=\ell}^{N} (-1)^{m-1} t^{m-1} = \frac{(-1)^{\ell-1} t^{\ell-1} - (-1)^N t^N}{1+t}$ and integrating over $[0,1]$ termwise (a finite sum, so no justification is needed) gives

$$\sum_{m=\ell}^{N} \frac{(-1)^{m-1}}{m} = (-1)^{\ell-1} \int_0^1 \frac{t^{\ell-1}}{1+t}\, dt - (-1)^N \int_0^1 \frac{t^N}{1+t}\, dt.$$

The last integral is at most $\int_0^1 t^N\, dt = \frac{1}{N+1} \to 0$, so letting $N \to \infty$,

$$T_\ell = (-1)^{\ell-1} \int_0^1 \frac{t^{\ell-1}}{1+t}\, dt.$$

Now put $f_\ell(t) = \dfrac{(-1)^{\ell-1} t^{\ell-1}}{(2\ell-1)(1+t)}$, continuous on $[0,1]$, so that $S = \sum_{\ell \ge 1} \int_0^1 f_\ell(t)\, dt$. For each fixed $t \in [0,1]$ the moduli $\frac{t^{\ell-1}}{(2\ell-1)(1+t)}$ decrease to 0 as ℓ grows, so the alternating tail bound applies pointwise and uniformly:

$$\left| \sum_{\ell=L+1}^{\infty} f_\ell(t) \right| \le \frac{t^L}{(2L+1)(1+t)} \le \frac{1}{2L+1} \qquad \text{for all } t \in [0,1].$$

Hence $\sum_\ell f_\ell$ converges uniformly on $[0,1]$ to a continuous function F, and a uniformly convergent series of continuous functions on a compact interval may be integrated term by term. Therefore

$$S = \int_0^1 F(t)\, dt, \qquad F(t) = \frac{1}{1+t} \sum_{\ell=1}^{\infty} \frac{(-1)^{\ell-1} t^{\ell-1}}{2\ell-1}.$$

For $0 < t < 1$, writing $u = \sqrt{t} \in (0,1)$ and using the Gregory series $\arctan u = \sum_{\ell \ge 1} \frac{(-1)^{\ell-1} u^{2\ell-1}}{2\ell-1}$, valid for $|u| < 1$,

$$\sum_{\ell=1}^{\infty} \frac{(-1)^{\ell-1} t^{\ell-1}}{2\ell-1} = \frac{1}{u} \sum_{\ell=1}^{\infty} \frac{(-1)^{\ell-1} u^{2\ell-1}}{2\ell-1} = \frac{\arctan \sqrt{t}}{\sqrt{t}}.$$

So $F(t) = \frac{\arctan\sqrt{t}}{\sqrt{t}\,(1+t)}$ on $(0,1)$. Both sides are continuous on $[0,1]$, the right side extending by the value 1 at $t = 0$; since F is continuous as a uniform limit of continuous functions, the identity holds on all of $[0,1]$, and no appeal to Abel's theorem at the endpoint is required. Substituting $t = u^2$, $dt = 2u\,du$,

$$S = \int_0^1 \frac{\arctan\sqrt{t}}{\sqrt{t}\,(1+t)}\,dt = \int_0^1 \frac{\arctan u}{u(1+u^2)} \cdot 2u\,du = \int_0^1 \frac{2\arctan u}{1+u^2}\,du.$$

The integrand is $2gg'$ with $g = \arctan$, so it is the derivative of g^2, and

$$S = \Big[\arctan^2 u\Big]_0^1 = \Big(\frac{\pi}{4}\Big)^2 = \frac{\pi^2}{16}.$$

Layer 1: WHAT

Block 1. Name the cofactor: $k = dm$, so the condition $d < \sqrt{2k}$ becomes $d < 2m$; with $d = 2\ell - 1$ it becomes $\ell \le m$.

Block 2. Read the parity: $2\ell - 1$ is odd, so $(-1)^{k-1} = (-1)^{m-1}$. The sign lives on m alone.

Block 3. Choose the order of summation from Block 2: ℓ outside, m inside, so the inner sum is a tail of the alternating harmonic series.

Block 4. Bound that tail: $|T_\ell| \le 1/\ell$, whence the outer sum $S = \sum_\ell T_\ell/(2\ell - 1)$ converges absolutely.

Block 5. Prove that the original partial sums converge to S, by bounding $S - S_N$ in two pieces: the tail in ℓ and the truncation error in m.

Block 6. Replace $1/m$ by $\int_0^1 t^{m-1}\,dt$ so that the alternating tail becomes a geometric series inside an integral, giving $T_\ell = (-1)^{\ell-1}\int_0^1 t^{\ell-1}(1+t)^{-1}dt$.

Block 7. Exchange the outer sum with the integral, justified by uniform convergence from the same alternating tail bound used in Block 4.

Block 8. Recognise the resulting power series as $\arctan\sqrt{t}/\sqrt{t}$, substitute $u = \sqrt{t}$ so the Jacobian cancels the $1/u$, and read off $2\arctan u/(1+u^2)$ as the derivative of $\arctan^2 u$.

Juxtapose that with the nominal route. The zombie writes $A(k)$, tries to compute it for small k, notices $1, 1, 1, 2, 1, 2, 1, 2, 2, 2, \ldots$, searches for a multiplicative structure that is not there, gives up on structure, expands the sum as $\sum_{d \text{ odd}} \frac{1}{d}\sum_m \frac{(-1)^{dm-1}}{m}$ with no attention to whether that rearrangement is legal or to the range of m, and either gets a divergent object or asserts the interchange and loses most of the marks. The bifurcation point is one line long, and it is this: after writing $k = dm$, do you square the inequality $d < \sqrt{2k}$? Squaring is what removes k from the condition and replaces it by a comparison between d and m. Every good thing that follows, the ordering $\ell \le m$, the choice of summation order, the tail bound, is downstream of that square. The zombie keeps $\sqrt{2k}$ because it is what the question wrote, and therefore never gets a lattice.

Layer 2: HOW

Block 1. Cue. The divisor bound $\sqrt{2k}$ mentions k, and k is the thing being divided. A condition that mentions both a divisor and its dividend is a condition on the pair, not on the divisor. **Why natural.** A divisor is never alone: $d \mid k$ means $k = dm$, and the honest coordinates on the set you are counting are (d, m), not d and k. In those coordinates the bound $d < \sqrt{2dm}$ is homogeneous of degree one in the pair after squaring, so squaring cancels one factor of d and leaves $d < 2m$. Squaring is legitimate because both sides are positive. This is the same reflex that turns "divisors below $\sqrt{n}$" into "the smaller member of each divisor pair". **Link to the next block.** The condition $d < 2m$ with d odd is a statement about integers of opposite parity, so it tightens; parametrising the odd d as $2\ell - 1$ makes the tightening visible and hands you the index ℓ that the arctangent series wants.

Block 2. **Cue.** There is a factor $(-1)^{k-1}$ and you have just written k as a product. **Why natural.** The sign of a product is decided by the parity of its factors, and one of the two factors is odd by construction. So the sign is carried entirely by m. Always compute what a given sign depends on before deciding anything else about a double sum; it is one line and it determines the architecture. **Link to the next block.** Knowing that the sign depends on m alone tells you which index must remain inside the summation.

Block 3. **Cue.** An index whose sign alternates is an index you want adjacent to a summation sign, because alternation is the only free convergence you get in a non absolutely convergent problem. **Why natural.** If m is on the outside, the inner sum over ℓ is a partial odd harmonic sum, which grows like $\frac{1}{2}\log m$ and carries no cancellation; you have thrown away the alternation and bought a logarithm. If m is on the inside, the inner sum is $\sum_{m\geq\ell}(-1)^{m-1}/m$, an honest alternating tail with a bound you already own. The choice is not aesthetic; it decides whether the outer sum is absolutely convergent. **Link to the next block.** With m inside you now need one quantitative fact about alternating tails.

Block 4. **Cue.** An alternating series whose terms decrease in modulus to zero. **Why natural.** The alternating series estimate says the tail is bounded in modulus by its first omitted term, here $1/\ell$. Combined with $2\ell-1\geq\ell$ this gives a summand of modulus at most $1/\ell^2$, so the rearranged series is absolutely convergent. This is the pivot of the whole solution: it converts a conditionally convergent mess into an absolutely convergent series of well understood objects. **Link to the next block.** Absolute convergence of the rearranged sum is not the same as the original series converging to it. That gap must now be closed, explicitly.

Block 5. **Cue.** The original series is not absolutely convergent, so Riemann's rearrangement theorem is in force and the rearrangement is a claim, not a step. **Why natural.** The correct discipline is to compare partial sums, never to invoke a theorem you cannot name. The partial sum S_N is a finite sum over lattice points under the hyperbola $(2\ell-1)m\leq N$; the difference $S-S_N$ splits into the part of S with ℓ too large and the alternating tails in m that S_N has truncated. Both are bounded by the two facts already in hand: $|T_\ell|\leq 1/\ell$ for the first, and the alternating tail estimate for the second, where the truncation point M_ℓ is at least $N/(2\ell-1)$, so the $2\ell-1$ in the denominator of the outer sum is exactly cancelled. That cancellation is why the estimate is clean: the outer weight $1/(2\ell-1)$ and the inner error $(2\ell-1)/N$ multiply to $1/N$, and there are at most $\sqrt{N}$ terms. **Link to the next block.** With convergence secured, the problem is now the purely analytic evaluation of an absolutely convergent series.

Block 6. **Cue.** You need a closed form for $\sum_{m\geq\ell}(-1)^{m-1}/m$, and $1/m$ is the obstruction to summing a geometric series. **Why natural.** $1/m=\int_0^1 t^{m-1}\,dt$ is the standard device for removing a linear denominator: it turns $\sum a^m/m$ into $\int\sum a^m t^{m-1}$, which is geometric. Doing it on the finite partial sum first, and only then letting $N\to\infty$, means the only limit you must justify is $\int_0^1 t^N(1+t)^{-1}dt\to 0$, which is immediate. That ordering is deliberate: it avoids needing the monotone or dominated convergence theorem at this step. **Link to the next block.** You now have S as a sum of integrals and want it as an integral of a sum.

Block 7. **Cue.** A series of continuous functions on a compact interval, alternating in the summation index with moduli decreasing in that index uniformly in t. **Why natural.** The alternating tail bound is uniform in t because $t^{\ell-1}\leq 1$ and $(1+t)^{-1}\leq 1$ on $[0,1]$: the tail after L terms is at most $1/(2L+1)$ for every t. Uniform convergence of continuous functions on $[0,1]$ licenses termwise integration. The Weierstrass M test would fail here since $\sum 1/(2\ell-1)$ diverges, so it is the alternation, not the size, that buys uniformity. Notice you used the very same inequality twice, at Block 4 and here; that

is the sign of a well chosen decomposition. **Link to the next block.** The bracket you are left with is a power series in t with odd denominators, which is one substitution away from a function you know.

Block 8. Cue. Odd denominators $2\ell - 1$ with alternating signs and a variable that wants to be a square. **Why natural.** $\sum_{\ell \geq 1} (-1)^{\ell-1} x^{2\ell-1}/(2\ell-1) = \arctan x$ is the defining series of the arctangent, and the powers of t appearing are $t^{\ell-1} = x^{2\ell-2}$, one power short, which is exactly why the answer carries a $1/\sqrt{t}$. Substituting $t = u^2$ produces $dt = 2u\,du$, which cancels that $1/u$ and simultaneously turns $1/(1+t)$ into $1/(1+u^2) = \arctan'(u)$. Both odd denominator structures in the problem, the one from the odd divisor and the one from the alternating harmonic tail, are the same function; that is why the answer is a perfect square. **Link to the next block.** Nothing is left: $2\arctan u \cdot \arctan'(u)$ integrates to $\arctan^2 u$, so the value is $\arctan(1)^2 = \pi^2/16$.

Layer 3: WHY

Three mathematical truths hold this route up. The first is that a sum weighted by a divisor counting function is always a sum over a lattice region, and you should convert it before doing anything analytic. The identity $\sum_k \big(\sum_{d|k} c_{d,k/d}\big) x_k = \sum_{d,m} c_{d,m} x_{dm}$ is trivial as bookkeeping but decisive as strategy, because every constraint written in terms of k becomes a constraint relating d and m, and constraints relating two free variables define regions you can draw. Here the region is $\{\ell \leq m\}$, a half plane, which is the simplest region there is. If the constraint had been $d < \sqrt{3k}$ you would have got $2\ell - 1 < 3m$ and the same method with a slightly uglier region; the technique does not depend on the luck of the constant.

The second is that conditional convergence is a property of an ordering, not of a set of numbers. The family $\{(-1)^{m-1}/((2\ell-1)m)\}$ over $\ell \leq m$ is not summable in the unordered sense, so "the sum" means nothing until you fix an order, and the problem fixes it: increasing k. Every other order you write down is a different object until proved otherwise. The discipline that follows is mechanical and should be automatic: when you rearrange a non absolutely convergent series, write $S - S_N$ explicitly and bound it. Do not gesture at Fubini. In this problem the bound falls out because the outer weight $1/(2\ell-1)$ and the inner truncation error $(2\ell-1)/N$ are reciprocal, and the number of surviving ℓ is $O(\sqrt{N})$, giving an error of order $N^{-1/2}$. That is also the true rate, which is why the numerical approach was hopeless.

The third is that $\pi^2/16 = (\pi/4)^2$ is the square of the Leibniz value, and squares of series values arise from integrals of the form $\int 2gg'$. Once you see $\int_0^1 2\arctan u\, d(\arctan u)$ you understand the design of the problem: the examiners built a double sum whose two index families both encode odd reciprocals, one as $\sum(-1)^{\ell-1}t^{\ell-1}/(2\ell-1)$ and one as $1/(1+t)$, and the change of variable $t = u^2$ is what reveals them to be the same. The nudge they planted is the word "odd" in the definition of $A(k)$ together with the factor 2 inside $\sqrt{2k}$. That 2 has no arithmetic purpose; its only function is to make the inequality collapse to $\ell \leq m$ with no floor functions surviving. When a constant in a problem statement exists purely to make one inequality clean, it is telling you where the intended first move is.

How to train the discernment. Drill the question "which index carries the sign" on every double sum you meet, before choosing an order, and drill the question "is this family absolutely summable" before writing any interchange. Both are ten second checks. Then drill the alternating tail bound until it is reflex, because in this problem it does three separate jobs: it makes the outer series absolutely convergent, it controls the truncation error, and it supplies uniform convergence for the integral swap. A single inequality doing three jobs is the mark of the correct decomposition, and noticing that is how you tell in the arena that you are on the right road rather than a road.

Revolving concepts

Odd divisors and the divisor pair. A divisor d of k comes with a cofactor $m = k/d$; the map $d \mapsto (d, m)$ turns divisor sums into lattice sums. The hyperbola method (splitting $\sum_{dm \le x}$ at $d \le \sqrt{x}$) is the standard exploitation, and Dirichlet convolution $(f * g)(k) = \sum_{d|k} f(d)g(k/d)$ is its algebraic form. Note that A is not multiplicative, because the constraint mixes d with m; do not waste time hunting for an Euler product. See Book 1, field: Number theory, topic: divisor sums and the hyperbola method.

Sums of consecutive integers. A run of j consecutive positive integers starting at a sums to $j(2a + j - 1)/2$, and the two factors j and $2a + j - 1$ have opposite parity with product $2k$. Hence the number of representations of k as a sum of one or more consecutive positive integers equals the number of odd divisors of k, and restricting to odd j gives exactly $A(k)$. See Book 1, field: Number theory, topic: representations by consecutive integers.

Alternating series and their tails. If $b_1 \ge b_2 \ge \cdots \to 0$ then $\sum(-1)^{m-1}b_m$ converges and every tail is bounded in modulus by its first term. Two generalisations you must own: Dirichlet's test (bounded partial sums of one factor times a monotone null sequence) and its uniform version, which is what licenses termwise integration when the Weierstrass M test fails, as it does here.

Conditional convergence and rearrangement. Riemann's rearrangement theorem: a real series that converges but not absolutely can be reordered to converge to any prescribed value or to diverge. Consequence for exam writing: an interchange of summation order in a non absolutely convergent double family is a claim requiring proof, and the proof is a partial sum comparison.

Recursion and telescoping, generalised. The tails obey the first order recursion $T_\ell - T_{\ell+1} = \frac{(-1)^{\ell-1}}{\ell}$, and any sum weighted by tails can be resummed by Abel summation by parts: for $C_m = \sum_{\ell \le m} c_\ell$ and $T_\ell = \sum_{m \ge \ell} a_m$ one has $\sum_{\ell \ge 1} c_\ell T_\ell = \sum_{m \ge 1} a_m C_m$ whenever either side is legitimate. That identity is precisely the passage between the third ranked approach and the ideal one, with $c_\ell = 1/(2\ell - 1)$, $C_m = O_m$ and $a_m = (-1)^{m-1}/m$. The general solution method for a whole family of these problems is: express the inner tail as $T_\ell = (-1)^{\ell-1} \int_0^1 t^{\ell-1}(1 + t)^{-1} dt$, so that for any weights with $\sum |c_\ell|/\ell < \infty$,

$$\sum_{\ell \ge 1} c_\ell T_\ell = \int_0^1 \frac{C(-t)}{1+t}\, dt, \qquad C(x) = \sum_{\ell \ge 1} c_\ell x^{\ell-1}.$$

Here $C(x) = \sum x^{\ell-1}/(2\ell - 1)$, so $C(-t) = \arctan(\sqrt{t})/\sqrt{t}$. Change the weights and you change only the generating function.

Power series you must have memorised. $\arctan x = \sum_{\ell \ge 1}(-1)^{\ell-1}x^{2\ell-1}/(2\ell - 1)$ and $\log(1 + x) = \sum_{m \ge 1}(-1)^{m-1}x^m/m$ for $|x| < 1$, together with Abel's theorem for the endpoint $x = 1$. Also $1/m = \int_0^1 t^{m-1} dt$ and $1/(2\ell - 1) = \int_0^1 u^{2\ell-2} du$ as denominator removal devices. See Book 1, field: Real analysis, topic: power series and Abel summation.

Knowledge gaps, stated plainly. You cannot approach this problem at all without four items that are outside Edexcel Further Mathematics. One: the alternating series test with its tail estimate, in the quantitative form "the tail is at most the first omitted term". Two: the notion of absolute versus conditional convergence and Riemann's rearrangement theorem, without which you will not know that an interchange needs proof, and you will lose the problem while believing you have solved it. Three: uniform convergence of a series of functions and the theorem that it permits termwise integration on a compact interval; the Weierstrass M test alone is not enough here, so you need the alternating or Dirichlet form. Four: the divisor pair parametrisation as a habit rather than a fact. A fifth, optional but comfortable, is the Lebesgue monotone convergence theorem, which shortens the interchange if you have measure theory; the solution above avoids it deliberately so that the write up stands on first year analysis only.

Circuit Bank

- **WHEN** a sum over k whose coefficient counts divisors of k subject to an inequality that mentions k itself **DO** substitute $k = dm$ and square the inequality **BECAUSE** the square root is an artefact of naming only one member of the divisor pair, and squaring converts the condition into a comparison between d and m, which is a region in the lattice
- **WHEN** a double sum in which the sign of the term depends on only one of the two indices **DO** put that index on the inside and the other on the outside **BECAUSE** the inner sum is then alternating, its tail is bounded by its first term, and that bound is usually exactly what makes the outer sum absolutely convergent
- **WHEN** yourself about to interchange two summations, or a sum and an integral, in a family that is not absolutely summable **DO** write the difference of the two partial sums and bound it explicitly **BECAUSE** Riemann's rearrangement theorem says the value can be changed by reordering, so the interchange is a theorem you owe, and the bound is usually two lines once you have an alternating tail estimate
- **WHEN** a denominator m or $2\ell - 1$ blocking a geometric summation **DO** write $1/m = \int_0^1 t^{m-1} dt$ or $1/(2\ell - 1) = \int_0^1 u^{2\ell-2} du$ and take the sum inside **BECAUSE** integration against a monomial is the inverse of differentiating a power series, so it exchanges a linear denominator for one extra integration
- **WHEN** an integrand of the form $2g(u)g'(u)$, or an answer that looks like the square of a known series value **DO** write it as the derivative of g^2 and evaluate at the endpoints **BECAUSE** a squared constant such as $(\pi/4)^2$ almost never arises from a single series; it arises from an integral of a function against its own differential

Backtesting

1. First useful cue: the divisor bound $\sqrt{2k}$ mentions k, so the condition is really a condition on the divisor pair (d, m); write $k = dm$ and square.
2. Method the expression suggested: convert to a lattice sum over $\{(\ell, m) : \ell \leq m\}$, put the sign bearing index m innermost so the inner sum is an alternating harmonic tail, then use the integral representation of that tail and the arctangent series.
3. Where you would hesitate, and the thought to reinforce: at the rearrangement. The thought to reinforce is that the hesitation is correct and the cure is arithmetic, not philosophy: bound $S - S_N$ in two pieces, the discarded ℓ and the truncated m, using the same tail inequality twice.
4. The trap the question sets: the coefficient $A(k)$ is neither bounded nor monotone and $\sum A(k)/k$ diverges, so a candidate who treats the series as an ordinary alternating series, or who interchanges without comment, writes a solution that reaches the right number and scores very little. The number is not the problem; the ordering is.
5. What makes you recognise it faster next time: the pairing of an arithmetic coefficient with the factor $(-1)^{k-1}$ and a $1/k$. That combination is always a lattice sum with the sign attached to one coordinate, and the first two questions are always "which coordinate carries the sign" and "is this family absolutely summable".
6. The reusable decision rule: in a divisor weighted series, parametrise by the pair, order the double sum so that the alternating index is innermost, and pay for the reordering immediately with an explicit partial sum estimate.

Mirror drills

1. Show that the number of ways to write a positive integer k as a sum of one or more consecutive positive integers equals the number of odd divisors of k. *Answer:* a run of j terms starting at a sums to $j(2a+j-1)/2$, so $2k = j \cdot (2a+j-1)$ with the two factors of opposite parity and the second larger than the first; sending the representation to whichever factor is odd is a bijection onto the odd divisors of k.
2. Prove that $\sum_{m=\ell}^{\infty} \frac{(-1)^{m-1}}{m} = (-1)^{\ell-1} \int_0^1 \frac{t^{\ell-1}}{1+t}\,dt$ and deduce that its modulus is at most $1/\ell$. *Answer:* sum the finite geometric progression $\sum_{m=\ell}^{N}(-1)^{m-1}t^{m-1}$ inside the integral, note the error term is $\int_0^1 t^N(1+t)^{-1}dt \le \frac{1}{N+1}$, and bound $\int_0^1 t^{\ell-1}(1+t)^{-1}dt \le \int_0^1 t^{\ell-1}dt = 1/\ell$.
3. Evaluate $\sum_{m=1}^{\infty} \frac{(-1)^{m-1}}{m}\left(1+\frac{1}{3}+\frac{1}{5}+\cdots+\frac{1}{2m-1}\right)$. *Answer:* $\pi^2/16$; it is the Abel summation by parts partner of the sum in this problem, since $\sum_{\ell\ge1} c_\ell T_\ell = \sum_{m\ge1} a_m C_m$ with $c_\ell = 1/(2\ell-1)$ and $a_m = (-1)^{m-1}/m$, and the same convergence estimate applies.

Chapter 12

Putnam 2014

12.1 A1. Prime numerators in an exponential Taylor series

Prove that every nonzero coefficient of the Taylor series of

$$(1 - x + x^2)e^x$$

about $x = 0$ is a rational number whose numerator (in lowest terms) is either 1 or a prime number.

Read it out loud

A fixed quadratic multiplies e^x, and you are asked about the numerator of a coefficient once it is written in lowest terms. The instant "in lowest terms" appears you are not being asked for calculus, you are being asked for number theory wearing a Taylor series as a costume. The series is only the delivery mechanism; the content lives entirely in what a fraction loses when you cancel it down. That is the first cue, and it should fire within the first sentence: whenever a coefficient's reduced numerator or denominator is the object of the question, the circuit is "combine into one fraction over a factorial, then ask which primes the factorial can certify are gone", because a factorial is the one denominator whose prime content you know completely.

The fields wired into the question: e^x brings exponential generating functions and the fact $[x^n]e^x = 1/n!$; "numerator in lowest terms" brings elementary number theory, specifically the divisibility of factorials and the three ways a positive integer can be built (it is 1, it is prime, or it is composite). What is really being tested is whether you resist differentiating $(1 - x + x^2)e^x$ several times in search of a pattern, and instead read the product as three shifted copies of a series you already know. Within thirty seconds you should have $[x^n](1 - x + x^2)e^x = \frac{1}{n!} - \frac{1}{(n-1)!} + \frac{1}{(n-2)!}$, with the convention that a factorial of a negative integer is 0. Everything after that line is arithmetic.

Approaches, ranked worst to best

1. **repeated differentiation.** *Cue:* "Taylor series...about $x = 0$". *Circuit:* $f^{(n)}(0)/n!$ by the product rule. (costs enormous ink: the product rule regenerates all three terms at every order and gives no structural reason a numerator would be prime; you compute blind, hoping a pattern appears.)
2. **numerical pattern spotting.** *Cue:* "either 1 or a prime". *Circuit:* tabulate the first ten coefficients, factor the numerators, guess a rule. (a legitimate way to discover the closed form if you have not met this cue before, but on its own it is a conjecture, not a proof, since it never explains why composite $n - 1$ forces the numerator down.)
3. **shift the series then classify one integer.** *Cue:* $(1 - x + x^2)e^x$ read as three copies of e^x shifted by $0, 1, 2$. *Circuit:* write the coefficient as one fraction over $n!$, cancel the shared factor, classify $n - 1$ as prime, composite with unequal factors, or a prime square. (the ideal route: least ink, and every case is forced by the definitions of prime and composite, never by inspection.)

The ideal solution

Adopt the convention $1/k! = 0$ for negative integers k. Then for every $n \geq 0$,

$$c_n := [x^n](1 - x + x^2)e^x = \frac{1}{n!} - \frac{1}{(n-1)!} + \frac{1}{(n-2)!}.$$

Multiply by $n!$: the integer $n!\,c_n$ equals $1 - n + n(n-1) = (n-1)^2$, a check that holds at $n = 0$ ($1 = (-1)^2$) and $n = 1$ ($0 = 0^2$) exactly as it holds for larger n, so with no separate base case,

$$c_n = \frac{(n-1)^2}{n!} \qquad \text{for every } n \geq 0.$$

This gives $c_0 = 1$ (numerator 1) and $c_1 = 0$ (excluded, it is not a nonzero coefficient). Fix $n \geq 2$ and set $m = n - 1 \geq 1$. Since $n! = n \cdot m \cdot (m-1)!$, one copy of m cancels against $(n-1)^2 = m^2$:

$$c_n = \frac{m}{n\,(m-1)!}.$$

Consecutive integers m and n share no common factor, so the only further cancellation is between m and $(m-1)!$. Let $d = \gcd(m, (m-1)!)$; the reduced numerator is m/d, and the claim is $m/d \in \{1\} \cup \{\text{primes}\}$.

If $m = 1$, then $(m-1)! = 1$, $d = 1$, numerator 1. If m is prime, every factor of $(m-1)! = 1 \cdot 2 \cdots (m-1)$ is smaller than m, so none carries the prime m; hence $d = 1$ and the numerator is the prime m itself.

If m is composite, let p be its smallest prime factor. Were m/p to have a prime factor below p, that factor would divide m, contradicting the minimality of p; so every prime factor of m/p is at least p, forcing $m/p \geq p$. Two shapes follow. If $m/p > p$, then p and m/p are distinct integers, both at most $m-1$, so both occur as separate factors inside $(m-1)!$; hence $m = p \cdot (m/p)$ divides $(m-1)!$, giving $d = m$ and numerator 1. If $m/p = p$, then $m = p^2$. For $p \geq 3$, $2p < p^2$ (since $p(p-2) > 0$), so p and $2p$ are distinct integers at most $m-1$, and again m divides $(m-1)!$, giving numerator 1. For $p = 2$, $m = 4$ and $(m-1)! = 3! = 6$, so $d = \gcd(4, 6) = 2$ and the numerator is $4/2 = 2$, a prime. In every case the reduced numerator of c_n is 1 or a prime. ■

Layer 1: WHAT

1. **Block 1.** Read $(1 - x + x^2)e^x$ as three shifted copies of the exponential series and write $c_n = 1/n! - 1/(n-1)! + 1/(n-2)!$.
2. **Block 2.** Combine over $n!$ and simplify the integer numerator $1 - n + n(n-1)$ to the perfect square $(n-1)^2$, unifying every $n \geq 0$ into one formula.
3. **Block 3.** Cancel one copy of $m = n - 1$ against $n! = n \cdot m \cdot (m-1)!$, reducing the whole problem to one question about one integer m against $(m-1)!$.
4. **Block 4.** Classify m by its smallest prime factor into three shapes (prime; composite with unequal factors; a prime square) and read off the numerator in each.

The nominal route differentiates $(1 - x + x^2)e^x$ repeatedly, hunting a pattern in raw numbers, and never rises above a conjecture. The ideal route never differentiates: it reads the product as a shifted sum on sight and moves straight into divisibility bookkeeping. The bifurcation point is the opening reflex itself, the choice between "differentiate" and "shift and combine", made before a single number is computed.

Layer 2: HOW

Block 1. **Cue.** The factor $(1 - x + x^2)$ is fixed and finite, while $e^x = \sum x^k/k!$ has coefficients you already know. **Why natural.** Multiplying a finite polynomial into a power series only shifts and rescales that series; there is no genuine interaction for the product rule to rediscover term by term. **Link to the next block.** Three known terms sitting at three different factorial denominators are unreadable until forced onto one denominator.

Block 2. **Cue.** The denominators $n!$, $(n-1)!$, $(n-2)!$ differ only by the small multipliers n and $n(n-1)$. **Why natural.** Clearing to $n!$ turns the coefficient into (integer)$/n!$, and that integer is a quadratic in n worth simplifying on sight. **Link to the next block.** Seeing $1 - n + n(n-1) = (n-1)^2$ guarantees a whole factor of $(n-1)$ is available for cancellation against the visible $(n-1)$ inside $n!$.

Block 3. **Cue.** $n! = n(n-1)(n-2)!$ displays $(n-1)$ as an explicit factor. **Why natural.** Consecutive integers are always coprime, so n can never absorb any part of $(n-1)^2$; the only real contest is between $(n-1)$ and $(n-2)!$. **Link to the next block.** This isolates one question about one integer $m = n-1$: how much of m does $(m-1)!$ already contain?

Block 4. **Cue.** The three-way shape of a positive integer under its smallest prime factor. **Why natural.** Prime, composite with unequal factors, and prime square are the only shapes that classification produces, and each gives a fully determined answer. **Link to the next block.** No further block is needed; each case terminates in an explicit numerator.

Layer 3: WHY

The truth underneath this problem is a companion to Wilson's theorem: a composite integer m divides $(m-1)!$ for every m except $m = 4$. You do not need Wilson's theorem's statement about primes, only this shadow of it on the composite side, and you should be able to reprove that shadow from the definition of smallest prime factor in under a minute rather than quote it and hope. The discernment mechanism that finds this route is a standing question: the instant a numerator in lowest terms appears, ask what the denominator is built from and which primes it can certify absent. Factorials answer this completely, since every prime up to n divides $n!$ and none above it does, which is exactly why the examiners chose e^x rather than, say, a geometric series, whose coefficients carry no factorial structure to interrogate. Train this by refusing, on any future factorial-numerator problem, to compute a single term before writing the coefficient as (small polynomial in n)/(a factorial). The examiners nudged you here by asking for the numerator specifically: a question about the value of a coefficient invites calculus; a question about its reduced numerator is a standing invitation to prime factorisation.

Revolving concepts

Exponential generating functions. For $P(x) = \sum_{i=0}^{d} c_i x^i$, $[x^n]\big(P(x)e^x\big) = \sum_{i=0}^{d} c_i/(n-i)!$, with negative factorials contributing 0; this problem is the case $d = 2$, $P(x) = 1 - x + x^2$. Meet any fixed polynomial against e^x, $\sin x$, $\cos x$, or another series with known coefficients, and write this shifted sum first, before differentiating. See Book 1, field: Calculus and integrals, topic: Taylor and Maclaurin series.

Factorials and their primes. $n!$ is divisible by exactly the primes up to n, to the power given by Legendre's formula $\sum_{i \geq 1} \lfloor n/p^i \rfloor$; here you only needed that every integer from 1 to $n-1$ is an explicit factor of $(n-1)!$. See Book 1, field: Number theory, topic: factorials and prime valuations.

The composite-factorial lemma. Composite m divides $(m-1)!$ unless $m = 4$. This is the engine of the whole proof and is worth installing by name, though its proof needs nothing beyond the classification used above. See Book 1, field: Number theory, topic: Wilson's theorem and its refinements.

Coprimality of consecutive integers. $\gcd(k, k+1) = 1$ for every integer k, since any common divisor divides their difference 1; this is what guarantees n never interferes with the cancellation of $n-1$. See Book 1, field: Number theory, topic: greatest common divisor.

There is no recursion or telescoping in this problem: c_n is handed to you in closed form by the product rule for generating functions, not by an earlier coefficient of itself, so there is nothing to generalise along that axis.

Circuit Bank

- **WHEN** a fixed polynomial multiplies a series with known coefficients **DO** write the coefficient of x^n as the finite shifted sum on sight **BECAUSE** differentiating regenerates the same

information at far higher cost and hides the factorial structure you need

- **WHEN** a question names the numerator or denominator of a coefficient in lowest terms **DO** express the coefficient as a small polynomial in n over a factorial, then hunt the shared factor **BECAUSE** a factorial's prime content is completely known, so it is the one denominator that lets you certify which primes survive
- **WHEN** you must decide whether an integer m divides $(m-1)!$ **DO** classify m as prime, composite with unequal factors, or a prime square, and check the single exception $m = 4$ **BECAUSE** these three shapes exhaust every composite integer's smallest-prime-factor decomposition
- **WHEN** two quantities differ by consecutive integers **DO** treat them as coprime without further checking **BECAUSE** $\gcd(k, k+1) = 1$ always

Backtesting

1. First useful cue: "numerator...in lowest terms" attached to a Taylor coefficient, converting calculus into number theory before you differentiate anything.
2. Method the expression suggested: read $(1 - x + x^2)e^x$ as three shifted copies of e^x and combine directly.
3. Where you would hesitate, and the thought to reinforce: after reaching $(n-1)^2/n!$ the three-way case split looks like three separate proofs; it is one question, does m divide $(m-1)!$, asked three times.
4. The trap the question sets: assuming every composite $n-1$ gives numerator 1 and missing the single exception $m = 4$, which survives as the prime 2.
5. What makes you recognise it faster next time: any coefficient built from factorials should trigger "which primes can the denominator certify absent" before any computation.
6. The reusable decision rule: a numerator-in-lowest-terms question over a factorial denominator reduces to classifying one integer against $(m-1)!$, in at most three cases.

Mirror drills

1. (drill) Show that the coefficient of x^n in $(1+x)e^x$ has reduced numerator 1 or prime for every $n \geq 0$. *Answer:* the coefficient is $(n+1)/n!$; classify $m = n+1$ by its smallest prime factor exactly as in the ideal solution, with $m = 4$ (that is $n = 3$) the lone exception, giving numerator 2.
2. (drill) Prove directly that every composite $m > 4$ divides $(m-1)!$. *Answer:* let p be the smallest prime factor of m; if $m/p > p$ use the distinct factors p, $m/p \leq m-1$, and if $m = p^2$ with $p \geq 3$ use the distinct factors p, $2p \leq m-1$.
3. (drill) Write the coefficient of x^n in $(1 + x + x^2 + x^3)e^x$ as a single fraction over $n!$ without differentiating. *Answer:* $\dfrac{1 + n + n(n-1) + n(n-1)(n-2)}{n!}$, read off term by term exactly as in Block 1.

12.2 A2. Determinant of the reciprocal minimum matrix

Let A be the $n \times n$ matrix whose entry in the i-th row and j-th column is

$$\frac{1}{\min(i,j)}$$

for $1 \leq i, j \leq n$. Compute $\det(A)$.

Read it out loud

A matrix built entirely from $\min(i,j)$, and the command term is "compute", not "prove": the ideal route has to terminate in a formula clean enough to write down, not an existence statement. The moment $\min(i,j)$ appears inside a matrix entry a memory should surface: the plain matrix $M_{ij} = \min(i,j)$ is a well known object with determinant 1 for every n, and the reflex to treat this problem as "that matrix, just reciprocated" is exactly the trap on offer. Reciprocating entries does not commute with inverting or with taking determinants, so whatever you remember about M tells you about the shape of A and nothing about its determinant.

What the structure actually offers is this: row i of A reads $1, \frac{1}{2}, \ldots, \frac{1}{i-1}$ and then a run of the constant $\frac{1}{i}$ out to column n, because $\min(i,j) = j$ while $j < i$ and $\min(i,j) = i$ once $j \geq i$. Two rows built this way agree on a long initial stretch and disagree only in a constant tail, and that is the guiding light: any operation that subtracts one row from an adjacent one annihilates the entire agreeing stretch at a stroke. You should have this reflex within thirty seconds of seeing $\min(i,j)$ inside a matrix, before touching a single cofactor: try adjacent row differencing first, because a matrix whose entries are a function of min or max of the indices is built for exactly this.

The fields embedded are linear algebra (row operations, and the determinant of a triangular matrix) and a small amount of series manipulation (the leftover product of consecutive differences telescopes into a ratio of factorials). Nothing here needs eigenvalues or a general cofactor expansion; you need only that left multiplication by a unit triangular matrix leaves the determinant unchanged, and that a triangular matrix's determinant is the product of its diagonal.

Approaches, ranked worst to best

1. **Leibniz or raw cofactor expansion.** *Cue:* "compute $\det(A)$" with no other hint. *Circuit:* sum over all $n!$ permutations, or expand by minors along a row. (stalls at once: $n!$ dense terms with no visible cancellation, and repeated cofactor expansion regenerates a dense $(n-1) \times (n-1)$ minor at every step.)

2. **recall the classical $\min(i,j)$ determinant and try to adapt it.** *Cue:* the visibly famous kernel $\min(i,j)$. *Circuit:* quote $\det(M) = 1$ for $M_{ij} = \min(i,j)$ and try to relate A to M's inverse or adjugate. (a trap: entrywise reciprocal is not matrix inverse, so the classical fact about M says nothing directly about A; chasing the relationship costs ink and never closes.)

3. **border and recurse along the last row.** *Cue:* the matrix grows by one row and column as n increases. *Circuit:* expand along row n to find D_n in terms of D_{n-1}. (works in principle, but row n is not sparse, every entry is $1/i$ or $1/n$, so extracting the recursion needs several lines of algebra and more chances for a sign slip than the route below.)

4. **adjacent row differencing via a single elimination matrix.** *Cue:* row i agrees with row $i-1$ on a long initial stretch, by the definition of min. *Circuit:* left multiply by a fixed unit lower bidiagonal matrix to expose an upper triangular matrix in one identity. (the ideal route: one matrix identity, the determinant read straight off a diagonal, and the leftover product telescopes into factorials.)

The ideal solution

Write the rows of A as $v_1, \dots, v_n$. Since $\min(i,j) = j$ for $j < i$ and $\min(i,j) = i$ for $j \geq i$,

$$v_i = \Big(1, \tfrac{1}{2}, \dots, \tfrac{1}{i-1}, \underbrace{\tfrac{1}{i}, \tfrac{1}{i}, \dots, \tfrac{1}{i}}_{\text{columns } i \text{ to } n}\Big).$$

Let L be the $n \times n$ unit lower bidiagonal matrix with $L_{11} = 1$, $L_{kk} = 1$ and $L_{k,k-1} = -1$ for $k = 2, \dots, n$, and every other entry 0. Then L is lower triangular with every diagonal entry 1, so $\det L = 1$, and the rows of LA are

$$w_1 = v_1, \qquad w_k = v_k - v_{k-1} \ (k = 2, \dots, n),$$

computed directly from the original rows of A, with no question of which row was modified first. It remains to compute $\det(LA) = \det(L)\det(A) = \det(A)$.

Fix $k \geq 2$ and compare v_k with v_{k-1} column by column. For $j \leq k-2$, both $\min(k,j)$ and $\min(k-1,j)$ equal j, so the entries agree. For $j = k-1$, $\min(k, k-1) = k-1 = \min(k-1, k-1)$, so they agree there too. For $j \geq k$, $\min(k,j) = k$ while $\min(k-1,j) = k-1$ (since $j \geq k > k-1$), so the entries differ by the constant $\frac{1}{k} - \frac{1}{k-1}$ across every such column. Hence

$$w_k = \Big(\underbrace{0, \dots, 0}_{k-1}, \underbrace{\tfrac{1}{k} - \tfrac{1}{k-1}, \dots, \tfrac{1}{k} - \tfrac{1}{k-1}}_{\text{columns } k \text{ to } n}\Big), \qquad k = 2, \dots, n,$$

and $w_1 = (1, 1, \dots, 1)$. Every w_k vanishes strictly before column k, so LA is upper triangular, with diagonal entries 1, $\frac{1}{2} - 1$, $\frac{1}{3} - \frac{1}{2}$, $\dots$, $\frac{1}{n} - \frac{1}{n-1}$. Therefore

$$\det(A) = \det(LA) = 1 \cdot \prod_{k=2}^{n} \Big(\frac{1}{k} - \frac{1}{k-1}\Big) = \prod_{k=2}^{n} \frac{-1}{k(k-1)} = (-1)^{n-1} \cdot \frac{1}{\prod_{k=2}^{n} k} \cdot \frac{1}{\prod_{k=2}^{n} (k-1)}.$$

The two products telescope on sight, $\prod_{k=2}^{n} k = n!$ and $\prod_{k=2}^{n} (k-1) = (n-1)!$, so

$$\boxed{\det(A) = \frac{(-1)^{n-1}}{n!\,(n-1)!}}.$$

(This also covers $n = 1$, where the product over $k = 2, \dots, n$ is empty and $\det A = 1$, matching $A = (1)$.)

Layer 1: WHAT

1. **Block 1.** Read off the row structure of A directly from the definition of min: an increasing prefix, then a constant tail.
2. **Block 2.** Notice adjacent rows agree on the entire prefix and differ only in the tail, so a row difference should annihilate the agreement.
3. **Block 3.** Package every row difference into one matrix identity, left multiplication by a unit lower bidiagonal L with $\det L = 1$, so no order of operations needs justifying.
4. **Block 4.** Verify LA is upper triangular and read the determinant off the diagonal.
5. **Block 5.** Telescope the resulting product of consecutive reciprocal differences into a ratio of two factorials.

The nominal route reaches for cofactor expansion or the Leibniz sum, treating A as an opaque array of numbers with no exploitable shape; it never terminates in a clean formula without an unmotivated leap. The ideal route never expands anything: it reads the min structure as an instruction to difference rows, and packages that instruction as a single matrix so no step is ambiguous. The bifurcation point is the opening reflex, whether $\min(i,j)$ inside a matrix triggers "expand" or "difference adjacent rows", fired before a single entry is computed.

Layer 2: HOW

Block 1. **Cue.** Row i is constant from column i onward, because $\min(i, j)$ stops growing once j reaches i. **Why natural.** A matrix entry defined by a comparison of indices always has this "capped" shape: once one index dominates, further increase of the other index changes nothing. **Link to the next block.** Two rows differing only in where the cap kicks in must be nearly identical, which begs for a comparison between adjacent rows.

Block 2. **Cue.** Rows i and $i-1$ share the exact same values on columns 1 through $i-1$. **Why natural.** Both are governed by the smaller index on that range, since $j < i-1 < i$ forces $\min(i, j) = \min(i-1, j) = j$ for both rows simultaneously. **Link to the next block.** Subtracting row $i-1$ from row i should zero out that entire shared range in one operation, which is the definition of progress toward a triangular matrix.

Block 3. **Cue.** You need every row difference to use the original, unmodified row above it, or the zero pattern breaks. **Why natural.** If you instead updated rows sequentially in increasing order, row k would difference against an already changed row $k-1$, corrupting the result; encoding all the differences as one multiplication by L applies them simultaneously to the original A and removes the question entirely. **Link to the next block.** Once LA is written down as a genuine matrix, checking its shape is now pure verification, not a procedure that can go wrong in execution.

Block 4. **Cue.** Every row of LA vanishes strictly before its own diagonal position, by direct computation. **Why natural.** That is the definition of upper triangular, and for such a matrix the determinant is exactly the product of the diagonal, with no cofactor work left to do. **Link to the next block.** The only content still needed is to name the diagonal entries themselves.

Block 5. **Cue.** The diagonal entries are the consecutive differences $\frac{1}{k} - \frac{1}{k-1}$. **Why natural.** Combining over a common denominator turns each term into $-1/(k(k-1))$, and a product of such terms splits into two separate products, one running over k and one over $k-1$, each of which is visibly $n!$ or $(n-1)!$. **Link to the next block.** Nothing further is needed; the two telescoping products are the final answer.

Layer 3: WHY

The truth underneath this problem is that any matrix entry depending only on $\min(i, j)$ (or, symmetrically, only on $\max(i, j)$) encodes a "prefix agreement" between rows that is invisible to cofactor expansion but is exactly what row differencing is built to exploit. The discernment mechanism is to ask, on sight of min or max inside a matrix entry, whether two adjacent rows or columns must agree on a long run purely from the definition of the comparison, before attempting any other manipulation; if they do, row or column differencing is close to free and cofactor expansion is close to the most expensive option available. Packaging the differencing as multiplication by an explicit unit triangular L is the discipline that removes the one way this route can go wrong, namely applying the differences in an order that reuses an already modified row; a single matrix identity has no order to get wrong. The examiners nudged you toward this by choosing $\min(i, j)$ specifically rather than, say, $i + j$ or ij: those entries do not create the prefix agreement between rows that makes differencing free, so the choice of min is itself the guiding light, not an incidental feature of the problem.

Revolving concepts

Matrices built from min **of the indices.** If $c_1, c_2, \ldots, c_n$ is any sequence and $A_{ij} = c_{\min(i,j)}$, the same argument gives $\det(A) = c_1 \prod_{k=2}^{n}(c_k - c_{k-1})$: row 1 is constant at c_1, and row k minus row $k-1$ vanishes before column k and equals $c_k - c_{k-1}$ from column k onward. This problem is the case $c_k = 1/k$; the classical fact $\det(\min(i,j)) = 1$ is the case $c_k = k$, where every difference $c_k - c_{k-1}$ equals 1. See Book 1, field: Matrices and determinants, topic: structured determinants.

Determinant of a triangular matrix. For an upper or lower triangular matrix, det is the product of the diagonal entries; this is the single fact that turns "matrix reduced to triangular form" into "answer written down". See Book 1, field: Matrices and determinants, topic: triangular matrices.

Row operations as left multiplication. Replacing the rows of A according to a fixed linear rule is the same as forming LA for a matrix L built from that rule; if L is unit triangular, $\det L = 1$ and $\det(LA) = \det(A)$. Framing row reduction this way, rather than as a sequence of instructions, is what lets you certify a computation without worrying about the order in which steps were carried out. See Book 1, field: Linear algebra, topic: elementary matrices.

Nested determinants and a one-step recursion. The top left $(n-1) \times (n-1)$ block of A is exactly the $(n-1) \times (n-1)$ version of the same matrix, and the triangularisation is compatible across n, so $D_n = (\frac{1}{n} - \frac{1}{n-1})\, D_{n-1}$: each new size contributes exactly one new diagonal entry. Generalised, whenever a family of matrices is nested this way and reduces to triangular form compatibly, its determinants satisfy $D_n = (\text{new diagonal entry}) \times D_{n-1}$, a first order recursion solved immediately by telescoping the ratios, exactly as the product $\prod(c_k - c_{k-1})$ above does for any such family. See Book 1, field: Sequences and recurrences, topic: telescoping products.

A remark worth knowing, not needed for the proof. The official solution notes that the inverse of A is tridiagonal. This is not a coincidence: the continuous kernel $\min(x,y)$ on $[0,1]^2$ is the Green's function of $-u'' = f$ with $u(0) = 0$, $u'(1) = 0$, and matrices built from $\min(i,j)$ are the discrete analogue of that kernel, so their inverses inherit the tridiagonal shape of the discrete second derivative operator. See Book 1, field: Real analysis, topic: Green's functions.

Circuit Bank

- **WHEN** a matrix entry depends only on $\min(i,j)$ or $\max(i,j)$ **DO** try adjacent row or column differencing before any cofactor expansion **BECAUSE** two adjacent rows of such a matrix agree on the entire capped prefix and differ only on the remainder, so differencing produces triangularity almost for free

- **WHEN** you want to justify a chain of row operations without worrying about their order **DO** exhibit the single matrix L with known determinant such that LA is the matrix you want **BECAUSE** $\det(LA) = \det(L)\det(A)$ settles the computation in one line and removes any question of which row was updated first

- **WHEN** a matrix is triangular, by construction or after reduction **DO** read the determinant straight off the diagonal **BECAUSE** that is the entire content of the triangular determinant formula, with no cofactor work left

- **WHEN** a product of consecutive-integer reciprocal differences appears **DO** combine each term into a single fraction and split the product into two separately telescoping factorial products **BECAUSE** $\prod_{k=a}^{b} k$ collapses immediately to a ratio of factorials

- **WHEN** a family of matrices is nested, with the $(n-1)$-th sitting as the top left block of the n-th, and triangularises compatibly **DO** look for the one-step recursion $D_n = (\text{new diagonal entry}) \times D_{n-1}$ **BECAUSE** the new diagonal entry is the only genuinely new information the larger matrix contributes once the reduction pattern is fixed

Backtesting

1. First useful cue: $\min(i, j)$ sitting inside a matrix entry, which should trigger adjacent row differencing before any other tool.
2. Method the expression suggested: compare row i with row $i-1$ directly from the definition of min, rather than expanding by cofactors.
3. Where you would hesitate, and the thought to reinforce: whether the row differences can be done in any order; reinforce that they cannot in general, and that packaging them as one matrix L removes the question.
4. The trap the question sets: recalling that $\det(\min(i, j)) = 1$ classically and assuming the reciprocated matrix inherits some simple relation to that fact, when reciprocation does not commute with either inversion or determinants.
5. What makes you recognise it faster next time: seeing that a matrix entry compares two indices at all should trigger "check what adjacent rows or columns share" before any other move.
6. The reusable decision rule: for $A_{ij} = c_{\min(i,j)}$, the determinant is always c_1 times the telescoping product of $c_k - c_{k-1}$, so identify the sequence c_k and substitute.

Mirror drills

1. (drill) Show that $\det(M) = 1$ for every n, where $M_{ij} = \min(i, j)$. *Answer:* apply the general lemma with $c_k = k$: $c_1 = 1$ and $c_k - c_{k-1} = 1$ for every k, so $\det(M) = 1 \cdot 1^{n-1} = 1$.
2. (drill) Compute $\det(A)$ where $A_{ij} = \min(i, j)^2$. *Answer:* take $c_k = k^2$ in the general lemma: $c_1 = 1$ and $c_k - c_{k-1} = 2k - 1$, so $\det(A) = \prod_{k=2}^{n}(2k-1)$, the product of the odd numbers from 3 to $2n - 1$.
3. (drill) In the 3×3 case, compute what happens if you update rows in increasing order instead of using the original rows throughout: replace row 2 by row 2 minus row 1, then replace row 3 by (new) row 2 minus row 1. *Answer:* you get row $3 \to (1, 1, \frac{5}{6})$, not triangular at all, which is exactly why the ideal solution defines every w_k from the original rows rather than updating sequentially.

12.3 A3. Telescoping infinite product from a doubling recursion

Let $a_0 = 5/2$ and $a_k = a_{k-1}^2 - 2$ for $k \geq 1$. Compute

$$\prod_{k=0}^{\infty} \left(1 - \frac{1}{a_k}\right)$$

in closed form.

Read it out loud

A recursion of the shape $a_k = a_{k-1}^2 - 2$, and the instant you see a squaring combined with subtracting exactly 2, one specific memory should fire: this is the algebraic shadow of doubling an exponent. If $t = y + \frac{1}{y}$ for some y, then $t^2 - 2 = y^2 + \frac{1}{y^2}$, the very same shape with y replaced by y^2. The recursion is not really about squaring numbers, it is about squaring an auxiliary variable y_k whose exponent doubles at every step, and the first useful move is to find y_0 with $y_0 + \frac{1}{y_0} = a_0 = \frac{5}{2}$, which is $y_0 = 2$ (solve $2y_0^2 - 5y_0 + 2 = 0$).

The command term "compute...in closed form" attached to an infinite product tells you the second half of the strategy before you have used the recursion at all: an infinite product only closes cleanly when it telescopes, meaning each factor can be written as (something depending on the next index) divided by (that same something one index earlier), so every interior factor cancels and only the two ends survive. So the moment $\prod_{k=0}^{\infty}(\cdots)$ appears around a recursively defined sequence, the guiding lights are, in order: find the closed form for a_k first, then hunt for a telescoping certificate for the product, an auxiliary expression that turns the k-th factor into a ratio linking index k to index $k+1$.

The fields embedded are sequences and recurrences (the doubling substitution), infinite products and their convergence (you must justify that the product tends to a nonzero limit, not merely compute as if it does), and a short piece of algebraic identity hunting to build the telescoping certificate. Nothing here needs more than quadratic identities in y and $1/y$; the entire difficulty is structural recognition, not computation, which is exactly why a_0 was handed to you as the suggestive fraction $5/2$ rather than a decimal.

Approaches, ranked worst to best

1. **numerical estimation.** *Cue:* "compute...in closed form" tempts a decimal check. *Circuit:* compute $a_0, a_1, a_2, \ldots$ and the partial products numerically, notice convergence to a suspicious decimal, guess a fraction. (useful only as a sanity check on a candidate answer: it cannot certify the limit is exactly $3/7$ rather than a nearby value indistinguishable at finite precision, and it explains nothing.)

2. **partial products by induction on the recursion alone.** *Cue:* $a_{k+1} + 1 = (a_k - 1)(a_k + 1)$ falls out of the recursion by one line of algebra. *Circuit:* guess, from Π_0, Π_1 computed as exact fractions, a formula for $\prod_{k=0}^{n}(1 - 1/a_k)$ in terms of a_{n+1}, then prove it by induction, without ever finding a_k itself in closed form. (rigorous, and it avoids guessing the closed form for a_k, but the auxiliary identities needed are not suggested by anything visible in the recursion; finding them costs more search time and more luck than the route below.)

3. **doubling substitution, then a matching telescoping certificate.** *Cue:* $a_k = a_{k-1}^2 - 2$ is the algebraic shadow of $y \mapsto y^2$ under $y + 1/y$. *Circuit:* solve for y_0, get $a_k = y_0^{2^k} + y_0^{-2^k}$ in closed form, then reuse the same square-minus-something identity to build an explicit telescoping ratio for the product. (the ideal route: the closed form is forced by the shape of the recursion itself, and the certificate is then a two-line identity, not a guess.)

The ideal solution

Step 1, linearise the recursion. Solve $y_0 + \frac{1}{y_0} = a_0 = \frac{5}{2}$, i.e. $2y_0^2 - 5y_0 + 2 = 0 = (2y_0 - 1)(y_0 - 2)$, giving $y_0 = 2$ (the root $y_0 = \frac{1}{2}$ gives the same sequence by the symmetry $y \leftrightarrow 1/y$). Claim: $a_k = y_0^{2^k} + y_0^{-2^k}$ for every $k \geq 0$. This holds at $k = 0$ by construction. If it holds at $k - 1$, write $z = y_0^{2^{k-1}}$, so $a_{k-1} = z + \frac{1}{z}$, and

$$a_k = a_{k-1}^2 - 2 = \left(z + \tfrac{1}{z}\right)^2 - 2 = z^2 + \tfrac{1}{z^2} = y_0^{2^k} + y_0^{-2^k},$$

which closes the induction. With $y_0 = 2$, $a_k = 2^{2^k} + 2^{-2^k}$.

Step 2, certify convergence. Since $2^{2^k} \geq 2$, every $a_k \geq 2 > 1$, so each factor $1 - \frac{1}{a_k}$ lies in $(0, 1)$. For an infinite product of terms $1 - \epsilon_k$ with $\epsilon_k \in [0, 1)$, the product converges to a strictly positive limit exactly when $\sum_k \epsilon_k$ converges. Here $\epsilon_k = 1/a_k \leq 2^{-2^k}$, and $\sum_k 2^{-2^k}$ converges (it is dominated by a geometric series), so the infinite product in the problem is a genuine, nonzero, well defined limit, not a formal expression.

Step 3, build the telescoping certificate. Let $y_k = y_0^{2^k}$, so $a_k = y_k + y_k^{-1}$ and $y_{k+1} = y_k^2$. For any $t \neq 0$,

$$(t + t^{-1})^2 - 1 = t^2 + 1 + t^{-2},$$

which rearranges, since $t + t^{-1} - 1$ is one factor of a difference of squares against $t + t^{-1} + 1$, into

$$t - 1 + t^{-1} = \frac{t^2 + 1 + t^{-2}}{t + 1 + t^{-1}} = \frac{P(t^2)}{P(t)}, \qquad P(t) := t + 1 + t^{-1}.$$

Separately, since $t^2 - t^{-2} = (t - t^{-1})(t + t^{-1})$,

$$t + t^{-1} = \frac{t^2 - t^{-2}}{t - t^{-1}} = \frac{Q(t^2)}{Q(t)}, \qquad Q(t) := t - t^{-1},$$

valid because $t = y_k \geq 2$ so $Q(t) \neq 0$ throughout. Since $1 - \frac{1}{a_k} = \dfrac{y_k - 1 + y_k^{-1}}{y_k + y_k^{-1}}$, substituting $t = y_k$ into both identities gives

$$1 - \frac{1}{a_k} = \left.\frac{P(t^2)/P(t)}{Q(t^2)/Q(t)}\right|_{t=y_k} = \frac{P(y_{k+1})}{P(y_k)} \cdot \frac{Q(y_k)}{Q(y_{k+1})}.$$

Step 4, telescope and take the limit. The partial product collapses immediately:

$$\prod_{k=0}^{n}\left(1 - \frac{1}{a_k}\right) = \prod_{k=0}^{n} \frac{P(y_{k+1})}{P(y_k)} \cdot \frac{Q(y_k)}{Q(y_{k+1})} = \frac{P(y_{n+1})}{P(y_0)} \cdot \frac{Q(y_0)}{Q(y_{n+1})}.$$

As $n \to \infty$, $y_{n+1} = 2^{2^{n+1}} \to \infty$, and both $P(y_{n+1}) = y_{n+1} + 1 + y_{n+1}^{-1}$ and $Q(y_{n+1}) = y_{n+1} - y_{n+1}^{-1}$ are dominated by y_{n+1} itself, so their ratio tends to 1. Hence

$$\prod_{k=0}^{\infty}\left(1 - \frac{1}{a_k}\right) = \frac{Q(y_0)}{P(y_0)} = \frac{y_0 - y_0^{-1}}{y_0 + 1 + y_0^{-1}} = \frac{2 - \frac{1}{2}}{2 + 1 + \frac{1}{2}} = \frac{3/2}{7/2} = \boxed{\frac{3}{7}}.$$

Layer 1: WHAT

1. **Block 1.** Recognise $a_k = a_{k-1}^2 - 2$ as squaring in disguise under $t = y + 1/y$, and solve for y_0 from a_0.
2. **Block 2.** Prove $a_k = y_0^{2^k} + y_0^{-2^k}$ by one line of induction, converting a numeric recursion into a doubling exponent.

3. **Block 3.** Confirm each factor lies in $(0,1)$ and that $\sum 1/a_k$ converges, certifying the infinite product is a genuine nonzero limit before computing it.
4. **Block 4.** Reuse the identity that produced the closed form to build a telescoping certificate P, Q linking consecutive doublings.
5. **Block 5.** Telescope the partial product to two boundary terms and take the limit as the far boundary's ratio tends to 1.

The nominal route computes decimals, notices $0.428571\ldots$, and stops, or else hunts directly for a partial-product formula in terms of a_{n+1} by unmotivated trial and error on the raw recursion. The ideal route finds the closed form for a_k first, a forced two-line induction, and then builds the telescoping certificate from the exact same algebraic identity used to prove that closed form, rather than searching for a second, unrelated idea. The bifurcation point is the opening reflex: whether "square, then subtract 2" triggers the substitution $y + 1/y$ before a single decimal is computed.

Layer 2: HOW

Block 1. **Cue.** The right-hand side of the recursion is exactly $(\cdot)^2 - 2$. **Why natural.** This is the one quadratic shift for which $t = y + 1/y$ linearises the map completely: $(y + 1/y)^2 - 2 = y^2 + 1/y^2$ has no leftover cross term, so squaring t corresponds exactly to squaring y. **Link to the next block.** Once $y_0 + 1/y_0 = a_0$ is solved, the only remaining question is whether the pattern persists, which is what induction is for.

Block 2. **Cue.** A claimed closed form matches the recursion at the base case $k = 0$. **Why natural.** Induction is the certificate that a closed form matches a recursion for every k, and here the inductive step is the same one-line algebra as Block 1, applied to $y_0^{2^{k-1}}$ instead of y_0. **Link to the next block.** With a_k explicit, the k-th factor of the product is now a fixed rational function of $y_0^{2^k}$, ready for algebraic manipulation rather than numerical estimation.

Block 3. **Cue.** The product is asked for over infinitely many factors. **Why natural.** An infinite product of terms in $(0,1)$ can converge to 0 if the terms shrink too slowly to 1; the correct test is whether $\sum(1 - \text{factor})$ converges, and here it does easily because a_k grows doubly exponentially. **Link to the next block.** With convergence certified, computing "the closed form" is now computing an honest limit, and any valid method, including a telescoping partial product, is permitted.

Block 4. **Cue.** The factor $1 - 1/a_k$, written in terms of y_k, is $\dfrac{y_k - 1 + y_k^{-1}}{y_k + y_k^{-1}}$. **Why natural.** An infinite product only closes cleanly when consecutive factors interlock, so you look for two auxiliary functions, one whose value at y_{k+1} appears in this factor's numerator and one whose value at y_{k+1} appears in its denominator, both built from the identity already used in Block 1. **Link to the next block.** Finding P and Q this way turns the entire infinite product into two boundary evaluations instead of infinitely many factors.

Block 5. **Cue.** The partial product collapses to $P(y_{n+1})/P(y_0)$ times $Q(y_0)/Q(y_{n+1})$. **Why natural.** As $y_{n+1} \to \infty$, the $+1$ inside P and the sign flip inside Q become negligible against the dominant term y_{n+1}, so their ratio tends to 1. **Link to the next block.** Only the two starting values $P(y_0)$ and $Q(y_0)$ survive, giving the closed form directly with no further work.

Layer 3: WHY

The truth underneath this problem is that $u \mapsto u^2 - 2$ is, up to the substitution $u = y + 1/y$ (equivalently $u = 2\cosh\theta$ for $u \geq 2$, or $u = 2\cos\theta$ for $|u| \leq 2$), literally squaring, and squaring is the one operation whose k-fold iterate you can write down immediately: iterate it on an exponent and the exponent doubles, with no approximation and no accumulating error. The discernment mechanism is to treat any recursion of the shape $t_k = t_{k-1}^2 - c$ as a search for the substitution $t = y + c'/y$ that turns it into $y \mapsto y^2$; the constant $c = 2$ is the signature to watch for, because $(y + 1/y)^2 - 2 = y^2 + 1/y^2$ matches with coefficient exactly 1 on both sides, whereas $c = 1$ or $c = 3$ would not linearise this cleanly. Once the closed form exists, an infinite product built from a doubling-exponent sequence should immediately suggest a telescoping certificate, because such a sequence's k-th term is always a fixed rational function of $y_0^{2^k}$, and the certificate is typically the same identity, reused, that produced the closed form in the first place. The examiners nudged you toward all of this by choosing $a_0 = \frac{5}{2}$, a fraction with a visibly clean partner $y_0 = 2$ under $y + 1/y$, rather than a value that would hide the substitution.

Revolving concepts

The recursion $t_k = t_{k-1}^2 - 2$. For $t_0 = y_0 + 1/y_0$ (real $y_0 \geq 1$, so $t_0 \geq 2$) the closed form is $t_k = y_0^{2^k} + y_0^{-2^k}$; for $t_0 = 2\cos\theta_0$ ($|t_0| \leq 2$) it is $t_k = 2\cos(2^k\theta_0)$. Both are the statement that $u \mapsto u^2 - 2$ is conjugate to doubling, and both are the k-fold iterate of the degree 2 Chebyshev polynomial: $t_k = 2T_{2^k}(t_0/2)$, using the composition law $T_m \circ T_n = T_{mn}$. This applies to any iterated quadratic recursion of exactly this shape, including computing cos of dyadically many multiples of an angle and Lucas-Lehmer-flavoured recursions. See Book 1, field: Polynomials, topic: Chebyshev polynomials.

Telescoping certificates for a product over an iterated map. To evaluate $\prod_k f(y_0^{2^k})$ in closed form, look for auxiliary functions P, Q with $f(t) = P(t^2)/P(t) \cdot Q(t)/Q(t^2)$; the partial product then collapses to $P(y_{n+1})/P(y_0) \cdot Q(y_0)/Q(y_{n+1})$ regardless of how complicated f looks termwise. See Book 1, field: Sequences and recurrences, topic: telescoping products.

Convergence of an infinite product. For $\epsilon_k \in [0, 1)$, $\prod_k (1 - \epsilon_k)$ converges to a strictly positive limit if and only if $\sum_k \epsilon_k$ converges; this is checked by comparing $\log(1 - \epsilon_k) \sim -\epsilon_k$ for small ϵ_k against the convergent series $\sum \epsilon_k$. See Book 1, field: Real analysis, topic: infinite products.

Sum of a number and its reciprocal. $y + 1/y = 2\cosh(\ln y)$ for $y > 0$, and for $y = e^{i\theta}$ this is $2\cos\theta$; the identity $(y + 1/y)^2 - 2 = y^2 + 1/y^2$ is exactly the double angle formula for cosh or cos written multiplicatively. Recognising this form on sight is what lets you treat an algebraic recursion and a trigonometric double angle identity as the same fact seen twice. See Book 1, field: Complex numbers, topic: hyperbolic and circular functions.

Circuit Bank

- **WHEN** a recursion has the shape $t_k = t_{k-1}^2 - 2$ **DO** substitute $t_0 = y_0 + 1/y_0$ and conclude $t_k = y_0^{2^k} + y_0^{-2^k}$ **BECAUSE** $(y + 1/y)^2 - 2 = y^2 + 1/y^2$ turns squaring the recursion into squaring the auxiliary variable, doubling its exponent
- **WHEN** an infinite product is built from a sequence whose exponent doubles at every step **DO** hunt for auxiliary functions P, Q with (term)$= P(\text{next})/P(\text{current}) \cdot Q(\text{current})/Q(\text{next})$ **BECAUSE** such a certificate collapses the whole product to the two boundary values at the first and, in the limit, the last index
- **WHEN** you are asked for the value of an infinite product **DO** check first that $\sum(1 - \text{term}_k)$ converges **BECAUSE** this is exactly the condition for the product to converge to a nonzero limit, and skipping it leaves the closed form unjustified even if the arithmetic is right

- **WHEN** an expression of the form $y + 1/y$ appears **DO** recognise it as $2\cosh(\ln y)$, or $2\cos\theta$ when it lies in $[-2, 2]$ **BECAUSE** this connects any algebraic identity you find to the matching angle doubling identity, often easier to recall under pressure

Backtesting

1. First useful cue: the exact combination "square, then subtract 2", the algebraic signature of doubling under $y + 1/y$.
2. Method the expression suggested: solve $y_0 + 1/y_0 = a_0$ for y_0, then prove $a_k = y_0^{2^k} + y_0^{-2^k}$ by one line of induction.
3. Where you would hesitate, and the thought to reinforce: after the closed form, the jump to a telescoping certificate looks unmotivated; reinforce that the certificate reuses the exact identity $(t + 1/t)^2 - 1 = t^2 + 1 + 1/t^2$ that proved the recursion.
4. The trap the question sets: computing decimals, spotting $0.428571\ldots$, and stopping, without proving the limit is exactly $3/7$ rather than a value indistinguishable at finite precision.
5. What makes you recognise it faster next time: any recursion of the shape variable squared minus a constant should immediately suggest hunting for the matching sum-with-reciprocal substitution before anything numeric.
6. The reusable decision rule: an infinite product over a doubling-exponent sequence telescopes via a certificate built from the same identity that produced the closed form; find that identity once and reuse it twice.

Mirror drills

1. (drill) Let $b_0 = 3$ and $b_k = b_{k-1}^2 - 2$. Find b_k in closed form. *Answer:* solve $y_0 + 1/y_0 = 3$, giving $y_0 = \frac{3+\sqrt{5}}{2}$, so $b_k = y_0^{2^k} + y_0^{-2^k}$.
2. (drill) With $a_0 = 5/2$ as in the problem, compute $\prod_{k=1}^{\infty}\left(1 - \frac{1}{a_k}\right)$, starting the product one index later. *Answer:* the same telescoping now starts at $y_1 = y_0^2 = 4$, giving $Q(4)/P(4) = (4 - \frac{1}{4})/(4 + 1 + \frac{1}{4}) = \frac{15}{21} = \frac{5}{7}$; check it against the full product by dividing: $(3/7) \div (1 - 1/a_0) = (3/7) \div (3/5) = 5/7$.
3. (drill) Show $(2\cos\theta)^2 - 2 = 2\cos(2\theta)$, and hence that iterating $t \mapsto t^2 - 2$ on $t_0 = 2\cos\theta_0$ gives $2\cos(2^k\theta_0)$. *Answer:* $4\cos^2\theta - 2 = 2(2\cos^2\theta - 1) = 2\cos 2\theta$ by the double angle formula, then induct on k exactly as in Block 2 of Layer 2.

12.4 A4. Minimising the mass at zero from three moments

Suppose X is a random variable that takes on only nonnegative integer values, with $E[X] = 1$, $E[X^2] = 2$, and $E[X^3] = 5$. (Here $E[Y]$ denotes the expectation of the random variable Y.) Determine the smallest possible value of the probability of the event $X = 0$.

Read it out loud

Say the structure aloud: a distribution on the nonnegative integers, three prescribed power moments, minimise the mass sitting at the origin. Once you say that, the probabilistic costume falls off. The unknown is not a number and it is not a random variable in any analytic sense; the unknown is the sequence $p_0, p_1, p_2, \ldots$ of nonnegative reals, $p_n = P(X = n)$. Every piece of data is linear in that sequence, and so is the thing you are asked to minimise. This is a linear programme, and it is an infinite dimensional one only in appearance.

Within thirty seconds the page should carry this and nothing else:

$$\sum_{n\geq 0} p_n = 1, \quad \sum_{n\geq 0} np_n = 1, \quad \sum_{n\geq 0} n^2 p_n = 2, \quad \sum_{n\geq 0} n^3 p_n = 5, \quad p_n \geq 0, \quad \text{minimise } p_0.$$

The fields wired into the question are linear programming duality, the classical moment problem, and, underneath both, polynomial positivity on a discrete set. The word "integer" is not decoration. It is the entire content of the problem: you will see below that if X were allowed arbitrary nonnegative real values with the same three moments, the mass at 0 could be pushed to zero exactly. The integers are what stop it at $\frac{1}{3}$.

Now the cue that decides the whole solution. You are given the moments of degree 1, 2 and 3 (and degree 0, which is the total mass). So the set of test functions whose expectation you can compute exactly, without knowing anything else about X, is precisely the set of polynomials of degree at most 3. That is your entire toolkit, stated exactly. The quantity you want is $E[\mathbf{1}[X = 0]]$, the expectation of an indicator. Thus the problem, fully undisguised, is: find the cubic that hugs the indicator of $\{0\}$ from below as tightly as possible on $\mathbb{Z}_{\geq 0}$. Everything after this sentence is bookkeeping.

Approaches, ranked worst to best

1. **Guess distributions and compare.** *Cue:* "determine the smallest possible value" reads like a search. *Circuit:* no circuit at all, this is consumption. You can stumble onto $\left(\frac{1}{3}, \frac{1}{2}, 0, \frac{1}{6}\right)$ in a few minutes of fiddling, and then you have zero of the ten marks, because a minimum claimed without a proof of optimality is a guess. Ranked last because it feels like progress.

2. **Cauchy and Schwarz on the positive part.** *Cue:* a first moment, a second moment and a tail probability in the same problem. *Circuit:* the second moment tail bound. From $1 = E[X\mathbf{1}[X \geq 1]]^2 \leq E[X^2]P(X \geq 1)$ you get $p_0 \leq \frac{1}{2}$. Correct, useless: it bounds p_0 from above when you were asked for a bound from below, and it never touches the third moment, which is the only reason the answer is not 0.

3. **Lagrange multipliers on a truncated support.** *Cue:* constrained optimisation of a smooth objective. *Circuit:* the multiplier circuit. You must first prove the optimum is finitely supported, which is most of the work, and then you are doing by calculus what the next two methods do by inspection. It costs ink and it hides the inequality that actually carries the proof.

4. **Probability generating function with Taylor remainder.** *Cue:* an integer valued random variable, so encode it as a power series. *Circuit:* the generating function circuit: $G(z) = E[z^X]$ turns moments into derivatives at $z = 1$ and turns p_0 into $G(0)$. Here $G(1) = G'(1) = G''(1) = G'''(1) = 1$, since the factorial moments $E[X]$, $E[X(X-1)]$, $E[X(X-1)(X-2)]$ are 1, 1, 1.

Taylor to third order about $z = 1$ evaluated at $z = 0$ gives $G(0) = 1 - 1 + \frac{1}{2} - \frac{1}{6} + \frac{1}{24}G''''(c) = \frac{1}{3} + \frac{1}{24}G''''(c) \geq \frac{1}{3}$, because a power series with nonnegative coefficients has nonnegative derivatives on $[0, 1)$. This is a genuinely good route and it generalises instantly to more moments. It ranks second only because the one sided derivatives at $z = 1$ need an Abel type justification before you may write them, and a grader is entitled to want that line.

5. **Dual certificate: the Lagrange basis cubic.** *Cue:* the data are exactly the moments of degree 0 to 3, and the target is the expectation of an indicator. *Circuit:* linear programming duality made concrete: to bound a linear functional of an unknown measure, test the measure against a polynomial you are allowed to evaluate. Best. Four lines, no analysis, and the certificate writes itself from the interpolation nodes, as shown below.

The ideal solution

The answer is $\boxed{\frac{1}{3}}$.

Write $p_n = P(X = n)$. Since $E[X^3] = 5$ is finite, $\sum n^3 p_n$ converges, hence so do $\sum n^2 p_n$, $\sum n p_n$ and $\sum p_n$, and every expectation below is a finite linear combination of these four convergent sums.

Let

$$q(x) = -\frac{(x-1)(x-2)(x-3)}{6} = -\frac{x^3 - 6x^2 + 11x - 6}{6},$$

the unique cubic taking the value 1 at $x = 0$ and 0 at $x = 1, 2, 3$.

Lemma 12.4.1. *For every integer $n \geq 0$ we have $q(n) \leq \mathbf{1}[n = 0]$.*

Proof. At $n = 0$, $q(0) = -\frac{(-1)(-2)(-3)}{6} = 1$, so the inequality holds with equality. At $n = 1, 2, 3$ we have $q(n) = 0 \leq 0$. For an integer $n \geq 4$ the three factors $n - 1, n - 2, n - 3$ are all positive, so $(n-1)(n-2)(n-3) > 0$ and $q(n) < 0$. There are no other nonnegative integers. □

Taking expectations in the pointwise inequality of the lemma (both sides have finite expectation, and the inequality holds at every point of the support of X),

$$E\left[q(X)\right] \leq E\left[\mathbf{1}[X = 0]\right] = p_0.$$

The left hand side is computable from the data alone:

$$E\left[q(X)\right] = -\frac{E[X^3] - 6E[X^2] + 11E[X] - 6}{6} = -\frac{5 - 12 + 11 - 6}{6} = -\frac{-2}{6} = \frac{1}{3}.$$

Therefore $p_0 \geq \frac{1}{3}$ for every admissible X.

The bound is attained. Let X take the values $0, 1, 3$ with probabilities $\frac{1}{3}, \frac{1}{2}, \frac{1}{6}$ respectively. Then

$$\sum p_n = \tfrac{1}{3} + \tfrac{1}{2} + \tfrac{1}{6} = 1, \quad E[X] = \tfrac{1}{2} + \tfrac{3}{6} = 1, \quad E[X^2] = \tfrac{1}{2} + \tfrac{9}{6} = 2, \quad E[X^3] = \tfrac{1}{2} + \tfrac{27}{6} = 5,$$

so this X satisfies every hypothesis and has $P(X = 0) = \frac{1}{3}$. Hence the smallest possible value of $P(X = 0)$ is $\frac{1}{3}$, and it is a minimum, not merely an infimum.

Layer 1: WHAT

Block 1. Rename the unknown: the object being optimised is the sequence (p_n), and every constraint is linear in it.

Block 2. Identify the admissible test functions: the given data determine $E[f(X)]$ for exactly one family, the polynomials of degree at most 3.

Block 3. Restate the target: $p_0 = E\left[\mathbf{1}[X = 0]\right]$, so you want a cubic lying below $\mathbf{1}[n = 0]$ on $\mathbb{Z}_{\geq 0}$ with the largest possible expectation.

Block 4. Build that cubic by interpolation: force it to equal the indicator at $n = 0, 1, 2, 3$. That is the Lagrange basis polynomial q for the node 0 on the node set $\{0, 1, 2, 3\}$.

Block 5. Check the only thing interpolation does not give you for free: that $q(n) \leq 0$ persists for every integer $n \geq 4$. It does, because past the last node all three factors are positive and the sign in front is negative.

Block 6. Take expectations, read off $p_0 \geq \frac{1}{3}$.

Block 7. Produce a distribution attaining it, which the nodes have already told you where to look: the mass must sit where q is tight.

The nominal route runs: parametrise $p_0, p_1, p_2, \ldots$, truncate the support at some guessed level, solve four linear equations in several unknowns, vary the free parameters, and try to argue that the minimum over the truncation is the minimum overall. It produces pages, it produces the right number, and it never produces a proof, because the truncation was never justified.

The bifurcation point is the line where you decide what your unknown is. If you write "let the support be $\{0, a, b, c\}$", you are on the zombie route. If you write "the data give me $E[f(X)]$ for every cubic f, so let me choose f well", you are on the ideal route. The zombie route treats the distribution as the unknown to be pinned down; the ideal route treats the distribution as an adversary and hands it an inequality it cannot escape.

Layer 2: HOW

Block 1. Cue. The phrase "takes on only nonnegative integer values" plus three numerical expectations plus "smallest possible value". **Why natural.** The data are values of linear functionals on an unknown measure, and the target is another linear functional. Optimisation of a linear functional subject to linear constraints and a positivity constraint is a linear programme, and the reflex for a linear programme is always the same: do not chase the primal optimum, construct a dual certificate. **Link to the next block.** Once you accept you are constructing a certificate, the next question is forced: a certificate made of what?

Block 2. Cue. You are given moments of degree $0, 1, 2, 3$ and nothing else. **Why natural.** A certificate must be a function whose expectation you can evaluate without knowing X. That set is exactly $\{$polynomials of degree at most $3\}$, no larger and no smaller. Naming the admissible set precisely is the move; most candidates never write this sentence and so never know what they are allowed to use. **Link to the next block.** You now need to compare a cubic with the quantity you want, so write that quantity as an expectation too.

Block 3. Cue. p_0 is a probability, and every probability is the expectation of an indicator. **Why natural.** $p_0 = E[\mathbf{1}[X = 0]]$ puts the target and the toolkit in the same currency. Any cubic q with $q \leq \mathbf{1}[\,\cdot = 0\,]$ pointwise on $\mathbb{Z}_{\geq 0}$ gives $E[q(X)] \leq p_0$, and $E[q(X)]$ is a known number. The problem has become: maximise a known number over such cubics. **Link to the next block.** So construct the best such cubic.

Block 4. Cue. A cubic has four degrees of freedom, and you want it to agree with a $0/1$ pattern. **Why natural.** Four coefficients, four interpolation conditions. Prescribe $q(0) = 1$ and $q(1) = q(2) = q(3) = 0$: the cubic that matches the indicator on the first four nonnegative integers exactly. This is the natural greedy attempt, and it is the only one worth trying first, because a certificate can only be optimal if it is tight wherever the extremal distribution has mass, and the extremal distribution of a four constraint linear programme has at most four atoms. The interpolation nodes and the support of the optimum are the same object seen from the two sides of duality. **Link to the next block.** Interpolation guarantees the inequality at the nodes and says nothing beyond them, so check beyond them.

Block 5. **Cue.** The nodes stop at 3, the integers do not. **Why natural.** $q(n) = -\frac{(n-1)(n-2)(n-3)}{6}$ is written in factored form precisely so this check is one sentence: for $n \geq 4$ every factor is positive. Had the sign gone the other way, the certificate would have failed and you would have known immediately that the answer involved larger atoms. **Link to the next block.** The certificate is verified, so cash it in.

Block 6. **Cue.** A verified pointwise inequality between two functions of X. **Why natural.** Expectation is monotone. The arithmetic $5 - 12 + 11 - 6 = -2$ is the only computation in the problem. **Link to the next block.** A lower bound is half an answer. The question said "smallest possible value", which asserts attainment; you must supply it.

Block 7. **Cue.** Equality in the certificate requires the mass to sit where $q(n) = \mathbf{1}[n = 0]$, that is, on $\{0, 1, 2, 3\}$. **Why natural.** Solve the three moment equations on that support. The solution is forced: $p_2 = 0$, $p_1 = \frac{1}{2}$, $p_3 = \frac{1}{6}$, $p_0 = \frac{1}{3}$. The vanishing of p_2 is not a coincidence to be explained; duality only demands that the support be contained in the tight set, not equal to it. **Link to the next block.** Bound plus construction equals a complete solution.

Layer 3: WHY

The mathematical truth underneath is the duality between measures and functions. A measure you cannot see is pinned down only by the functionals you are allowed to integrate against it. Give me the moments up to degree d and you have given me the linear map $f \mapsto E[f(X)]$ on polynomials of degree at most d, and nothing else. Any bound on any other functional must therefore be obtained by sandwiching that functional between polynomials of degree at most d. This is the entire theory of the truncated moment problem in one sentence, and it is why the certificate is a polynomial and why its degree is 3.

The discernment mechanism, the thing to install so that you choose this route in the arena and not the truncation route: count the constraints. Four linear constraints, including the normalisation, mean the extreme points of the feasible set have at most four atoms; a linear objective is minimised at an extreme point; so the optimum is a four atom distribution, and the natural guess for where those atoms sit is the smallest available integers, because moments this small ($E[X] = 1$) forbid mass far out. That reasoning gives you the primal guess. Complementary slackness then tells you that the dual certificate must be tight at every atom of the optimum, and a cubic tight at four prescribed points is unique. In other words, the interpolation nodes were never a guess: they were dictated by the number of constraints.

Now the sentence the model answers never write. Why is the answer $\frac{1}{3}$ and not 0? Because of integrality, and only because of integrality. The certificate q satisfies $q(n) \leq 0$ for integers $n \geq 1$, but it fails badly on the reals: $q\left(\frac{1}{2}\right) = -\frac{(-\frac{1}{2})(-\frac{3}{2})(-\frac{5}{2})}{6} = \frac{5}{16} > 0$, and indeed q is positive across the whole interval $(0, 1)$, where all three factors are negative. So the same argument collapses for real valued X, and it should, because for real valued X the mass at 0 can be zero: let X take the two values $\frac{3 \pm \sqrt{5}}{2}$ with probabilities $\frac{5 \mp \sqrt{5}}{10}$. Those two values are the roots of $t^2 - 3t + 1$, and the moment recursion $m_{k+1} = 3m_k - m_{k-1}$ with $m_0 = 1$, $m_1 = 1$ gives $m_2 = 2$, $m_3 = 5$ exactly. All three moments match, and $P(X = 0) = 0$. The examiners chose the numbers $1, 2, 5$ so that a two point real distribution exists with no mass at the origin, and then restricted to the integers so that the nearest admissible atoms, 1 and 3, force one third of the mass down to zero. That is the trap and the design.

To train the discernment: every time you meet "given these moments, bound this probability", write down the two lists side by side, the functionals you know and the functional you want, and then interpolate. The training reps are the mirror drills below.

Revolving concepts

Moment. The number $E[X^k]$. The map $k \mapsto E[X^k]$ determines the distribution when the moments do not grow too fast (Carleman's condition), and for a bounded or finitely supported variable it always does. What orbits this term for the Putnam is the truncated version: finitely many moments never determine the distribution, they only determine a convex set of distributions, and every question of the form "how large or small can this be" is an optimisation over that convex set. See Book 1, field: Probability, topic: moment problems.

Factorial moment. $E[X(X-1)\cdots(X-k+1)]$, the natural moment for integer valued variables, because it is the kth derivative of the probability generating function at 1. Here $E[X] = 1$, $E[X(X-1)] = 2-1 = 1$, $E[X(X-1)(X-2)] = 5-6+2 = 1$: the data are much prettier in this basis than in the power basis, which is the signal that generating functions are close to the surface. See Book 1, field: Probability, topic: generating functions.

Probability generating function. $G(z) = E[z^X] = \sum_{n\geq 0} p_n z^n$, a power series with nonnegative coefficients, radius of convergence at least 1, $G(1) = 1$, $G(0) = p_0$, and $G^{(k)}(1)$ the kth factorial moment. Nonnegativity of coefficients gives nonnegativity of every derivative on $[0, 1)$, which is exactly the ingredient the Taylor remainder route needs. See Book 1, field: Generating functions, topic: probability generating functions.

Lagrange basis polynomial. For nodes $x_0, \ldots, x_d$ the polynomial $\ell_i(x) = \prod_{m\neq i} \frac{x-x_m}{x_i-x_m}$ is the unique polynomial of degree at most d with $\ell_i(x_j) = \delta_{ij}$. Our q is ℓ_0 for nodes $0, 1, 2, 3$. The orbiting fact worth carrying: interpolation is how you manufacture a polynomial with a prescribed $0/1$ pattern, and prescribed sign patterns beyond the nodes are then read off from the factored form. See Book 1, field: Polynomials, topic: interpolation.

Linear programming duality and complementary slackness. Minimising $c^{\mathsf{T}}p$ over $p \geq 0$ with $Ap = b$ has the dual: maximise $b^{\mathsf{T}}y$ over y with $A^{\mathsf{T}}y \leq c$. Weak duality is the single line we actually used; complementary slackness (the dual constraint is tight at every index where the primal has mass) is the navigational tool that told us where the nodes go. See Book 1, field: Inequalities, topic: linear programming duality.

The recursion in the background, generalised. A measure supported on the two roots of $t^2 - st + p = 0$ has moments satisfying the linear recursion $m_{k+1} = s\,m_k - p\,m_{k-1}$, because the roots satisfy $t^{k+1} = st^k - pt^{k-1}$ and expectation is linear. Generally, a measure supported on the r roots of a monic $f(t) = t^r - c_1 t^{r-1} - \cdots - c_r$ has $m_{k+r} = c_1 m_{k+r-1} + \cdots + c_r m_k$ for all $k \geq 0$, and conversely a moment sequence satisfying a linear recursion of order r with the right positivity is realised by an r atom measure, the atoms being the roots of the characteristic polynomial and the weights being solved from the first r moments. That is the general machine behind "find the extremal finitely supported distribution": build the characteristic polynomial from the moment recursion, take its roots as atoms. It is also the Hankel determinant story: a moment sequence comes from an r atom measure exactly when the Hankel matrices of size $r+1$ become singular. See Book 1, field: Sequences and recurrences, topic: linear recurrences and characteristic polynomials.

Circuit Bank

- **WHEN** you see a quantity bounded using only finitely many moments of an unknown measure **DO** write down the exact family of test functions the data allow, then hunt for the best member of that family **BECAUSE** finitely many moments determine a linear functional on exactly that family, so every valid bound factors through it
- **WHEN** you see a probability you must bound **DO** rewrite it as the expectation of an indicator **BECAUSE** it puts the target in the same currency as the data, which is the only way an inequality between them can be written
- **WHEN** you need a polynomial with a prescribed sign or value pattern on a discrete set **DO** interpolate at the pattern and keep the answer in factored form **BECAUSE** the factored form

makes the sign beyond the last node a one line check, and interpolation is the only construction with the right number of degrees of freedom

- **WHEN** you see a linear objective, linear equality constraints and a nonnegativity constraint **DO** count the equalities, conclude the optimum has at most that many atoms, and make the dual certificate tight exactly there **BECAUSE** extreme points of such a feasible set have support size at most the number of equalities, and complementary slackness ties the certificate to the support
- **WHEN** you prove a lower bound for an extremal problem **DO** immediately construct the object attaining it before moving on **BECAUSE** "smallest possible value" is two claims, and a bound alone is at best half the marks

Backtesting

1. First useful cue: three moments and nonnegative integer values, so the data are a linear functional on cubics and the answer is a linear programme.
2. Method the expression suggested: test the unknown distribution against the cubic that interpolates the indicator of $\{0\}$ at the nodes $0, 1, 2, 3$.
3. Where you would hesitate, and the thought to reinforce: at the moment of choosing the nodes. Reinforce this: four constraints means four atoms means four nodes; there is nothing to choose.
4. The trap the question sets: the numbers $1, 2, 5$ are exactly the moments of a two point real distribution with no mass at the origin, so any argument that does not use integrality must fail, and several natural inequalities (Cauchy and Schwarz among them) do not use it and give bounds in the wrong direction.
5. What makes you recognise it faster next time: the shape "$E[X^k]$ given for $k \le d$, bound a probability" is always the truncated moment problem, and the certificate is always a polynomial of degree d.
6. The reusable decision rule: to bound an unknown measure, do not describe the measure; hand it a test function it cannot beat.

Mirror drills

1. Let X be a nonnegative integer valued random variable with $E[X] = 1$ and $E[X^2] = 2$ only. Show that $P(X = 0)$ can be made arbitrarily small, so that the third moment is doing all the work in A4. *Answer:* for $N \ge 3$ take $p_1 = 1 - \frac{1}{N-1}$, $p_N = \frac{1}{N(N-1)}$, $p_0 = \frac{1}{N}$; both moments check, and $p_0 \to 0$.
2. Let X be nonnegative integer valued with $E[X] = 1$, $E[X^2] = 2$. Prove $P(X = 0) \le \frac{1}{2}$ and find the equality case. *Answer:* $1 = E[X\mathbf{1}[X \ge 1]]^2 \le E[X^2]P(X \ge 1)$ gives $P(X \ge 1) \ge \frac{1}{2}$; equality forces X constant on $\{X \ge 1\}$, hence $X \in \{0, 2\}$ with probabilities $\frac{1}{2}, \frac{1}{2}$.
3. Same three moments as A4, but now X may take arbitrary nonnegative real values. Show $P(X = 0) = 0$ is achievable. *Answer:* put the mass on the roots of $t^2 - 3t + 1$, that is $\frac{3 \pm \sqrt{5}}{2}$, with weights $\frac{5 \mp \sqrt{5}}{10}$; the recursion $m_{k+1} = 3m_k - m_{k-1}$ from $m_0 = m_1 = 1$ gives $m_2 = 2$ and $m_3 = 5$.

12.5 A5. Coprimality forced by disjoint root annuli

Let

$$P_n(x) = 1 + 2x + 3x^2 + \cdots + nx^{n-1}.$$

Prove that the polynomials $P_j(x)$ and $P_k(x)$ are relatively prime for all positive integers j and k with $j \neq k$.

Read it out loud

"A family of polynomials whose coefficients are $1, 2, 3, \ldots, n$, and the claim is that no two members share a factor." Two structural facts are audible in that sentence before you write anything. First, the coefficients are positive and strictly increasing. Second, the family is nested: P_j starts with the whole of P_i and then continues. Both facts will be load bearing, and the second one is the reason the problem is about a family rather than about one polynomial.

Coprimality is not really an algebraic condition here, it is a geometric one. Two polynomials with rational coefficients are relatively prime exactly when they have no common root in $\mathbb{C}$: a nonconstant common divisor has a complex root by the fundamental theorem of algebra, and conversely a common root z makes the minimal polynomial of z over $\mathbb{Q}$ a common divisor. So the task is: prove that the root sets of P_j and P_k are disjoint. That is a strong demand. You are not being asked to compute a single root; you are being asked to confine the roots of each member of an infinite family to a region so precisely that different members get disjoint regions.

The fields wired in are polynomial algebra (gcd, content, Gauss), complex root location, and elementary modulus inequalities. What is really being tested is whether you own a tool that converts coefficient data directly into root location. There is exactly one cheap such tool, and it is the theorem of Enestrom and Kakeya. If it is not installed, install it now; it is four lines to prove and it recurs.

Within thirty seconds you should have written: the roots of P_i satisfy $|z| \leq \frac{i-1}{i}$, and $P_j - P_i = x^i\left((i+1) + (i+2)x + \cdots\right)$.

Approaches, ranked worst to best

1. **Factorise the P_n or compute resultants.** *Cue:* "relatively prime" is a divisibility statement, so attack divisibility. *Circuit:* the school circuit: to show no common factor, find the factors. Worst by a distance. Nobody knows an easy proof that P_n is irreducible (Kedlaya records it as expected but apparently hard), and the resultant of P_i and P_j is a determinant of size $i + j - 2$ with no visible structure. This route consumes the entire session.

2. **Compute roots numerically and observe separation.** *Cue:* a claim about roots. *Circuit:* reconnaissance. Legitimate as reconnaissance, worthless as a proof: there are infinitely many pairs. It does tell you the truth quickly, namely that the roots of P_i sit well inside the unit disc and drift outwards as i grows, which is the shape of the real argument.

3. **Telescope to a closed form and separate curves.** *Cue:* the coefficients $1, 2, 3, \ldots$ are the derivative of a geometric series. *Circuit:* the generating function circuit. From $(1-x)^2 P_n(x) = 1 - (n+1)x^n + nx^{n+1}$, a root $z \neq 1$ of P_n lies on the curve $|z|^n\,|n + 1 - nz| = 1$. Showing these curves are pairwise disjoint means studying $E_z(t) = t\log|z| + \log|t + 1 - tz|$ as a function of a real variable t and proving it has at most one positive zero, via a concavity computation. Fully rigorous, roughly a page, and every line of it is calculus you must not slip in.

4. **One auxiliary real function and Rolle.** *Cue:* a common root would satisfy two equations of the same shape with different exponents. *Circuit:* the circuit: when several exponents satisfy one identity, interpolate the exponent and count zeros. Set $w = z^{-1}$; then $P_n(z) = 0$ forces $w^N = Nw - N + 1$ for $N = n + 1$, and this identity also holds trivially for $N = 0$ and

$N = 1$. Multiplying the identity by its conjugate and replacing the integer N by a real variable t produces

$$f(t) = |w|^{2t} - t^2|w|^2 + 2t(t-1)\mathrm{Re}(w) - (t-1)^2$$

which vanishes at the four values $t \in \{0, 1, i+1, j+1\}$, while $f'''(t) = (2\log|w|)^3|w|^{2t}$ never vanishes provided $|w| \neq 1$. Rolle then caps the number of zeros at three. Beautiful and it generalises (it proves the rank 3 statement about the matrix with rows 1, exponents, powers). It ranks second only because you must invent f under time pressure and you must dispose of $|w| = 1$ separately, a case the published solution passes over.

5. **Two disjoint annuli from Enestrom and Kakeya.** *Cue:* coefficients positive and increasing, and the family is closed under differences. *Circuit:* the annulus circuit: consecutive coefficient ratios bracket the modulus of every root. Best. After a four line lemma the problem dies in three lines, with no calculus and no case analysis beyond one degenerate index.

The ideal solution

We show that P_j and P_k have no common root in $\mathbb{C}$ when $j \neq k$; that is equivalent to the assertion. Indeed, if $d = \gcd(P_j, P_k)$ in $\mathbb{Q}[x]$ were nonconstant it would have a complex root, which would be a common root of P_j and P_k. (In $\mathbb{Z}[x]$ nothing changes: both polynomials have constant term 1, hence are primitive, so by Gauss's lemma their coprimality in $\mathbb{Q}[x]$ gives coprimality in $\mathbb{Z}[x]$.)

Lemma 12.5.1 (Enestrom and Kakeya)**.** *Let $f(x) = a_0 + a_1x + \cdots + a_dx^d$ with $d \geq 1$ and $0 < a_0 \leq a_1 \leq \cdots \leq a_d$. Then every complex root z of f satisfies $|z| \leq 1$.*

Proof. Expanding,

$$(x-1)f(x) = a_dx^{d+1} - \sum_{t=1}^{d}(a_t - a_{t-1})x^t - a_0.$$

Suppose $f(z) = 0$ with $|z| > 1$. Then $a_dz^{d+1} = \sum_{t=1}^{d}(a_t - a_{t-1})z^t + a_0$, and since $|z|^t \leq |z|^d$ for $1 \leq t \leq d$ and $1 \leq |z|^d$, and since every $a_t - a_{t-1} \geq 0$,

$$a_d|z|^{d+1} \leq \sum_{t=1}^{d}(a_t - a_{t-1})|z|^t + a_0 \leq |z|^d\left(\sum_{t=1}^{d}(a_t - a_{t-1}) + a_0\right) = a_d|z|^d.$$

Hence $|z| \leq 1$, a contradiction. □

Corollary 12.5.2. *Let $f(x) = a_0 + a_1x + \cdots + a_dx^d$ with $d \geq 1$ and every $a_t > 0$. Put*

$$r = \min_{0\leq t\leq d-1}\frac{a_t}{a_{t+1}}, \qquad R = \max_{0\leq t\leq d-1}\frac{a_t}{a_{t+1}}.$$

Then every complex root z of f satisfies $r \leq |z| \leq R$.

Proof. The polynomial $g(x) = f(Rx)$ has coefficients $b_t = a_tR^t$, which are positive and satisfy $b_t/b_{t+1} = \frac{a_t}{a_{t+1}R} \leq 1$, so $b_0 \leq b_1 \leq \cdots \leq b_d$. By the lemma every root w of g has $|w| \leq 1$, and the roots of f are the numbers Rw, giving $|z| \leq R$. For the other bound, let $f^*(x) = x^df(1/x) = a_d + a_{d-1}x + \cdots + a_0x^d$, of degree d since $a_0 \neq 0$. Its roots are exactly the reciprocals of the roots of f (no root of f is 0, again since $a_0 \neq 0$). Its consecutive coefficient ratios are the numbers a_{s+1}/a_s, whose maximum is $1/r$, so by the case already proved every root w of f^* has $|w| \leq 1/r$, that is, every root z of f has $|z| \geq r$. □

Now let $1 \leq i < j$ and suppose $z \in \mathbb{C}$ satisfies $P_i(z) = P_j(z) = 0$.
If $i = 1$ then $P_1(x) = 1$ has no root at all, so no such z exists. Assume from here that $i \geq 2$.

The polynomial P_i has $\deg P_i = i-1 \geq 1$ and coefficients $a_t = t+1 > 0$ for $0 \leq t \leq i-1$, with consecutive ratios $a_t/a_{t+1} = \frac{t+1}{t+2}$, increasing in t. The corollary therefore gives

$$|z| \leq \max_{0\leq t\leq i-2} \frac{t+1}{t+2} = \frac{i-1}{i}. \tag{1}$$

Next subtract. We have

$$P_j(x) - P_i(x) = \sum_{m=i+1}^{j} m x^{m-1} = x^i Q(x), \qquad Q(x) = \sum_{t=0}^{j-i-1} (i+1+t)\, x^t,$$

and z is a root of $P_j - P_i$. Since $P_i(0) = 1 \neq 0$ we have $z \neq 0$, so $Q(z) = 0$.

If $j = i+1$ then Q is the nonzero constant $i+1$, which has no roots: contradiction.

If $j \geq i+2$ then $\deg Q = j-i-1 \geq 1$ and Q has positive coefficients $b_t = i+1+t$ with consecutive ratios $b_t/b_{t+1} = \frac{i+1+t}{i+2+t}$, again increasing in t. The corollary gives

$$|z| \geq \min_{0\leq t\leq j-i-2} \frac{i+1+t}{i+2+t} = \frac{i+1}{i+2}. \tag{2}$$

But $i(i+1) = i^2+i > i^2+i-2 = (i-1)(i+2)$, so $\frac{i+1}{i+2} > \frac{i-1}{i}$, and (1) and (2) are incompatible. Contradiction.

Hence P_i and P_j have no common complex root, so $\gcd(P_j, P_k) = 1$ for all positive integers $j \neq k$.

Layer 1: WHAT

Block 1. Translate "relatively prime" into "no common complex root", with the fundamental theorem of algebra as the bridge and Gauss's lemma as the footnote for $\mathbb{Z}[x]$.

Block 2. Read the coefficient pattern of P_i: positive, increasing, ratios $\frac{t+1}{t+2}$. Conclude every root lies in the closed disc of radius $1 - \frac{1}{i}$.

Block 3. Use the nesting: $P_j - P_i = x^i Q(x)$, and Q is again a polynomial with positive increasing coefficients, only with the index shifted up by i.

Block 4. A common root is nonzero (constant term 1), so it is a root of Q, whose coefficient ratios all exceed $\frac{i+1}{i+2}$; hence its modulus is at least $1 - \frac{1}{i+2}$.

Block 5. Compare the two windows. They are disjoint because the ratio sequence $\frac{t+1}{t+2}$ is strictly increasing. Contradiction.

Block 6. Sweep the degenerate indices: $i = 1$ (no roots at all) and $j = i+1$ (the difference is a monomial).

The nominal route runs: expand both polynomials, run the Euclidean algorithm on P_i and P_j, watch the remainders lose all structure after one step, then attempt irreducibility of P_n and stall permanently. Notice that the nominal route and the ideal route share their first move, subtraction: $\gcd(P_i, P_j) = \gcd(P_i, P_j - P_i)$. The bifurcation point is what you do with $P_j - P_i$. The zombie divides again. The ideal solution stops dividing and asks where the roots of the two objects live, because the difference has landed back in the same class of polynomials with a shifted index, and a class with a shifted index means a shifted root window. Subtraction here is not a step of the Euclidean algorithm; it is a way of manufacturing a second polynomial whose roots are pinned to a different annulus.

Layer 2: HOW

Block 1. Cue. The words "relatively prime" applied to two explicit polynomials with integer coefficients. **Why natural.** Divisibility in $\mathbb{Q}[x]$ is invisible; roots are visible. The gcd of two polynomials is unchanged under field extension (the Euclidean algorithm does not know which field it is in), so a nonconstant gcd over $\mathbb{Q}$ survives over $\mathbb{C}$, where it must have a root. Coprimality

and disjoint root sets are therefore the same statement, and only one of the two is something you can measure. **Link to the next block.** Now you need to measure root sets, so look at what the question gives you about the roots. It gives you the coefficients and nothing else.

Block 2. Cue. Coefficients $1, 2, 3, \ldots, n$: all positive, monotonically increasing. **Why natural.** Positivity plus monotonicity is the exact hypothesis of the one classical theorem that turns coefficients into root location for free. The intuition it formalises is the balance principle: a root of $\sum a_t x^t$ occurs where two terms $a_t z^t$ and $a_{t+1} z^{t+1}$ are comparable in size, that is, where $|z| \approx a_t / a_{t+1}$; so all roots must live between the smallest and largest such ratio. Enestrom and Kakeya makes the approximate statement exact. **Link to the next block.** You now have a disc for P_i. One disc is not a contradiction, so you need a second, incompatible statement about the same z.

Block 3. Cue. Two members of a nested family and a hypothesis about both. **Why natural.** If z kills P_i and P_j it kills every linear combination, and in a nested family the cheapest combination is the difference, because it cancels the shared head and leaves the tail. The tail $\sum_{m=i+1}^{j} m x^{m-1}$ still has positive increasing coefficients, so the tool from Block 2 applies to it as well. This is the whole design of the problem: the family is chosen so that differences stay inside the class. **Link to the next block.** A common root of P_i and P_j is a root of the tail, but only after you strip the factor x^i.

Block 4. Cue. The tail is visibly divisible by x^i, and the constant term of P_i is 1. **Why natural.** Stripping x^i is legitimate only because $z \neq 0$, and $z \neq 0$ because $P_i(0) = 1$. Write that sentence; it costs six words and it is the sort of step whose absence a grader notices. Once stripped, Q has ratios starting at $\frac{i+1}{i+2}$, and the corollary now supplies a lower bound for $|z|$, which is the opposite kind of bound to Block 2. **Link to the next block.** Two bounds on the same modulus, in opposite directions, must be compared.

Block 5. Cue. An upper bound $\frac{i-1}{i}$ and a lower bound $\frac{i+1}{i+2}$. **Why natural.** The ratios $\frac{t+1}{t+2}$ increase strictly towards 1, so the head's largest ratio is strictly smaller than the tail's smallest ratio. In scale language: the roots of the head sit at a strictly smaller scale than the roots of the tail, because the head's coefficients grow proportionally faster than the tail's. The gap between $\frac{i-1}{i}$ and $\frac{i+1}{i+2}$ never closes, and does not need to be large. **Link to the next block.** Only the boundary indices remain.

Block 6. Cue. Every bound above needed $\deg \geq 1$. **Why natural.** $i = 1$ makes P_i constant and $j = i + 1$ makes Q constant. In both cases the conclusion is immediate and in both cases an argument that ignores them is incomplete. Sweeping degenerate indices is not pedantry on the Putnam; it is where marks go.

Layer 3: WHY

The truth under this problem is that the modulus of a root of a polynomial with positive coefficients is controlled by the consecutive coefficient ratios, and by nothing else. Look at $f(z) = \sum a_t z^t$ with all $a_t > 0$ and ask when cancellation is even possible. If $|z|$ is much smaller than every ratio a_t / a_{t+1}, the constant term dominates every other term put together and $f(z)$ cannot vanish; if $|z|$ is much larger than every ratio, the top term dominates. So roots can only live in the window bracketed by the smallest and largest ratio. This is the archimedean shadow of the Newton polygon, the same object that in the p-adic world tells you the valuations of the roots from the valuations of the coefficients; Kedlaya's remark that this problem also yields to a p-adic valuation argument is exactly that duality showing itself.

The discernment mechanism, the thing that makes you pick this route in the arena: ask what the question has given you that is unusual. It has given you a coefficient sequence that is monotone.

Monotone coefficients are worth nothing for algebra and everything for root location, so the question is a root location question. Then ask what varies as the index moves. The ratio sequence $\frac{t+1}{t+2}$ increases strictly, so different truncations of the same coefficient sequence have root windows that slide outwards. Two objects with disjoint windows cannot share a root. That is the whole proof, and it is visible before any lemma is written.

Say the generalisation out loud, because it is the real theorem and it costs nothing. Let $a_0, a_1, a_2, \ldots$ be positive reals whose consecutive ratios a_t/a_{t+1} are strictly increasing (equivalently, $a_t a_{t+2} < a_{t+1}^2$ for all t, strict log concavity). Then the truncations $F_n(x) = a_0 + a_1 x + \cdots + a_{n-1}x^{n-1}$ are pairwise relatively prime. The proof is the one above verbatim: the head's window is $\left[\frac{a_0}{a_1}, \frac{a_{i-2}}{a_{i-1}}\right]$, the tail's window starts at $\frac{a_i}{a_{i+1}}$, and strict monotonicity of the ratios makes $\frac{a_i}{a_{i+1}} > \frac{a_{i-2}}{a_{i-1}}$. Our case is $a_t = t+1$, where $(t+1)(t+3) = t^2+4t+3 < (t+2)^2$. Knowing this is what converts a one off Putnam problem into a circuit: you now recognise the entire class of families to which the argument applies, and you will recognise it the next time the coefficients are $1, 2, 4, 8, \ldots$ or $1!, 2!, 3!, \ldots$ or any strictly log concave sequence.

To train it: whenever a problem hands you an explicit coefficient sequence, compute the consecutive ratios before doing anything else. That single reflex converts most root location problems into arithmetic.

Revolving concepts

Relatively prime polynomials. $\gcd(f, g)$ is a nonzero constant. Orbiting facts: the gcd is computed by the Euclidean algorithm, so it does not change when the field is enlarged; coprimality is equivalent to the Bezout identity $uf + vg = 1$ with u, v in the same polynomial ring; and by Gauss's lemma, primitive polynomials in $\mathbb{Z}[x]$ that are coprime in $\mathbb{Q}[x]$ are coprime in $\mathbb{Z}[x]$. See Book 1, field: Polynomials, topic: gcd and Bezout.

Enestrom and Kakeya theorem. As proved above, together with its scaling corollary. The proof technique deserves its own slot: multiply by $(x-1)$ to telescope the coefficients into differences, then use the triangle inequality on the differences. That "multiply by $(x-1)$ to convert coefficients into consecutive differences" move recurs across the whole subject. See Book 1, field: Polynomials, topic: root location.

Reverse polynomial. $f^*(x) = x^{\deg f} f(1/x)$ reverses the coefficient list and inverts the roots. It is the standard device for converting an upper bound theorem into a lower bound theorem, and it costs one line. See Book 1, field: Polynomials, topic: transformations of roots.

Other root location tools. Cauchy's bound: every root of $x^d + c_{d-1}x^{d-1} + \cdots + c_0$ satisfies $|z| \leq 1 + \max_t |c_t|$. Rouché's theorem: if $|f - g| < |g|$ on a circle then f and g have the same number of zeros inside. Both are worth having; Rouché in particular proves the same disc statement here with more machinery. See Book 1, field: Complex numbers, topic: argument principle.

The closed form and the recursion, generalised. The family satisfies $P_{n+1}(x) = P_n(x) + (n+1)x^n$, a first order recursion in the index whose increment is a monomial; summing the recursion is exactly the telescoping that gives $P_j - P_i = \sum_{m=i+1}^{j} m x^{m-1}$. The closed form comes from differentiating a geometric sum: $P_n(x) = \frac{d}{dx}\left(1 + x + \cdots + x^n\right) = \frac{1-(n+1)x^n+nx^{n+1}}{(1-x)^2}$. Generalise the pattern: for any sequence (a_t), the truncation family $F_n = \sum_{t<n} a_t x^t$ satisfies $F_{n+1} - F_n = a_n x^n$, so a common root of two members is a root of a contiguous block $\sum_{i \leq t < j} a_t x^t$, and if the block is again a member of a class with known root windows you get a contradiction for free. When (a_t) itself satisfies a linear recursion with characteristic polynomial χ, the generating function is $\frac{\text{numerator}}{\chi^*(x)}$ and every truncation is a numerator of a partial sum, which gives closed forms of the same shape as the one above. See Book 1, field: Sequences and recurrences, topic: generating functions of truncations.

Interpolating an exponent. The route ranked fourth turns the integer exponent n into a real variable t and applies Rolle to bound the number of solutions. The orbiting statement, worth memorising: an equation $e^x = P(x)$ with P real of degree d has at most $d+1$ real solutions, since differentiating

$d+1$ times kills P; more generally, counting zeros by repeated differentiation is the elementary end of the theory of o-minimality. See Book 1, field: Real analysis, topic: zero counting by Rolle.

Circuit Bank

- **WHEN** you are asked to prove two polynomials are relatively prime **DO** convert immediately to "no common complex root" and start locating roots **BECAUSE** gcd is invisible but roots are measurable, and the Euclidean algorithm does not care which field you work over, so the two statements are identical
- **WHEN** you see a polynomial with all coefficients positive **DO** compute the consecutive ratios and quote the annulus theorem **BECAUSE** a root can only occur where two consecutive terms balance, so every root modulus lies between the smallest and the largest consecutive ratio
- **WHEN** you have two members of a nested family sharing a hypothesis **DO** subtract them and identify the class the difference belongs to **BECAUSE** a common root kills every linear combination, and in a nested family the difference cancels the shared head and hands you a second object with a shifted index
- **WHEN** you strip a factor of x^m from an equation **DO** first say why the root is nonzero, citing the constant term **BECAUSE** stripping x^m is division by zero unless $z \neq 0$, and the constant term of the other polynomial is usually the cheapest reason
- **WHEN** you have an upper bound and a lower bound for the same quantity from two different sources **DO** write both, then compare with one cross multiplication **BECAUSE** contradiction arguments in root location almost always take this shape, and the gap needed is never large

Backtesting

1. First useful cue: the coefficients are positive and increasing, so the problem is about where the roots sit, not about factorisation.
2. Method the expression suggested: bound the roots of P_i above by the largest consecutive coefficient ratio, then bound the roots of the tail $P_j - P_i$ below by its smallest consecutive ratio.
3. Where you would hesitate, and the thought to reinforce: after subtracting, when the difference is not another member of the family. Reinforce this: it does not need to be a member, it only needs to be in the same class, and the class is "positive increasing coefficients".
4. The trap the question sets: it invites you to prove something about P_n alone (irreducibility), which is hard and unnecessary. The statement is about pairs, so the argument must use both indices at once.
5. What makes you recognise it faster next time: coefficient sequences with strictly increasing consecutive ratios have truncations with disjoint root annuli, hence pairwise coprime truncations. This is the general theorem; $1, 2, 3, \ldots$ is one instance.
6. The reusable decision rule: coefficients to ratios, ratios to annuli, annuli to disjointness.

Mirror drills

1. Prove the Enestrom and Kakeya lemma from scratch in four lines. *Answer:* multiply by $(x-1)$ to get $a_d x^{d+1} - \sum_{t\geq 1}(a_t - a_{t-1})x^t - a_0$; if $|z| > 1$ the triangle inequality bounds the tail by $a_d|z|^d$, forcing $a_d|z|^{d+1} \leq a_d|z|^d$.
2. Locate all complex roots of $1 + x + 2x^2 + 3x^3 + 5x^4 + 8x^5$ inside an annulus. *Answer:* the consecutive ratios are $1, \frac{1}{2}, \frac{2}{3}, \frac{3}{5}, \frac{5}{8}$, so every root satisfies $\frac{1}{2} \leq |z| \leq 1$.

3. Show without any root location that P_k and P_{k+1} are relatively prime. *Answer:* $P_{k+1} - P_k = (k+1)x^k$, so a common root would have to be 0, but $P_k(0) = 1$.

12.6 A6. Diagonal nonvanishing bounded by a tensor pairing

Let n be a positive integer. What is the largest k for which there exist $n \times n$ matrices $M_1, \dots, M_k$ and $N_1, \dots, N_k$ with real entries such that for all i and j, the matrix product $M_i N_j$ has a zero entry somewhere on its diagonal if and only if $i \neq j$?

Read it out loud

"Two families of square matrices, and the only thing anyone ever looks at is the diagonal of a product; the diagonal must be nowhere zero on the matched pairs and must have a zero somewhere on every mismatched pair; how long can the families be?" Say that and then say the one identity that governs everything: the tth diagonal entry of $M_i N_j$ is

$$(M_i N_j)_{tt} = (\text{row } t \text{ of } M_i) \cdot (\text{column } t \text{ of } N_j).$$

Nothing else about the matrices is ever used. So M_i is not a matrix in this problem, it is an ordered list of n vectors in $\mathbb{R}^n$, and N_j is another ordered list of n vectors in $\mathbb{R}^n$, and the matrix product is a red herring dressed as structure. Invertibility is never required, determinants never appear, and you should register both facts as permissions rather than as omissions.

Restated in the honest language: for each $t \in \{1, \dots, n\}$ you have a pairing, call it channel t, between the vectors $r_{i,t}$ (rows) and $c_{j,t}$ (columns). The condition is that all n channels agree simultaneously exactly on the diagonal $i = j$. Each channel is a bilinear form on $\mathbb{R}^n \times \mathbb{R}^n$, and there are n of them, and the conditions are combined by an AND. An AND of nonvanishing conditions is a single nonvanishing condition on a product. That sentence is the problem.

The fields wired in are linear algebra (dimension and independence), multilinear algebra (tensor powers), and the linear algebra method of extremal combinatorics. What is being tested is whether you know that the maximum size of a family carrying a dual family is a dimension, and whether you can find the right space.

Within thirty seconds you should have written $(M_i N_j)_{tt} = r_{i,t} \cdot c_{j,t}$, the reformulation $\prod_{t=1}^{n} r_{i,t} \cdot c_{j,t} \neq 0 \iff i = j$, and the small cases $n = 1 \Rightarrow k = 1$, $n = 2 \Rightarrow k = 4$.

Approaches, ranked worst to best

1. **Rank and determinant bookkeeping on the M_i alone.** *Cue:* the objects are matrices, so use matrix invariants. *Circuit:* the linear algebra reflex aimed at the wrong space. There are only n^2 entries in each matrix, so this route generates bounds that are polynomial in n, or no bound at all. It cannot reach an exponential answer, and everything it computes is invariant under changes of basis that the problem is not invariant under (the product of diagonal entries is not a similarity invariant). Worst.

2. **Colour each mismatched pair by a witnessing diagonal position and run pigeonhole or Ramsey.** *Cue:* "has a zero entry somewhere" is a disjunction over n positions. *Circuit:* the extremal combinatorics reflex. For each $i \neq j$ choose $t(i,j)$ with $(M_i N_j)_{t(i,j)\,t(i,j)} = 0$; you now have an n colouring of ordered pairs. This is a real idea, and inside one colour class the vectors $r_{i,t}$ and $c_{j,t}$ do form a useful configuration. But the colour classes interact, and reassembling them multiplicatively is exactly what the tensor product does properly; done by hand it stalls or produces a far weaker bound.

3. **Small cases and pattern matching.** *Cue:* "what is the largest k" with n free. *Circuit:* the reconnaissance circuit. $n = 1$ forces $k = 1$ (if $m_1 n_1 \neq 0$ and $m_2 n_2 \neq 0$ then $m_1 n_2 \neq 0$), and building $n = 2$ by hand gives 4. Then $1, 4, \dots$ against n suggests n^n rather than n^2 only if you also test $n = 2$ against the alternatives, so this is not decisive alone. It is essential, though: it tells you the answer is exponential, and it tells you which space to look for.

4. **Product of the diagonal entries, then a dual family in the tensor power.** *Cue:* an AND of n nonvanishing bilinear conditions, and an answer that must be exponential. *Circuit:* the linear algebra method: bound a family by embedding it in a vector space and exhibiting a dual family that pairs nonzero exactly on the diagonal. Best, and it is the only route here that is short. It also hands you the construction, because the proof shows exactly where the bound can be tight.

The ideal solution

The answer is $\boxed{n^n}$.

Throughout, $e_1, \dots, e_n$ is the standard basis of $\mathbb{R}^n$, and $\mathcal{A} = \{1, \dots, n\}^n$ is the set of n tuples $A = (a_1, \dots, a_n)$ with entries in $\{1, \dots, n\}$, so $|\mathcal{A}| = n^n$.

Step 1: the condition, restated. For any $n \times n$ matrices M and N, the tth diagonal entry of MN is $\sum_{a=1}^{n} M_{ta} N_{at}$. Since a product of real numbers vanishes exactly when one factor vanishes, the requirement of the problem is equivalent to

$$D(i,j) := \prod_{t=1}^{n} (M_i N_j)_{tt} \neq 0 \iff i = j. \tag{$*$}$$

Step 2: the construction, giving $k = n^n$. For $A \in \mathcal{A}$ let M_A be the matrix whose tth row is e_{a_t}, and let $N_A = M_A^{\mathsf{T}}$, so that the tth column of N_A is e_{a_t}. Then for $A, B \in \mathcal{A}$,

$$(M_A N_B)_{tt} = e_{a_t} \cdot e_{b_t} = \begin{cases} 1 & a_t = b_t \\ 0 & a_t \neq b_t. \end{cases}$$

If $A = B$ every diagonal entry equals 1, so there is no zero on the diagonal. If $A \neq B$ then $a_t \neq b_t$ for some t, and that diagonal entry is 0. So the n^n pairs (M_A, N_A) satisfy the requirement, indexed by $\mathcal{A}$.

Step 3: the upper bound. Suppose $M_1, \dots, M_k$ and $N_1, \dots, N_k$ satisfy $(*)$. Work in the space $V = \mathbb{R}^{\mathcal{A}}$ of real vectors indexed by $\mathcal{A}$, with the standard inner product; $\dim V = n^n$. For each i define $u_i, v_i \in V$ coordinatewise by

$$u_i(A) = \prod_{t=1}^{n} (M_i)_{t,a_t}, \qquad v_i(A) = \prod_{t=1}^{n} (N_i)_{a_t,t} \qquad (A = (a_1, \dots, a_n) \in \mathcal{A}).$$

Then for all i, j,

$$u_i \cdot v_j = \sum_{A \in \mathcal{A}} \prod_{t=1}^{n} (M_i)_{t,a_t} (N_j)_{a_t,t} = \prod_{t=1}^{n} \left(\sum_{a=1}^{n} (M_i)_{t,a} (N_j)_{a,t} \right) = \prod_{t=1}^{n} (M_i N_j)_{tt} = D(i,j).$$

The middle equality is the distributive law: expanding a product of n sums of n terms each produces exactly one term for each way of choosing an index a_t from the tth sum, that is, one term for each $A \in \mathcal{A}$.

By $(*)$ we have $u_i \cdot v_j = 0$ for $i \neq j$ and $u_i \cdot v_i \neq 0$. Suppose $\sum_{i=1}^{k} c_i u_i = 0$ with $c_i \in \mathbb{R}$. Taking the inner product with v_j gives

$$0 = \sum_{i=1}^{k} c_i (u_i \cdot v_j) = c_j (u_j \cdot v_j),$$

and since $u_j \cdot v_j \neq 0$ we get $c_j = 0$, for every j. Hence $u_1, \dots, u_k$ are linearly independent in V, so

$$k \leq \dim V = n^n.$$

Combining Steps 2 and 3, the largest such k is n^n.

Layer 1: WHAT

Block 1. Strip the matrices: only $(M_iN_j)_{tt} = r_{i,t} \cdot c_{j,t}$ matters, so the data are n independent channels of vector pairings.

Block 2. Replace the disjunction "some diagonal entry is zero" by the single scalar equation "the product of the diagonal entries is zero". One number $D(i,j)$ now carries the whole hypothesis.

Block 3. Recognise the shape of $(*)$: a family and a dual family pairing to nonzero exactly on the diagonal. That shape always caps the family size by the dimension of the ambient space.

Block 4. Notice the obstruction: D is not bilinear in (M_i, N_j), it is a product of n bilinear forms, so there is no ambient space yet. Manufacture one by expanding the product: the monomials are indexed by tuples $A \in \{1,\dots,n\}^n$, so the ambient space is $\mathbb{R}^{n^n}$.

Block 5. Run the standard independence argument: $k \le n^n$.

Block 6. Achieve the bound by making each index a codeword A and each channel a test for agreement in one coordinate, using $e_a \cdot e_b = \delta_{ab}$.

The nominal route: try to build large families by hand, discover n^2 or 2^n examples, then try to bound k with rank arguments about the M_i, since the M_i live in an n^2 dimensional space and that is the only dimension count in sight. It fails permanently, because the truth is exponential and the space of matrices is not the space the problem lives in.

The bifurcation point is Block 2, and it is one keystroke wide. Faced with "has a zero entry somewhere on its diagonal", the zombie keeps the disjunction and starts case work over which position vanishes. The ideal solution multiplies the diagonal entries together, because over a field the statement "one of these is zero" and the statement "their product is zero" are the same statement, and the second one is a single algebraic equation while the first is a case analysis of size n. Every good thing afterwards is downstream of that one move.

Layer 2: HOW

Block 1. **Cue.** The hypothesis mentions only the diagonal of the product. **Why natural.** The diagonal entry $(M_iN_j)_{tt}$ depends only on row t of M_i and column t of N_j. Different t involve disjoint data. So the problem decomposes into n channels which share nothing except the index set $\{1,\dots,k\}$. Recognising a decomposition into independent factors is what makes an exponential answer plausible: independent factors multiply. **Link to the next block.** If the channels are independent, the way to combine them is a product, not a case split.

Block 2. **Cue.** "Has a zero entry somewhere" is a disjunction. **Why natural.** Over a field, a product vanishes precisely when a factor does. Turning n conditions into one is not cosmetic: it converts the hypothesis into an algebraic identity that can be manipulated, and it makes $(*)$ symmetric and finite. Any time a hypothesis is an OR of equalities, multiply; any time it is an AND of equalities, add squares or stack into a vector. **Link to the next block.** The resulting statement, $D(i,j) \neq 0 \iff i = j$, is a shape you must recognise instantly.

Block 3. **Cue.** A number attached to every ordered pair of indices, nonzero exactly on the diagonal. **Why natural.** This is the signature of a dual pair of families. The reusable fact: if $u_i \cdot v_j = 0$ for $i \neq j$ and $u_i \cdot v_i \neq 0$, then the u_i are linearly independent, because pairing a vanishing linear combination against v_j isolates c_j. So the family size is at most the dimension of whatever space the u_i live in. This is the linear algebra method, and it is the standard weapon whenever a combinatorial family is constrained by an "exactly on the diagonal" condition. **Link to the next block.** The lemma needs vectors. You have matrices and a degree n expression. So build the vectors.

Block 4. **Cue.** $D(i,j)$ is a product of n bilinear forms, hence multilinear of degree n in each argument. **Why natural.** A product of linear things is linear on a bigger space: this is the entire

purpose of the tensor product. Concretely you do not need the abstract construction, you need its coordinates. Expand $\prod_t \left(\sum_a (M_i)_{t,a}(N_j)_{a,t}\right)$ by the distributive law and look at what indexes the resulting monomials: one choice of a_t per factor, that is, a tuple $A \in \{1,\dots,n\}^n$. Each monomial factors as (something depending only on M_i) times (something depending only on N_j). That factorisation is the definition of u_i and v_j, and it turns the multilinear D into an honest inner product on $\mathbb{R}^{n^n}$. **Link to the next block.** With the vectors in hand, Block 3 applies verbatim.

Block 5. Cue. Linear independence in a space of known dimension. **Why natural.** $k \le \dim V = n^n$. Note that the argument never used any property of the matrices beyond $(*)$, which is the sign that the bound is structural rather than accidental. **Link to the next block.** A bound is half an answer; now saturate it.

Block 6. Cue. The bound is $n^n = |\{1,\dots,n\}^n|$, and the upper bound proof identified the coordinates with tuples. **Why natural.** The proof itself tells you where equality can hold: the u_i must be n^n independent vectors, and the cheapest independent set is a basis, so aim for u_i to be the standard basis vectors of $\mathbb{R}^{\mathcal{A}}$. That happens exactly when each M_i has rows drawn from $\{e_1,\dots,e_n\}$, so that the product $\prod_t (M_i)_{t,a_t}$ is 1 for one tuple and 0 for the rest. Read backwards: index the pairs by tuples, let channel t test agreement in coordinate t, and use orthonormality $e_a \cdot e_b = \delta_{ab}$ to make agreement detectable. So the construction is not a separate act of invention; it is the equality case of the bound.

Layer 3: WHY

Two mathematical truths carry this problem, and they are worth more than the problem.

The first is the linear algebra method: to bound the size of a family of combinatorial objects, map the objects to vectors in a space of computable dimension and prove the vectors are independent; the bound is the dimension. The most common way to prove independence is to exhibit a dual family with $u_i \cdot v_j$ nonzero exactly on the diagonal, and that is precisely what the hypothesis of this problem hands you for free. The archetype in the literature is the set pair inequality of Bollobas, which follows the same skeleton. Once you have met three examples of this method you stop seeing "largest k" questions as combinatorics and start seeing them as dimension counts.

The second is that products of linear forms become linear on tensor powers. A bilinear form on $\mathbb{R}^n \times \mathbb{R}^n$ is an inner product after a change of coordinates; a product of n such forms, applied to n independent pairs of vectors, is an inner product on the n fold tensor power, whose dimension is n^n. The coordinates of a pure tensor $w_1 \otimes \cdots \otimes w_n$ are $\prod_t (w_t)_{a_t}$, which is exactly the $u_i(A)$ we wrote down, and the pairing satisfies $\langle w_1 \otimes \cdots \otimes w_n,\ y_1 \otimes \cdots \otimes y_n\rangle = \prod_t \langle w_t, y_t\rangle$. If you prefer to avoid the word tensor entirely, the distributive law does the same job in one line, which is what the ideal solution does. Naming the concept is still worth it, because the name is what lets you predict the answer before proving it.

Now the discernment mechanism, which is the part you must be able to run in the arena. You compute $n = 1$ and get 1; you build $n = 2$ by hand and get 4. Two data points do not determine the pattern, but they do determine the search: the answer is at least 4 for $n = 2$, so the ambient space you are looking for has dimension at least 4, and the natural spaces functorially built out of $\mathbb{R}^n$ are few. The nth tensor power has dimension n^n; the nth symmetric power has dimension $\binom{2n-1}{n}$; the nth exterior power has dimension 1; the space of matrices has dimension n^2. For $n = 2$ these are 4, 3, 1, 4. The construction rules out the exterior power and the symmetric power, and the difference between n^2 and n^n shows at $n = 3$, where the tuple construction gives 27 and the matrix space would allow only 9. So the answer names its own space, and the space tells you the proof. That is the discernment: for an extremal problem with linear algebraic data and an exponential answer, identify the space whose dimension matches the small cases, then find the map into it.

The knowledge gaps, stated without cosmetics, because this is an A6. If tensor products and their dimension are not installed, you can still write the construction and state the answer, and you will have a partial solution and nothing more; the upper bound is the entire difficulty. If the dual family lemma is not installed, you will not know that the hypothesis $D(i,j) \neq 0 \iff i = j$ is worth anything. Install, in this order: dual families and independence; the distributive expansion of a product of sums; tensor powers and their dimension; then the linear algebra method as a named strategy. None of it is deep; all of it is beyond A level and beyond NOIR PREMIERE.

Revolving concepts

Diagonal of a product. $(MN)_{tt} = \sum_a M_{ta} N_{at}$, the pairing of row t with column t. Its sum over t is the trace, which is a similarity invariant; its product over t is not an invariant of anything, which is the structural signal that this problem is combinatorial and not representation theoretic, and that basis changing manoeuvres will not help. See Book 1, field: Matrices and determinants, topic: products and traces.

Dual (biorthogonal) families. If $u_1, \dots, u_k$ and $v_1, \dots, v_k$ lie in an inner product space with $u_i \cdot v_j = 0$ for $i \neq j$ and $u_i \cdot v_i \neq 0$, then each family is linearly independent and $k \leq \dim$. Orbiting facts: a basis and its dual basis are the equality case; the same argument in a bilinear (not necessarily symmetric or definite) pairing works verbatim; the rank of the matrix $\left[u_i \cdot v_j\right]$ is k because it is diagonal with nonzero diagonal, and rank is at most the dimension of either space. See Book 1, field: Linear algebra, topic: independence via a dual family.

Tensor power. $V^{\otimes n}$ has basis $e_{a_1} \otimes \cdots \otimes e_{a_n}$ indexed by $A \in \{1, \dots, n\}^n$, so $\dim(\mathbb{R}^n)^{\otimes n} = n^n$; the pure tensor $w_1 \otimes \cdots \otimes w_n$ has A coordinate $\prod_t (w_t)_{a_t}$; and the induced pairing multiplies the factorwise pairings. The comparison points worth holding are $\dim \operatorname{Sym}^n(\mathbb{R}^n) = \binom{2n-1}{n}$ and $\dim \Lambda^n(\mathbb{R}^n) = 1$. See Book 1, field: Linear algebra, topic: multilinear algebra.

Distributive expansion. $\prod_{t=1}^{n} \left(\sum_{a=1}^{n} x_{t,a}\right) = \sum_{A \in \{1,\dots,n\}^n} \prod_{t=1}^{n} x_{t,a_t}$. This is the elementary content of the tensor identity and the reason the exponent is n^n: one free choice per factor. See Book 1, field: Combinatorics, topic: product principle.

The multiplicativity recursion, generalised. The structure here is a product of independent channels, and independent channels multiply the count. State it as a recursion: let $K(m)$ be the largest family of pairs of m tuples of vectors in $\mathbb{R}^n$ with $\prod_{t \leq m} r_{i,t} \cdot c_{j,t} \neq 0 \iff i = j$. Adjoining one more channel multiplies the ambient dimension by n and, by the same tensor argument, gives $K(m) \leq n\,K(m-1)$, with $K(0) = 1$ and equality achievable at every step by appending one more coordinate to the codeword. Hence $K(m) = n^m$, and the problem is $m = n$. The same recursion proves the rectangular generalisation Elkies notes: if the M_i are $m \times n$ and the N_j are $n \times m$, the diagonal has m entries, the ambient space is $(\mathbb{R}^n)^{\otimes m}$, and the answer is n^m. Generalise once more: if channel t pairs $\mathbb{R}^{d_t}$ with $\mathbb{R}^{d_t}$, the answer is $\prod_t d_t$, because the tensor product of the channels has that dimension and codewords over alphabets of sizes d_t realise it. See Book 1, field: Combinatorics, topic: product constructions and dimension bounds.

The linear algebra method. Named strategy: bound a combinatorial family by exhibiting an injective map to independent vectors. Its most quoted instance is the set pair inequality: if (A_i, B_i) are pairs of sets with $A_i \cap B_i = \emptyset$ and $A_i \cap B_j \neq \emptyset$ for $i \neq j$, with $|A_i| = a$ and $|B_i| = b$, then the number of pairs is at most $\binom{a+b}{a}$. Note the identical skeleton: a condition that holds exactly off the diagonal, converted into independence. See Book 1, field: Combinatorics, topic: the linear algebra method.

Circuit Bank

- **WHEN** a hypothesis says "some one of these quantities is zero" **DO** multiply them and say "the product is zero" **BECAUSE** over a field the two statements are identical, and one algebraic equation can be manipulated while a disjunction of n cases can only be split

- **WHEN** you meet a quantity attached to ordered pairs of indices that is nonzero exactly when the indices agree **DO** find vectors realising it as an inner product and conclude the family is linearly independent **BECAUSE** pairing a vanishing linear combination with the dual vector isolates one coefficient, so the family size is at most the dimension of the space
- **WHEN** the quantity you want to realise as an inner product is a product of several bilinear forms **DO** expand the product by the distributive law and index the resulting monomials by tuples **BECAUSE** a product of linear forms is linear on the tensor power, and the monomial index set is exactly a basis of that power
- **WHEN** an extremal answer looks exponential in n and the data are linear algebraic **DO** compute the small cases and match the numbers against n^n, n^2, $\binom{2n-1}{n}$, 2^n **BECAUSE** the bound will be the dimension of a space built from $\mathbb{R}^n$, and matching the small case identifies which space before you prove anything
- **WHEN** a question asks "what is the largest k" **DO** write the answer on line one, then a construction, then a matching bound **BECAUSE** these are two independent proofs and a grader marks them independently, so mixing them costs marks even when the mathematics is right

Backtesting

1. First useful cue: only diagonal entries appear, and $(M_i N_j)_{tt}$ couples row t with column t alone, so the problem is n independent channels rather than a matrix problem.
2. Method the expression suggested: multiply the n diagonal entries into one scalar, realise that scalar as an inner product of two vectors in a space of dimension n^n, and read off independence.
3. Where you would hesitate, and the thought to reinforce: at the moment the product of bilinear forms refuses to be bilinear. Reinforce this: products linearise on tensor powers, and in coordinates that is nothing but expanding brackets.
4. The trap the question sets: the word matrix. It invites determinant, rank and invertibility reflexes, all of which are useless because the product of diagonal entries is not invariant under any change of basis.
5. What makes you recognise it faster next time: the pattern "nonzero exactly on the diagonal" is a dual family, and dual families are always bounded by a dimension; the only work is identifying the space.
6. The reusable decision rule: an AND of nonvanishing conditions is one nonvanishing product, and a product of pairings is a pairing on the tensor product.

Mirror drills

1. Write out four explicit pairs of 2×2 matrices achieving $k = 4$ for $n = 2$. *Answer:* index by $(a_1, a_2) \in \{1,2\}^2$, let M have rows e_{a_1}, e_{a_2} and $N = M^{\mathsf{T}}$; the four matrices are I, $\left(\begin{smallmatrix} 1 & 0 \\ 1 & 0 \end{smallmatrix}\right)$, $\left(\begin{smallmatrix} 0 & 1 \\ 0 & 1 \end{smallmatrix}\right)$ and $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$.
2. Let $u_1, \dots, u_k$ and $v_1, \dots, v_k$ be vectors in $\mathbb{R}^d$ with $u_i \cdot v_j = 0$ for $i \neq j$ and $u_i \cdot v_i \neq 0$. Prove $k \leq d$. *Answer:* if $\sum c_i u_i = 0$, pair with v_j to get $c_j(u_j \cdot v_j) = 0$, so all $c_j = 0$; independent vectors in $\mathbb{R}^d$ number at most d.
3. Solve the same problem when the M_i are $m \times n$ and the N_j are $n \times m$, so that $M_i N_j$ is $m \times m$. *Answer:* n^m, by codewords in $\{1, \dots, n\}^m$ and the same pairing in $(\mathbb{R}^n)^{\otimes m}$.

12.7 B1. Unique over-expansions and the missing zero digit

A base 10 *over-expansion of a positive integer* N *is an expression of the form*

$$N = d_k 10^k + d_{k-1} 10^{k-1} + \cdots + d_0 10^0$$

with $d_k \neq 0$ *and* $d_i \in \{0, 1, 2, \ldots, 10\}$ *for all* i*. For instance, the integer* $N = 10$ *has two base* 10 *over-expansions:* $10 = 10 \cdot 10^0$ *and the usual base* 10 *expansion* $10 = 1 \cdot 10^1 + 0 \cdot 10^0$*. Which positive integers have a unique base* 10 *over-expansion?*

Read it out loud

This is a positional representation question wearing a uniqueness classification mask. The field underneath is elementary number theory, the arithmetic of base ten place value, but the command term is not compute or find, it is which N, so the real task is a full classification proved as an if and only if. The structural feature the examiners planted is not subtle: they enlarged the legal digit alphabet from the usual $\{0, 1, \ldots, 9\}$ to $\{0, 1, \ldots, 10\}$, a single extra value at the top, then handed you a worked example of exactly what that extra value buys you. Read that example as a gift, not as decoration.

Within the first thirty seconds you should have written down the exchange this extra digit enables: $10 \cdot 10^i = 1 \cdot 10^{i+1}$, one unit at position $i + 1$ traded for ten units at position i. That trade produces a legal alternative expansion only when position i currently reads 0, so there is room to receive ten units without breaking the digit bound, and position $i + 1$ currently reads at least 1, so there is a unit there to give up. Look again at the worked example: $N = 10$ has usual digits $(d_1, d_0) = (1, 0)$, and the trade converts it to $(0, 10)$, exactly the pattern just described. The examiners are not hiding the mechanism, they are demonstrating it once so that you generalise it.

What is really being tested is proof discipline on a two directional claim, not cleverness. Once the extra freedom is seen to live entirely in that one exchange identity, the classification writes itself: a unique over-expansion should correspond exactly to having no zero digit in the usual expansion, since a zero digit is the only place the exchange can land. What remains is to prove both directions properly, existence of a second expansion whenever a zero digit is present and uniqueness whenever it is not, without conflating them into one argument that serves neither direction well.

Approaches, ranked worst to best

1. **Enumerate small cases by hand.** *Cue:* the worked example for $N = 10$ invites you to try $N = 1$ up to about 100 and tally over-expansions. *Circuit:* brute force digit string search. (this finds the pattern quickly but proves neither direction; every hour spent enumerating is thrown away the moment the real argument is written, and a coincidence across the first twenty cases is easy to mistake for a theorem).

2. **Count the total number of over-expansions as a function of the zero digits.** *Cue:* noticing that $N = 1000$, with three zero digits, plainly has more than two over-expansions. *Circuit:* a run length or generating function count over blocks of consecutive zero digits. (this answers a harder question than the one asked; the problem wants unique versus not unique, not the exact count, and the exact count is not even a simple function of the number of zero digits, so this route spends ink solving a different problem).

3. **Split into existence and uniqueness, each with its native tool.** *Cue:* the phrase which positive integers is a classification, and classifications proved as an if and only if always split cleanly. *Circuit:* explicit local exchange for existence, residue driven induction on digit count for uniqueness. (this is the direct route: one line constructs the second expansion whenever a zero digit is present, and one induction, peeling the last digit by its forced residue modulo 10, rules out any second expansion whenever no zero digit is present).

The ideal solution

Claim. A positive integer N has a unique base 10 over-expansion if and only if its usual base 10 expansion contains no digit equal to 0.

Write the usual base 10 expansion of N as $N = d_k 10^k + \cdots + d_0 10^0$ with $d_k \neq 0$ and $d_i \in \{0, \ldots, 9\}$ for all i; every over-expansion of N is compared against this fixed reference.

Existence of a second expansion when some digit is 0. Suppose $d_i = 0$ for some $i < k$, and let i be the largest such index. Because i is the largest index below k at which the digit vanishes, the digit immediately above it cannot also vanish without contradicting that maximality, so $d_{i+1} > 0$. Replace the two terms $d_{i+1}10^{i+1} + d_i 10^i = d_{i+1}10^{i+1}$ by $(d_{i+1} - 1)10^{i+1} + 10 \cdot 10^i$; both expressions equal the same value since $10 \cdot 10^i = 10^{i+1}$, and the new digit at position i, namely 10, is legal. If $i + 1 < k$, the digit $d_{i+1} - 1$ sitting at position $i + 1$ is a perfectly legal interior digit, possibly 0, since only the top digit of an expansion is required to be nonzero. If $i + 1 = k$ and $d_k = 1$, the coefficient at the old top position becomes 0; simply read the new expansion with top index i instead of k, since the coefficient 10 at position i is nonzero. Either way this is a second, genuinely different over-expansion of N, so N does not have a unique one.

Uniqueness when no digit is 0. Suppose $d_i \geq 1$ for every $i = 0, \ldots, k$. Induct on k, the number of digits of N minus one. If $k = 0$ then $N = d_0 \in \{1, \ldots, 9\}$, and any over-expansion of N is a single digit $e_0 \in \{0, \ldots, 10\}$ with $e_0 = N$; this is forced, so the expansion is unique.

Let $k \geq 1$ and suppose the claim holds for every positive integer whose usual expansion has fewer than $k + 1$ digits. Let $N = e_l 10^l + \cdots + e_0 10^0$ be any over-expansion of N, with $e_l \neq 0$ and every $e_i \in \{0, \ldots, 10\}$. Reducing modulo 10, $e_0 \equiv N \equiv d_0 \pmod{10}$. Since $d_0 \in \{1, \ldots, 9\}$, the only value of e_0 in $\{0, \ldots, 10\}$ congruent to d_0 modulo 10 is $e_0 = d_0$ itself, since the other candidate $d_0 + 10$ already exceeds 10. So $e_0 = d_0$ is forced, and

$$\frac{N - d_0}{10} = e_l 10^{l-1} + \cdots + e_1 10^0$$

exhibits $e_l, \ldots, e_1$ as an over-expansion of $(N - d_0)/10$. But $(N - d_0)/10 = d_k 10^{k-1} + \cdots + d_1 10^0$ is precisely the usual expansion of this smaller integer, which has k digits, all nonzero. By the induction hypothesis this smaller integer has a unique over-expansion, its own usual one, so $l - 1 = k - 1$ and $e_i = d_i$ for $i = 1, \ldots, k$. Together with $e_0 = d_0$, the over-expansion of N is exactly the usual one, and since it was arbitrary, N's over-expansion is unique.

Both directions close the claim: N has a unique base 10 over-expansion exactly when its usual expansion has no zero digit.

Layer 1: WHAT

Block 1: fix the usual expansion as the reference and state the claim as an if and only if. Block 2: for existence, locate the largest zero digit and perform one local exchange via $10 \cdot 10^i = 10^{i+1}$. Block 3: handle the bookkeeping when that exchange empties the old top coefficient. Block 4: for uniqueness, set up induction on the number of digits. Block 5: force the last digit of any rival expansion by a residue argument. Block 6: reduce to the induction hypothesis on the smaller integer and conclude both the digits and the top index agree.

The nominal route hunts for one master argument that proves both directions at once, or tries to count every over-expansion of N in general, which answers more than was asked. The bifurcation point is the decision to split the if and only if into two independently toolled arguments before writing a single line of algebra, construction for existence, induction for uniqueness. A second, smaller bifurcation sits inside the uniqueness half: peeling the *last* digit by its forced residue modulo 10, rather than reasoning from an unknown top index downward, since the last digit is the only one pinned by the value of N alone.

Layer 2: HOW

Block 1. **Cue.** The command term "which positive integers" demands a classification, and the problem already supplies both a positive instance (the definition) and a negative one (the worked example) of that classification. **Why natural.** Fixing the usual expansion as a reference object is natural because it is the one expansion every positive integer already has for free; every other over-expansion is naturally described as a deviation from it. **Link to the next block.** With a fixed reference in hand, the two directions of the iff become two separate, comparable questions about that reference.

Block 2. **Cue.** The digit alphabet is the usual one plus exactly one extra value, 10, sitting one unit above the usual ceiling of 9. **Why natural.** A single extra legal value can only ever be reached through a single identity relating adjacent positions, $10 \cdot 10^i = 10^{i+1}$, so the entire search for a second expansion reduces to asking where that identity's two preconditions, a receiving zero and a paying nonzero neighbour, can both be met. **Link to the next block.** Choosing the *largest* zero index below the top, rather than any zero index, is what guarantees the paying neighbour is available, which sets up the bookkeeping in the next block.

Block 3. **Cue.** The exchange can land exactly at the old top position. **Why natural.** An over-expansion's defining rule is only that its own top digit is nonzero, not that the top index matches the usual expansion's, so a coefficient collapsing to 0 at the old top simply means the new top index is one smaller. **Link to the next block.** This closes the existence direction cleanly and hands over to the uniqueness direction, where the top index of a rival expansion is genuinely unknown in advance.

Block 4. **Cue.** No digit is 0, so the exchange identity from Block 2 has nowhere to land. **Why natural.** Induction on the number of digits is the natural tool whenever a claim about arbitrary length digit strings needs to be reduced to a claim about a strictly shorter one. **Link to the next block.** The base case, a single nonzero digit, is immediate, so the entire burden falls on relating a $(k+1)$-digit rival expansion to a k-digit one.

Block 5. **Cue.** Any rival expansion's constant term is only visible modulo 10 from the value of N itself. **Why natural.** The digit bound $\{0, \ldots, 10\}$ contains exactly one representative of each residue class modulo 10 except the class of 0, which contains two, 0 and 10; since N's own last digit is nonzero, only the smaller representative survives the bound. **Link to the next block.** Once the last digit is forced to agree with the usual expansion, everything above it is literally an over-expansion of the strictly smaller integer $(N - d_0)/10$.

Block 6. **Cue.** The smaller integer inherited from Block 5 has one fewer digit and, since it is just N with its nonzero last digit stripped, still has no zero digits. **Why natural.** The induction hypothesis applies verbatim to this smaller integer, and uniqueness there means uniqueness of its entire digit string, including its length. **Link to the next block.** Matching lengths forces the rival expansion's top index to equal k, and matching digits forces every coefficient to equal the usual one, closing the induction.

Layer 3: WHY

The digit bound lemma, $\sum_{i<k} 9 \cdot 10^i = 10^k - 1 < 10^k$, is what makes ordinary positional representations rigid: no combination of digits below a position can ever match or exceed one unit at that position. Over-expansion adds exactly one unit of slack per position, and that lemma shows the slack can only ever be absorbed where a position is already empty; anywhere a usual digit is

nonzero, the position is already too full to receive a compensating unit without a further, cascading adjustment that the induction shows never actually materialises once the bottom digit is pinned. The discernment mechanism to train is this: whenever a digit alphabet is widened by exactly one extra value at one end, name the single carry identity that value encodes, then ask precisely where in a legal digit string that identity's preconditions can both hold. That localises the entire phenomenon before any casework begins. Rehearsing the same question with the alphabet widened at the opposite end, as in the first mirror drill below, is what turns "spot the zero" into a reflex that also recognises which digit plays the analogous role when the direction of the carry is reversed. The examiners' worked instance for $N = 10$ is not decoration; it is a fully explicit demonstration of the exchange identity, planted so that a solver who tests it against the digit bound lemma reaches the classification without any outside machinery.

Revolving concepts

Positional base b representation. Every positive integer has a unique expansion with digits in $\{0, \ldots, b-1\}$; the proof is exactly the digit bound lemma above with 10 replaced by b. See Book 1, field: Number theory, topic: base representations.

The carrying identity and enlarged alphabets. Widening the alphabet to $\{0, \ldots, b\}$ introduces exactly the identity $b \cdot b^i = b^{i+1}$ as the sole source of extra representations.

Proposition 12.7.1. *Fix an integer $b \geq 2$ and enlarge the digit alphabet to $\{0, 1, \ldots, b\}$. A positive integer N has a unique base b over-expansion if and only if the usual base b expansion of N has no digit equal to 0.*

The proof is the argument above verbatim with b in place of 10 throughout; nothing about the base 10 was ever load bearing.

Residue induction, peeling the last digit. The general reduction $N \mapsto (N - d_0)/b$, with d_0 the residue of N modulo b, turns any claim about arbitrary length base b digit strings into an induction on the number of digits, with a one digit base case. This is the same self-similar step that underlies converting between number bases by repeated division, and mixed radix systems more generally.

Other uniqueness of representation theorems, a genuine knowledge gap. Not every uniqueness of representation result comes from a value bound like the one here. Zeckendorf's theorem states that every positive integer has a unique representation as a sum of non-consecutive Fibonacci numbers; the constraint enforcing uniqueness there is an adjacency rule on which terms may appear together, not a bound on any single digit. Knowing that a second family of such theorems exists, governed by a structurally different kind of constraint, is worth installing before meeting it cold on a later problem.

Circuit Bank

- **WHEN** a positional digit alphabet is enlarged by exactly one extra value at one end **DO** write down the single carrying identity that extra value encodes and find its two preconditions on adjacent digits **BECAUSE** non-uniqueness of representation can only ever be generated by that one identity, so naming it first turns the whole problem into locating where its preconditions hold
- **WHEN** a claim has the shape "for all N, property $P(N)$ holds if and only if digit condition Q" **DO** split immediately into the two directions and choose an independent tool for each, typically an explicit construction for the existence direction and an induction for the uniqueness direction **BECAUSE** conflating the two directions into one combined argument obscures which lemma is doing the load bearing work and tends to smuggle in an unjustified assumption on one side
- **WHEN** a uniqueness claim about base b digit strings of unknown length must be proved by induction **DO** induct on the number of digits and peel off the last digit via its forced residue

modulo b, not the leading digit **BECAUSE** the residue of N modulo b is the one digit value pinned by N alone, independent of any assumption about how many digits a rival expansion uses

- **WHEN** a bound on individual digits needs to be turned into a statement about the whole number **DO** compare the sum of all lower digits to the geometric total $\sum_{i<k}(b-1)b^i = b^k - 1$ rather than bounding term by term **BECAUSE** this exact identity is what proves a single higher digit dominates every combination of digits below it, the standard lemma behind every base representation uniqueness argument

Backtesting

1. First useful cue: the problem hands you a worked example of non-uniqueness for $N = 10$, manufactured exactly at a zero digit, and that placement is the cue, not the arithmetic.
2. Method the expression suggested: the enlarged digit alphabet suggested naming the one carrying identity $10 \cdot 10^i = 10^{i+1}$ it encodes, then localising rather than globally searching.
3. Where you would hesitate, and the thought to reinforce: worrying whether a rival expansion's top index could differ from the usual one; the fix is to notice the induction hypothesis's uniqueness already includes uniqueness of length, so the top index is pinned automatically once every digit below it is pinned.
4. The trap the question sets: assuming the total number of over-expansions is some simple function of how many zero digits are present, when the question never asked for a count at all, only for the binary classification unique versus not.
5. What makes you recognise it faster next time: seeing any digit alphabet fattened by one extra value at one end as an instant instruction to find the single identity that extra value encodes.
6. The reusable decision rule: when a positional system's legal digit set is $\{0, \ldots, b\}$ instead of $\{0, \ldots, b-1\}$, check the usual expansion for zero digits, because a zero digit is precisely the only slot the extra value's carrying identity can occupy.

Mirror drills

1. (drill) Which positive integers have a unique base 2 over-expansion, with digit alphabet $\{0, 1, 2\}$ in place of the usual $\{0, 1\}$? *Answer:* exactly those whose usual binary expansion has no zero digit, that is $N = 2^{k+1} - 1$ for some $k \geq 0$; the identity $2 \cdot 2^i = 2^{i+1}$ plays the role of $10 \cdot 10^i = 10^{i+1}$ verbatim.
2. (drill) How many distinct base 10 over-expansions does $N = 100$ have in total? *Answer:* exactly 3: the usual $(1, 0, 0)$, and two more with top index one smaller, $(d_1, d_0) = (10, 0)$ and $(9, 10)$; the count is not simply twice the number of zero digits, so always enumerate directly rather than pattern matching a formula for the count.
3. (drill) Exhibit a base 10 over-expansion of $N = 1000$ other than the usual one, and explain why the exchange has to be applied at the digit in the hundreds place rather than the tens or units place. *Answer:* $(d_2, d_1, d_0) = (10, 0, 0)$, since $1000 = 10 \cdot 10^2$; trying the exchange at the tens or units place fails because the digit immediately above it is also 0, violating the precondition that the paying neighbour be nonzero.

12.8 B2. Maximising a weighted integral under an area constraint

Suppose that f is a function on the interval $[1,3]$ such that $-1 \le f(x) \le 1$ for all x and $\int_1^3 f(x)\,dx = 0$. How large can $\int_1^3 \frac{f(x)}{x}\,dx$ be?

Read it out loud

Two hypotheses are given about f, a pointwise box bound and a single integral condition, and then a different integral is asked about. That pairing, a box bound plus one linear integral constraint, together with a question that is itself linear in f, is the signature of an extremal problem whose best function is not smooth at all but a step function sitting on the boundary of the box. The field underneath is real analysis and inequalities, and the caveat worth clarifying immediately is that $\int f(x)/x\,dx$ presupposes f is integrable in the first place, since the problem never says so explicitly; that assumption is used from the first line onward.

The first useful cue is the kernel $1/x$ itself: it is strictly decreasing on $[1,3]$. A linear objective wants f to be as large as the box allows wherever the kernel is large and as small as the box allows wherever the kernel is small, since that is the only way to correlate f with $1/x$ as strongly as the box permits. The single constraint $\int f = 0$ over an interval of length 2 then forces the region where $f = 1$ and the region where $f = -1$ to have equal measure, one unit each, once you accept that the extremal f should only ever take the two boundary values. Combine the two observations, decreasing kernel and an equal length split, and the candidate writes itself within the first thirty seconds: f should be 1 on the left half $[1,2]$ and -1 on the right half $(2,3]$, since a decreasing kernel is always largest on an initial segment.

What is really being tested is whether you trust that heuristic enough to state the candidate immediately and then spend all your remaining ink proving it, rather than trying to discover it through algebra. The examiners are not asking for calculus of variations; they are asking whether you recognise a bang bang extremal problem on sight and can verify a single guessed function with an elementary comparison.

Approaches, ranked worst to best

1. **Guess and check with smooth test functions.** *Cue:* no structural cue is used at all, only the temptation to try something explicit like a cosine or a linear ramp. *Circuit:* plugging in candidates and comparing numbers. (this never proves an upper bound, only ever produces lower bounds on the answer, and after several candidates you still do not know whether a better one exists).

2. **Calculus of variations with a Lagrange multiplier.** *Cue:* a linear objective under one linear equality constraint is the classic setting for a multiplier. *Circuit:* Pontryagin style reasoning, $f = \operatorname{sign}(1/x - \lambda)$ pointwise, then solve $\int f = 0$ for λ. (this correctly discovers the candidate switching function and even finds $\lambda = 1/2$, but turning "the unconstrained pointwise optimum is a sign function" into a rigorous statement over an infinite dimensional constraint set costs real machinery that a Putnam write-up should not need to import).

3. **Integration by parts against the primitive of f.** *Cue:* the constraint $\int_1^3 f = 0$ makes $F(x) = \int_1^x f(t)\,dt$ vanish at both endpoints. *Circuit:* trade a rough pointwise bound on f for a tight Lipschitz bound on F, then bound the transformed integral directly. (this is genuinely elegant and fully competition legal, but needs one honest remark about approximating a merely integrable f by continuous functions before the boundary terms in the parts formula are justified without qualification).

4. **Guess the extremal from the bathtub heuristic, then verify by one direct comparison.** *Cue:* the same decreasing kernel and equal split cue as above. *Circuit:* subtract the guessed extremal

from f and find one pointwise inequality valid on the whole domain. (this is the direct route: the guess costs no ink to state, and the verification is a single inequality integrated once, with no machinery beyond monotonicity of $1/x$).

The ideal solution

Define

$$g(x) = \begin{cases} 1 & 1 \le x \le 2 \\ -1 & 2 < x \le 3. \end{cases}$$

First check g is admissible: $-1 \le g \le 1$ trivially, and $\int_1^3 g\,dx = \int_1^2 1\,dx + \int_2^3 (-1)\,dx = 1 - 1 = 0$, so g satisfies exactly the hypotheses imposed on f.

Let $h = g - f$. Since f satisfies $\int_1^3 f = 0$ by hypothesis and $\int_1^3 g = 0$ as just checked, $\int_1^3 h\,dx = 0$. The key claim is the single pointwise inequality

$$h(x)\left(\frac{1}{x} - \frac{1}{2}\right) \ge 0 \qquad \text{for every } x \in [1,3].$$

On $[1,2]$, $x \le 2$ gives $1/x - 1/2 \ge 0$, and $g(x) = 1 \ge f(x)$ gives $h(x) = 1 - f(x) \ge 0$; a product of two nonnegative numbers is nonnegative. On $(2,3]$, $x > 2$ gives $1/x - 1/2 < 0$, and $g(x) = -1 \le f(x)$ gives $h(x) = -1 - f(x) \le 0$; a product of two nonpositive numbers is again nonnegative. This proves the claim on all of $[1,3]$, with the two cases exactly covering the domain and agreeing (trivially) at $x = 2$.

Integrate the claim over $[1,3]$:

$$0 \le \int_1^3 h(x)\left(\frac{1}{x} - \frac{1}{2}\right) dx = \int_1^3 \frac{h(x)}{x}\,dx - \frac{1}{2}\int_1^3 h(x)\,dx = \int_1^3 \frac{h(x)}{x}\,dx,$$

using $\int_1^3 h = 0$ from above. So $\int_1^3 h(x)/x\,dx \ge 0$, that is,

$$\int_1^3 \frac{f(x)}{x}\,dx \le \int_1^3 \frac{g(x)}{x}\,dx.$$

Compute the right side directly:

$$\int_1^3 \frac{g(x)}{x}\,dx = \int_1^2 \frac{dx}{x} - \int_2^3 \frac{dx}{x} = \ln 2 - (\ln 3 - \ln 2) = 2\ln 2 - \ln 3 = \ln\frac{4}{3}.$$

So $\int_1^3 f(x)/x\,dx \le \ln(4/3)$ for every admissible f, and this bound is attained by $f = g$ itself, which is admissible as checked above. Hence the largest possible value is

$$\boxed{\ln\frac{4}{3}}.$$

Layer 1: WHAT

Block 1: read the two hypotheses as a box bound plus one linear constraint, and the kernel $1/x$ as monotonic, which together flag a bang bang extremal problem. Block 2: use the equal length split forced by $\int f = 0$ together with the decreasing kernel to name the candidate g before doing any verification. Block 3: check g is admissible. Block 4: form $h = g - f$ and note $\int h = 0$ for free. Block 5: find the single pointwise inequality $h(x)(1/x - 1/2) \ge 0$ that holds on the whole domain at once. Block 6: integrate that one inequality and compute the resulting bound explicitly, then exhibit equality.

The nominal route tries to discover g by algebra, either by direct optimisation over an ansatz or by grinding through a Lagrange multiplier calculation until a switching function falls out, and

then re-derives the bound by splitting the domain into $[1,2]$ and $(2,3]$ at the integration stage as two separate estimates. The bifurcation point is the decision to hunt for one inequality valid on the entire domain, built by comparing the kernel $1/x$ against its own value $1/2$ at the switching point, rather than comparing f and g separately on each half. That one shift by $1/2$ is what collapses two case dependent estimates into a single integrated line.

Layer 2: HOW

Block 1. **Cue.** A pointwise box bound $-1 \leq f \leq 1$ appears together with exactly one linear integral constraint, and the target is itself linear in f. **Why natural.** Linear objectives over a set defined by a box bound and finitely many linear constraints are always optimised at an extreme point of that set, and here the extreme points are precisely the functions taking only the values ± 1 almost everywhere. **Link to the next block.** Accepting that the optimal f is boundary valued turns the search for it into a search for one set, the region where $f = 1$.

Block 2. **Cue.** The kernel $1/x$ is strictly decreasing on $[1,3]$, and the constraint $\int f = 0$ over a length 2 interval is a statement purely about measure. **Why natural.** A decreasing kernel is maximised on any fixed measure set by choosing the leftmost such set, and the constraint fixes that measure at exactly one unit on each side by matching the plus and minus regions. **Link to the next block.** These two facts together pin down the candidate completely, an initial segment of length one carrying the value 1 and the rest carrying -1, with the actual switching point falling exactly at $x = 2$.

Block 3. **Cue.** Any candidate produced by a heuristic must be checked against the problem's own hypotheses before it is used in a comparison. **Why natural.** g was built to have measure one on each side by construction, so its own integral vanishing is really the same fact as the construction, restated. **Link to the next block.** Knowing g is admissible means f and g can now be compared on equal footing.

Block 4. **Cue.** Two functions both satisfying the same linear constraint invite subtraction. **Why natural.** Subtracting cancels the constraint itself, $\int h = 0$ costs nothing to state once both integrals are known to vanish, and this is exactly the piece of information the final integration step needs. **Link to the next block.** With $\int h = 0$ available for free, only a pointwise fact about h is still needed to finish.

Block 5. **Cue.** g was built by comparing the kernel $1/x$ to the single value $1/2$, so that same value is the natural pivot to test h against. **Why natural.** g and f differ only where the box bound is active, and the box bound is active in a direction that always matches the sign of $1/x - 1/2$ by the very construction of g; this is not a coincidence, it is what defines g. **Link to the next block.** Once the sign of h is known to match the sign of $1/x - 1/2$ everywhere, their product is nonnegative everywhere, a single fact valid on the whole domain rather than two facts valid on two halves.

Block 6. **Cue.** A pointwise inequality that holds everywhere integrates to a global inequality in one step. **Why natural.** Expanding the product recovers exactly $\int h/x$ minus a multiple of $\int h$, and the second term is already known to vanish, so the entire inequality collapses onto the one integral that was actually wanted. **Link to the next block.** This closes the upper bound, and exhibiting $f = g$ as an admissible function achieving it upgrades the bound from a supremum to an attained maximum.

Layer 3: WHY

Two facts from outside the elementary toolkit are doing the discovery work here even though neither is needed in the final write-up. The first is the bang bang principle: a linear functional maximised over a convex set defined by a pointwise bound and linear constraints attains its maximum at an extreme point of that set, and for the set $\{f : |f| \leq 1\}$ the extreme points are exactly the ± 1-valued functions, because any f taking a value strictly between -1 and 1 on a set of positive measure could be perturbed within that set, keeping the constraint fixed while strictly increasing the objective unless the kernel happens to be constant there. The second is the bathtub principle: among all subsets of a fixed measure, the integral of a decreasing function is maximised by the leftmost such subset, since moving any mass rightward within a fixed measure set only ever trades a larger kernel value for a smaller one. Neither fact needs to be cited by name in a write-up, because once the candidate they jointly produce is in hand, an elementary direct comparison finishes the job with no further machinery; this is exactly why the ideal solution above never mentions either principle.

The discernment mechanism worth training is this: whenever a problem hands you a pointwise box bound together with one linear integral constraint and then asks you to bound a second linear integral, immediately identify the kernel of that second integral and ask whether it is monotonic on the domain. If it is, the extremal is forced to be a step function switching at whatever point makes the measure split match the constraint, and the entire remaining task is an elementary verification, not a search. What the examiners nudged toward is precisely this reflex: the numbers in the problem, the interval $[1, 3]$ of length 2 and the constraint value 0, are chosen so that the split is the cleanest possible one, an exact half and half, so that a solver who has the reflex reaches the candidate in seconds and can spend the remaining time on the one inequality that actually needs proving.

Revolving concepts

Bathtub principle for monotonic kernels. For a fixed measure m and a function ϕ decreasing on the domain, $\int_S \phi$ over measurable S with $|S| = m$ is maximised by taking S to be an initial segment of the domain, and minimised by taking a terminal segment. See Book 1, field: Inequalities, topic: rearrangement and the bathtub principle.

Bang bang principle for linear functionals. A linear functional of f, maximised subject to $|f| \leq 1$ pointwise and one linear integral constraint, attains its maximum at a ± 1-valued function; this is the same idea that appears as Pontryagin's maximum principle in optimal control, where the optimal control is always found on the boundary of its admissible range. Genuine knowledge gap: this is a real theorem from optimisation and control theory, not elementary calculus, and is worth installing precisely because it explains discovery, not verification.

Kernel independence of the optimal set. If the linear constraint on f forces a fixed measure split of the domain, maximising against any strictly decreasing kernel is achieved by the same leftmost set, regardless of which decreasing kernel is used; only the resulting numeric value depends on the kernel. Flipping the kernel to strictly increasing flips the optimal set to the rightmost one instead. This is why the mirror drills below can reuse the same g for a different kernel but must flip g when the kernel's monotonicity flips.

Trading a rough bound for a smooth one via a primitive. Setting $F(x) = \int_1^x f$, the hypotheses give $F(1) = F(3) = 0$ and, since $|f| \leq 1$, F is 1-Lipschitz, so $|F(x)| \leq \min(x - 1, 3 - x)$. Integrating $f(x)/x$ by parts converts the integral into one involving $F(x)/x^2$, where this sharper bound on F can be used directly; this is the official second solution's route and is worth knowing as a general reflex whenever a rough pointwise bound on f is not tight enough to finish an estimate involving a smooth kernel.

Circuit Bank

- **WHEN** a linear integral objective is paired with a pointwise box bound on f and one linear integral constraint **DO** expect the extremal to be a ± 1-valued step function, and look for the single switching point that the constraint forces **BECAUSE** a linear objective over a box shaped constraint set is always optimised at an extreme point, and the extreme points of this particular set are exactly the boundary valued functions
- **WHEN** the objective's kernel is monotonic on the domain **DO** place the value $+1$ on the piece of the domain where the kernel is largest, sized exactly to the measure the constraint demands **BECAUSE** a monotonic kernel is always maximised on a fixed measure set by an initial or terminal segment, never a scattered set, so only the split point remains unknown
- **WHEN** a guessed extremal g needs to be verified against every competitor f subject to the same two hypotheses **DO** subtract, $h = g - f$, and search for one pointwise inequality against the kernel shifted by its value at the switching point, valid on the whole domain at once **BECAUSE** a single global inequality integrates in one line, while splitting the domain into pieces at the integration stage repeats the same sign argument twice for no benefit
- **WHEN** a rough pointwise bound on f is not tight enough once multiplied by a kernel and integrated **DO** consider the primitive $F(x) = \int f$, exploit any vanishing boundary values it inherits from a given integral constraint, and integrate by parts **BECAUSE** a primitive of a bounded function is Lipschitz, converting a rough pointwise bound into a genuinely tight one near the boundary

Backtesting

1. First useful cue: a pointwise box bound on f together with a single integral condition equal to zero is exactly the signature of a bang bang extremal problem, before any calculus is attempted.
2. Method the expression suggested: dividing by x marks the kernel as strictly decreasing, and a decreasing kernel paired with an equal measure constraint always points to a single switching point at the midpoint of the domain's length, not the midpoint of the kernel's range.
3. Where you would hesitate, and the thought to reinforce: wondering whether a smooth candidate might beat the discontinuous step function g; reinforce by recalling that the objective and constraint are both linear in f, and linear problems over a box are never improved by moving away from the boundary.
4. The trap the question sets: assuming the answer wants a formula in terms of a general f, when actually a single explicit numeric bound is being asked for, achieved by one specific, easily written down function.
5. What makes you recognise it faster next time: seeing $-1 \le f \le 1$ paired with $\int f =$ a fixed constant as an instant cue for a bang bang extremal, independent of which kernel the actual objective uses.
6. The reusable decision rule: when bounding $\int f\phi$ under $|f| \le 1$ and a fixed value of $\int f$, guess a ± 1-valued step function switching at the point that matches the required measure split, then prove optimality with one pointwise comparison against the kernel shifted by its value at that point.

Mirror drills

1. (drill) Under the same two hypotheses on f, how large can $\int_1^3 f(x)/x^2\,dx$ be? *Answer:* the same switching function g is still optimal, since $1/x^2$ is still strictly decreasing on $[1, 3]$ and the

measure split forced by the constraint has not changed; the bound is $\int_1^2 dx/x^2 - \int_2^3 dx/x^2 = 1/2 - 1/6 = 1/3$.

2. (drill) If the constraint is changed to $\int_1^3 f(x)\,dx = 1$ instead of 0, where does the switching point move, and what is the new bound on $\int_1^3 f(x)/x\,dx$? *Answer:* writing the plus region's length as m_+, $m_+ - (2 - m_+) = 1$ gives $m_+ = 3/2$, so the switch moves to $x = 2.5$; the new bound is $2\ln(2.5) - \ln 3 = \ln(25/12)$.

3. (drill) True or false: if the kernel in the objective were x itself instead of $1/x$, the same g, equal to 1 on $[1,2]$, would still maximise $\int_1^3 f(x)\,x\,dx$. *Answer:* false; x is increasing, not decreasing, on $[1,3]$, so the optimal set flips to the rightmost half, giving the flipped function, -1 on $[1,2]$ and 1 on $(2,3]$, as the true maximiser.

12.9 B3. distinct primes among entries force rank two

Let A be an $m \times n$ matrix with rational entries. Suppose that there are at least $m + n$ distinct prime numbers among the absolute values of the entries of A. Show that the rank of A is at least 2.

Read it out loud

Say the hypothesis back to yourself in two separate pieces, because the problem is built from two pieces of mathematics that have nothing to do with each other until the very last line. The first piece is arithmetic: at least $m + n$ of the entries, read as absolute values, are distinct primes. The second piece is a bound on an integer invariant, the rank, phrased as a lower bound rather than an exact value: you are not asked to compute the rank, only to rule out the two smallest possibilities for it.

Look at the number $m + n$ itself before you look at anything else. It is not a fixed constant like 5 or 100, and it is not a product like mn. It is rows plus columns, and a matrix problem that states its hypothesis as rows plus columns is all but naming its own method: build a graph whose two vertex classes are the rows and the columns, of size m and n, so that $m + n$ is the vertex count of something you can draw. The moment you notice that coincidence of counts is the moment you should have written down, within the first thirty seconds, the sentence "one vertex per row, one vertex per column, an edge for every prime."

The fields wired into this problem are three, and they are deliberately kept apart until the final step. Linear algebra supplies the classification of rank at most 1 as an explicit two-factor formula for every entry. Graph theory supplies the exact threshold at which a graph stops being able to avoid a cycle, which is precisely when its edge count reaches its vertex count. Number theory, specifically unique factorisation, supplies the contradiction, because a product of pairwise distinct primes and a perfect square of a rational number are mutually exclusive descriptions of the same number. None of the three fields alone proves anything; the problem is testing whether you can chain them without dropping a piece.

What is really being tested is a discernment skill, not a technique: recognising which branch of mathematics a given numerical threshold belongs to. A weaker candidate reads "$m + n$" as an arbitrary bound and tries to attack the problem with linear algebra alone, hunting for two rows or two columns that are visibly independent. That hunt has nowhere to stand, because the primes need not sit inside any single 2×2 block of the matrix.

Approaches, ranked worst to best

1. **Hunt directly for a nonvanishing 2×2 minor.** *Cue:* "rank at least 2" restated as "some 2×2 minor is nonzero". *Circuit:* brute inspection of whichever two prime entries you notice first. (why it ranks here: with m and n arbitrary and the $m + n$ primes scattered anywhere in the grid, nothing tells you which two rows and which two columns to compare, and in general no two of the primes need share both a row and a column with two others, so this approach has no way to even choose its first move.)

2. **Embed the entries in the valuation vector space over all primes and run a dimension count.** *Cue:* "distinct primes" read as coordinates of a vector. *Circuit:* the valuation homomorphism from the positive rationals under multiplication into the group of integer sequences indexed by primes. (why it ranks here: this is correct and it generalises further than the problem asks, but you pay for that generality with a heavier setup, an infinite-dimensional ambient space, a hyperplane cut out by a sum-zero condition on auxiliary coefficients, and a dimension bound you must justify with care before it reproduces the same $m + n$ threshold that the graph route hands you immediately.)

3. **Model rows and columns as a bipartite graph and invoke the forest bound.** *Cue:* the count "$m+n$" is literally rows plus columns. *Circuit:* a simple graph with as many edges as vertices cannot be a forest, so it contains a cycle. (best: the least machinery of the three, every step forced by the last, and the threshold $m+n$ falls out of a single elementary lemma instead of being reverse-engineered from a dimension count.)

The ideal solution

Suppose, for contradiction, that the rank of A is at most 1.

If A is the zero matrix, none of its entries has prime absolute value, since 0 is not prime, so zero distinct primes occur among the entries of A. This already contradicts the hypothesis, because $m, n \geq 1$ forces $m+n \geq 2$ primes to be required. So from now on, $\operatorname{rank}(A) = 1$ exactly.

A rational matrix of rank exactly 1 is an outer product with rational factors. To see this, pick a row index i_0 for which row i_0 is not the zero row, and set $b_j = A_{i_0,j}$ for $j = 1, \ldots, n$, so that b is a nonzero vector in $\mathbb{Q}^n$. Because $\operatorname{rank}(A) = 1$, every row of A lies in the one dimensional row space spanned by row i_0, so for each row index i there is a scalar a_i with row i equal to a_i times row i_0. Row i_0 has some nonzero entry, in column j_0 say, and reading off that single column forces $a_i = A_{i,j_0} / A_{i_0,j_0}$, a ratio of two rational numbers, hence itself rational. By construction $A_{ij} = a_i b_j$ for every i and j, with $a \in \mathbb{Q}^m$ and $b \in \mathbb{Q}^n$ both nonzero.

Now build a bipartite graph G: one vertex for each row index $1, \ldots, m$, one vertex for each column index $1, \ldots, n$, giving $m+n$ vertices in total. For each of the at least $m+n$ distinct primes occurring among the $|A_{ij}|$, fix one entry realising that prime and join its row vertex to its column vertex. An entry occupies a single position in the grid and carries a single absolute value, so two different primes are always realised at two different positions, hence give two different edges. So G has at least $m+n$ edges on exactly $m+n$ vertices.

Lemma 12.9.1. *A finite simple graph with V vertices and no cycle has at most $V-1$ edges.*

Proof. Induct on V. For $V = 1$ there is no edge to draw, and $0 = V - 1$. For $V > 1$, if the graph has no edges the bound is immediate. Otherwise take a path of maximum length in the graph and let v be one of its endpoints. Every neighbour of v already lies on the path: a neighbour outside the path would extend it, contradicting maximality, and a neighbour further along the path than the vertex adjacent to v would close a cycle with the path itself, contradicting acyclicity. So v's only neighbour is the next vertex on the path, meaning v has degree 1. Delete v: the remaining graph still has no cycle, has $V-1$ vertices, so by induction has at most $V-2$ edges, and restoring v restores at most one edge, giving at most $V-1$ in total. □

Since G has $m+n$ vertices and at least $m+n$ edges, the lemma rules out G being a forest, so G contains a cycle. Every edge of G joins a row to a column, so G is bipartite, and a bipartite graph has no odd cycle; write the cycle as row vertices $\rho_1, \ldots, \rho_k$ and column vertices $\gamma_1, \ldots, \gamma_k$, indices read modulo k, visited in the order $\rho_1, \gamma_1, \rho_2, \gamma_2, \ldots, \rho_k, \gamma_k, \rho_1$, with $k \geq 2$ since a simple bipartite graph has no cycle shorter than 4.

The $2k$ edges of this cycle were chosen for $2k$ distinct primes, say $|A_{\rho_t,\gamma_t}| = p_{2t-1}$ and $|A_{\rho_{t+1},\gamma_t}| = p_{2t}$ for $t = 1, \ldots, k$, all $2k$ of the p's pairwise distinct. Write $r_t = |a_{\rho_t}|$ and $c_t = |b_{\gamma_t}|$, so that $p_{2t-1} = r_t c_t$ and $p_{2t} = r_{t+1} c_t$. Multiply all $2k$ primes together:

$$p_1 p_2 \cdots p_{2k} = \prod_{t=1}^{k} (r_t c_t)(r_{t+1} c_t) = \left(\prod_{t=1}^{k} r_t \right) \left(\prod_{t=1}^{k} r_{t+1} \right) \left(\prod_{t=1}^{k} c_t \right)^2 .$$

The map $t \mapsto t+1 \pmod{k}$ permutes $\{1, \ldots, k\}$, so $\prod_t r_{t+1} = \prod_t r_t$, and the right side collapses to $\left(\prod_t r_t \prod_t c_t\right)^2$, the square of a positive rational number q.

Write $q = s/t$ in lowest terms with s, t positive integers. Then $p_1 \cdots p_{2k}\, t^2 = s^2$, so $t^2 \mid s^2$; since $\gcd(s,t) = 1$ gives $\gcd(s^2, t^2) = 1$, this forces $t = 1$, so $q = s$ is a positive integer and $p_1 \cdots p_{2k} = s^2$

is a perfect square of an integer. Every prime in the factorisation of a perfect square occurs to an even exponent. But $p_1, \ldots, p_{2k}$ are pairwise distinct primes, so their product has each of them occurring to the exponent exactly 1, which is odd. This contradicts the previous sentence.

The contradiction shows that $\operatorname{rank}(A) \leq 1$ is impossible, so $\operatorname{rank}(A) \geq 2$, as required.

Layer 1: WHAT

1. Negate the goal: assume $\operatorname{rank}(A) \leq 1$ and aim for a contradiction; dispose of rank 0 immediately, since the zero matrix has no prime entries at all.
2. Convert rank 1 into the rigid formula $A_{ij} = a_i b_j$ for explicit rational vectors a, b.
3. Convert the counting hypothesis into a graph: rows and columns as vertices, one edge per distinct prime, exactly $m + n$ vertices and at least $m + n$ edges.
4. Invoke the forest bound to extract a cycle, necessarily of even length at least 4 because the graph is bipartite.
5. Substitute the outer product formula around the cycle and telescope the product of the $2k$ distinct primes, using a cyclic shift of index, into an explicit perfect square.
6. Contradict unique factorisation: a squarefree product of distinct primes cannot equal a rational square.

The nominal route stops before block 3. It tries to answer "rank at least 2" by pointing at two rows and two columns directly and computing a 2×2 determinant, which works instantly on hand-picked examples where the primes happen to cluster in a small block, and fails to generalise the moment m and n grow, because nothing in the hypothesis tells you which rows and columns to compare. The bifurcation point is block 3: the instant you read "$m + n$" as rows plus columns rather than as an arbitrary number, and reach for a graph on exactly those two vertex classes instead of continuing to search the grid by eye.

Layer 2: HOW

Block 1. **Cue.** An integer invariant, the rank, is bounded below by a small integer, 2. **Why natural.** Integer invariants bounded below are most cheaply attacked by ruling out every smaller value, because each smaller value usually has a closed, rigid description, whereas "rank at least 2" itself has no single formula to manipulate. **Link to the next block.** Ruling out rank 0 costs one sentence; what remains is the single case rank 1, which is exactly the case with a known rigid form.

Block 2. **Cue.** The phrase "rank at most 1", the negation you just introduced. **Why natural.** Rank at most 1 is definitionally the statement that the row space has dimension at most 1, which means every row is a scalar multiple of one fixed row; writing that out coordinatewise gives $A_{ij} = a_i b_j$, and rationality of the scalars follows for free by dividing two of A's own rational entries. **Link to the next block.** Every entry's absolute value is now a product of exactly two numbers, $|a_i|$ and $|b_j|$, which is the only algebraic handle the rest of the proof needs.

Block 3. **Cue.** The number "$m + n$" appearing as a hypothesis, exactly rows plus columns. **Why natural.** A bound phrased as rows plus columns, rather than a fixed constant or a product, is the fingerprint of a bipartite graph argument, because rows and columns are the two natural vertex classes of a matrix and $m + n$ is their combined size; no other natural object attached to an $m \times n$ grid has that count. **Link to the next block.** The arithmetic hypothesis, a count of primes, becomes a purely combinatorial one, an edge count against a vertex count, and the primes' actual values are set aside until the last block.

Block 4. **Cue.** Edge count at least equal to vertex count in a simple graph. **Why natural.** A cycle is the only obstruction to a graph being a forest, and forests are exactly the graphs that achieve the extremal bound of $V - 1$ edges on V vertices; reaching V edges leaves no forest able to hold them, so a cycle is forced, and because every edge in this particular graph crosses from a row to a column, that cycle cannot be odd. **Link to the next block.** The cycle supplies a closed, alternating list of row and column indices, exactly the shape needed to set up one product taken all the way round.

Block 5. **Cue.** A product taken cyclically around a closed alternating sequence of row and column values. **Why natural.** Each row value r_t is used in exactly two of the $2k$ factors around the cycle, once as the "current" row and once as the "next" row, so multiplying every factor counts each r_t and each c_t exactly twice; reindexing a product over all k indices by a cyclic shift does not change its value, and that single fact is what lets the two copies of the r's collapse into one squared term. **Link to the next block.** The product now has an explicit closed form, the square of a rational number, ready to be set against the other thing you separately know about that same product.

Block 6. **Cue.** A product of pairwise distinct primes on one side, a perfect square on the other side, of the same equation. **Why natural.** Unique factorisation assigns every rational number one well defined exponent at each prime; a square forces that exponent to be even everywhere, while a squarefree product of distinct primes forces it to be exactly 1, odd, at each of those primes, and no number carries two different exponents at the same prime. **Link to the next block.** There is no further block: this is the contradiction, and it closes the proof.

Layer 3: WHY

The route rests on a general pattern for proving an integer invariant is at least k: assume at most $k - 1$, find the exact classification of that boundary case, and break the classification with a piece of structure the boundary case cannot also satisfy. Here the boundary case, rank at most 1, has an unusually explicit classification, an outer product, and the structure that breaks it is arithmetic rather than further linear algebra, which is precisely why hunting for a second independent row inside the matrix itself never gets off the ground: the contradiction was never going to live inside linear algebra alone.

The discernment mechanism worth training is recognising which branch of mathematics owns a given numerical threshold before you commit to a method. A bound stated as a product, mn, would smell of counting entries or a double sum. A bound stated as a fixed constant would smell of an extremal example to pin down exactly. A bound stated as rows plus columns smells of a bipartite graph, because $m + n$ is the one count that a graph on rows and columns produces for free as its vertex total. Train this by asking, every time a matrix problem states a bound, "what natural object attached to this grid has exactly this many elements", before reaching for any technique.

The examiners' nudge sits in exactly one place: the linear algebra fact, rank at most 1 is an outer product, is the single piece of machinery you are assumed to know cold, and it is disposed of in one paragraph. The actual difficulty, the graph theory, is dressed in ordinary matrix language so that a candidate who only reaches for linear algebra stalls at "which two rows and columns do I compare", never suspecting that the real threshold belongs to a different field entirely.

Revolving concepts

Rank one matrices as outer products. A matrix A over a field has rank at most 1 exactly when $A = ab^T$ for some vectors a, b, possibly zero; when the entries of A lie in $\mathbb{Q}$, the vectors a, b can be chosen in $\mathbb{Q}$ as well, by solving for the scaling constants against two of A's own nonzero rational entries. The same idea extends one level up: rank at most r means A is a sum of r such outer products, and rank is unchanged by extending the field of scalars, which is why working over $\mathbb{Q}$

throughout never loses generality here. See Book 1, field: Linear algebra, topic: rank and matrix factorisations.

Unique factorisation and rational squares. Every nonzero rational number factors uniquely as a sign times a product of primes to integer exponents, and this assignment of an exponent to each prime, at each rational number, is additive under multiplication: the exponent of a product is the sum of the exponents of its factors. A positive rational number is the square of a rational number exactly when every one of its exponents is even, and that criterion, applied to a number that is separately known to be a product of pairwise distinct primes, each to the first power, is the exact contradiction this problem manufactures. See Book 1, field: Number theory, topic: unique factorisation and prime exponents.

Forests, trees and the edge against vertex threshold. A tree is a connected graph with no cycle; a forest is a disjoint union of trees. A tree on k vertices has exactly $k-1$ edges, provable by repeatedly deleting a vertex of degree 1, which always exists in a nonempty acyclic graph by taking a longest path and looking at its endpoint; a forest with several components inherits the bound $V-1$ on V vertices, with equality only for a single tree. The immediate corollary used here, a simple graph with at least as many edges as vertices contains a cycle, and in a bipartite graph that cycle has even length at least 4, since row to row or column to column edges do not exist. See Book 1, field: Discrete structures and graphs, topic: forests and the edge against vertex threshold. The leaf removal argument that proves the tree bound is itself a small induction, remove one vertex, apply the same statement to what remains, add back what you removed, and the identical shape of argument reappears whenever a finite structure is built by adding one relation at a time to a fixed set of objects: more relations than objects forces a redundancy, a cycle in a graph, a linear dependency among vectors once you have more of them than the ambient dimension. Recognising that a graph theory threshold and a linear algebra threshold are the same statement in different language is worth carrying forward as its own revolving concept. See Book 1, field: Linear algebra, topic: dependency thresholds and their graph theory analogue.

Circuit Bank

- **WHEN** a problem asks you to prove an integer invariant, rank, dimension, a count, is at least k **DO** assume it is at most $k-1$, find the exact classification of that boundary case, and break the classification with an independent piece of structure **BECAUSE** the boundary case is almost always far more rigid and describable in closed form than the open condition itself, so a contradiction against the rigid form costs less ink than attacking "at least k" directly
- **WHEN** a hypothesis in a matrix problem is stated as a count equal to the number of rows plus the number of columns **DO** build a bipartite graph with rows and columns as the two vertex classes and turn the count into an edge count **BECAUSE** $m+n$ is exactly the vertex count of that graph, so the hypothesis becomes a forest against cycle threshold, the one setting where "rows plus columns" is a forced number rather than an arbitrary one
- **WHEN** you need to know whether a simple graph on V vertices must contain a cycle **DO** check whether it has at least V edges **BECAUSE** a forest on V vertices has at most $V-1$ edges by the leaf removal induction, so V or more edges rules out being a forest
- **WHEN** a quantity is simultaneously known to be a product of pairwise distinct primes and forced by other algebra to equal a perfect square of a rational number **DO** declare the contradiction immediately through unique factorisation, comparing the exponent at any one of those primes **BECAUSE** a square has every exponent even, a squarefree product of distinct primes has every occurring exponent equal to 1, and no rational number carries two exponents at the same prime
- **WHEN** the rank of a matrix is at most 1 **DO** rewrite every entry as $A_{ij} = a_i b_j$ for explicit

vectors a, b over the same field as the entries **BECAUSE** this is exactly what "row space of dimension at most 1" means, and it turns every entry from a matrix condition you can only manipulate linearly into a two-factor product you can manipulate arithmetically

Backtesting

1. First useful cue: the number $m + n$ sitting in the hypothesis, instantly readable as rows plus columns rather than an arbitrary constant.
2. Method the expression suggested: a bipartite graph with rows and columns as vertex classes, one edge per distinct prime, compared against the forest bound.
3. Where you would hesitate, and the thought to reinforce: after finding the cycle, wondering whether the $2k$ chosen primes are still genuinely distinct at that point; reinforce that one grid position carries exactly one absolute value, so distinct primes could never have shared a position to begin with.
4. The trap the question sets: assuming two rows and two columns exist whose four intersection entries are all prime, so that a 2×2 minor can be read off directly; in general the $m + n$ primes are scattered with no such block guaranteed, and only the graph argument survives that scattering.
5. What makes you recognise it faster next time: seeing "the number of rows plus the number of columns" anywhere in a matrix hypothesis should fire the bipartite graph circuit before any other reading of the sentence is attempted.
6. The reusable decision rule: to prove a rank lower bound, negate to the largest forbidden rank, write out that rank's rigid classification explicitly, then hunt for a contradiction from an independent field, arithmetic here, but counting or algebra elsewhere.

Mirror drills

1. (drill) An $m \times n$ rational matrix has at least $m + n$ entries equal to 1 in absolute value, not necessarily at distinct values. Must its rank be at least 2? *Answer:* No. Take every entry equal to 1: the matrix has rank 1 and every one of its $mn \geq m + n$ entries (for $m, n \geq 2$) has absolute value 1. This isolates exactly why the primes in the original problem had to be distinct, not merely numerous.
2. (drill) Explain, using only the graph, why a 3×3 rational matrix can carry as many as 5 distinct primes among its entries while still having rank 1, but never 6. *Answer:* Five edges on six vertices can still form a forest, for instance a single path touching every row and column vertex once, so no cycle and no contradiction; six edges on six vertices cannot avoid a cycle.
3. (drill) A connected graph on 10 vertices has exactly 9 edges. Does it contain a cycle, and why does this feel like the boundary case of the Putnam problem above? *Answer:* No, a connected graph with $V - 1$ edges on V vertices is by definition a tree; this is the extremal forest case, the reason the Putnam hypothesis needed "at least $m + n$" primes and not "at least $m + n - 1$".

12.10 B4. All roots real for a log concave polynomial

Show that for each positive integer n, all the roots of the polynomial

$$\sum_{k=0}^{n} 2^{k(n-k)} x^k$$

are real numbers.

Read it out loud

Say it as it is built: this is a polynomial of degree n whose coefficients are all positive, all powers of two, and the exponent of the coefficient is $k(n-k)$, a concave quadratic in the index k. That last clause is the entire problem. You are not looking at a polynomial, you are looking at a parabola sitting in the exponent, and the parabola is symmetric about $k = n/2$.

Two things must be on your page within thirty seconds. First, $c_k = c_{n-k}$, so the coefficient list is palindromic and $x^n f_n(1/x) = f_n(x)$. Second, and far more important, compute the log concavity ratio, because positive coefficients plus a real rootedness claim always means log concavity is the hidden hypothesis:

$$\frac{c_k^2}{c_{k-1}c_{k+1}} = 2^{2k(n-k)-(k-1)(n-k+1)-(k+1)(n-k-1)} = 2^2 = 4.$$

Not "at least 4", not "roughly 4". Exactly 4, for every k and every n. That is a signature, and you should recognise it as one: the quantity $c_k^2 - 4c_{k-1}c_{k+1}$ is the discriminant of the local quadratic $c_{k-1} + c_k y + c_{k+1} y^2$, so this problem sits precisely on the boundary where every consecutive triple of terms is a perfect square. A problem placed exactly on a threshold is a problem where the naive estimate will give you zero and you will have to look at the next order term. Expect that, and it will not surprise you when it happens.

The fields wired in are: root location for real polynomials, the intermediate value theorem used as a counting device, log concavity of coefficient sequences, and finite alternating sums with rapidly decaying terms. What is really being tested is whether you know that "prove all roots are real" for a polynomial you cannot factor has exactly one elementary certificate, and whether you can choose the test points that make that certificate computable rather than merely conceivable.

Approaches, ranked worst to best

1. **Find the roots.** *Cue:* "all the roots" reads like an instruction to produce them. *Circuit:* solve the equation. Ranked last because it is the reflex of a candidate who has not read the coefficient. For $n = 3$ the palindrome gives $f_3(x) = (1+x)(x^2+3x+1)$ and you feel encouraged; for $n = 4$ the substitution $y = x + 1/x$ gives $y^2 + 8y + 14$ and you feel very encouraged; by $n = 6$ you need a cubic in y all of whose roots are real *and* of modulus at least 2, and there is no pattern to ride. It costs pages and it does not generalise, which is the definition of zombie maths.

2. **Newton's inequalities.** *Cue:* positive coefficients and a real rootedness claim. *Circuit:* check the standard necessary conditions. Newton's inequalities say that if $\sum a_k x^k$ is real rooted then $p_k^2 \geq p_{k-1}p_{k+1}$ for $p_k = a_k / \binom{n}{k}$. They are necessary and never sufficient, so verifying them proves nothing at all. Worth thirty seconds as a sanity check that the claim is not false, worth zero marks as a proof.

3. **Induct with the coefficient recursion.** *Cue:* c_k for n is 2^k times c_k for $n-1$. *Circuit:* turn a coefficient identity into a functional identity. Here $f_n(x) = f_{n-1}(2x) + x^n$, which is a clean identity and the fastest way to generate the family numerically. As a proof engine it stalls:

adding x^n to a real rooted polynomial destroys real rootedness in general, and there is no interlacing statement available to control it. Rank it above the previous two because it is structural rather than blind.

4. **Quote a log concavity theorem.** *Cue:* the ratio $c_k^2/(c_{k-1}c_{k+1})$ is a clean constant. *Circuit:* invoke Hutchinson or Kurtz. Hutchinson's theorem says that positive coefficients with $a_k^2 \geq 4a_{k-1}a_{k+1}$ for all k force all zeros to be real and negative; Kurtz's theorem gives simplicity from the strict inequality. This is exactly our situation, on the nose. It ranks high because it is the right idea, and it ranks below the winner because you may not assume a grader accepts an uncommon named theorem, and proving Hutchinson in general is harder than proving this one case. Know the theorem so that you know what to expect; write the case.

5. **Sign alternation at powers of two.** *Cue:* degree n, cannot factor, must show n real roots. *Circuit:* find $n+1$ points where the sign alternates and let the intermediate value theorem count. The winner. The second cue tells you which points: since $c_k x^k = 2^{k(n-k)+kt}$ up to sign when $x = -2^t$, and $k(n-k)+kt$ is the same parabola with its vertex slid to $k = (n+t)/2$, choosing $t = 2j-n$ puts the vertex exactly on the integer $k = j$ and turns every coefficient into a power of two indexed by $(k-j)^2$. The algebra collapses to a single universal sum with no n in it.

The ideal solution

Write $f_n(x) = \sum_{k=0}^{n} 2^{k(n-k)}x^k$, a polynomial of degree n with leading coefficient $2^{n(n-n)} = 1$.

For $n = 1$, $f_1(x) = 1 + x$. For $n = 2$, $f_2(x) = 1 + 2x + x^2 = (1+x)^2$. Both have all roots real, so assume $n \geq 3$ from now on.

Throughout, put

$$g(m) = 2^{-m^2} \qquad (m \in \mathbb{Z}),$$

so g is positive, even, and strictly decreasing in $|m|$, with $g(0) = 1$ and $g(1) = \frac{1}{2}$.

Lemma 12.10.1. *For $j = 0, 1, \ldots, n$ set $x_j = -2^{2j-n}$. Then*

$$f_n(x_j) = (-1)^j 2^{j^2}\, T_j, \qquad \textit{where} \qquad T_j = \sum_{m=-j}^{n-j} (-1)^m g(m).$$

Proof. For each k,

$$2^{k(n-k)}x_j^k = (-1)^k 2^{k(n-k)+k(2j-n)} = (-1)^k 2^{2jk-k^2} = (-1)^k 2^{j^2-(k-j)^2},$$

since $2jk - k^2 = j^2 - (k-j)^2$. Summing over k and substituting $m = k - j$ gives

$$f_n(x_j) = (-1)^j 2^{j^2} \sum_{m=-j}^{n-j} (-1)^m 2^{-m^2},$$

which is the claim. □

So every question about the sign of f_n at these $n+1$ points is a question about the sign of T_j, and T_j is a truncation of one fixed doubly infinite alternating sum. Note also the reflection: replacing m by $-m$ maps the index range $[-j,\ n-j]$ onto $[-(n-j),\ j]$, and g is even, so

$$T_j = T_{n-j} \qquad (0 \leq j \leq n). \tag{R}$$

This is the palindromic symmetry $x^n f_n(1/x) = f_n(x)$ in disguise, since $1/x_j = x_{n-j}$.

Claim 12.10.2. *If $n \geq 3$ then $T_j > 0$ for every $j \in \{0, 1, \ldots, n\}$.*

Proof. By (R) we may assume $2j \le n$. Split the sum at $|m| = j$:

$$T_j = u_j + R_j, \qquad u_j = \sum_{m=-j}^{j} (-1)^m g(m), \qquad R_j = \sum_{m=j+1}^{n-j} (-1)^m g(m),$$

where R_j is the empty sum exactly when $n = 2j$.

First, u_j. Using evenness of g and the exact identity $2g(1) = 1$,

$$u_j = g(0) + 2\sum_{m=1}^{j} (-1)^m g(m) = \big(1 - 2g(1)\big) + 2\sum_{m=2}^{j} (-1)^m g(m) = 2\sum_{m=2}^{j} (-1)^m g(m).$$

So $u_0 = 1$, $u_1 = 0$, and for $j \ge 2$ the sum $\sum_{m=2}^{j}(-1)^m g(m)$ is alternating with strictly decreasing positive terms and first term $g(2)$, hence lies between $g(2) - g(3)$ and $g(2)$. Therefore

$$j \ge 2 \implies u_j \ge 2\big(g(2) - g(3)\big) = 2\left(\tfrac{1}{16} - \tfrac{1}{512}\right) = \tfrac{31}{256} > \tfrac{1}{16}.$$

Second, R_j. When it is nonempty it is alternating with strictly decreasing positive terms and first term $g(j+1)$, so it has the sign of $(-1)^{j+1}$ and $|R_j| \le g(j+1)$.

Now three cases.

Case $j = 0$. $T_0 \ge u_0 - g(1) = 1 - \frac{1}{2} = \frac{1}{2} > 0$.

Case $j = 1$. Here $u_1 = 0$, so everything rests on $R_1 = \sum_{m=2}^{n-1}(-1)^m g(m)$. Since $n \ge 3$ this sum is nonempty, its first term is $+g(2)$, and by the alternating bound $R_1 \ge g(2) - g(3) > 0$. Hence $T_1 > 0$.

Case $j \ge 2$. $T_j \ge u_j - g(j+1) > \frac{1}{16} - 2^{-9} > 0$.

In all cases $T_j > 0$. □

Finish. The points $x_0 > x_1 > \cdots > x_n$ are $n+1$ distinct negative reals, and by the Lemma and the Claim,

$$\operatorname{sgn} f_n(x_j) = (-1)^j,$$

so the sign alternates along the list. By the intermediate value theorem, each of the n pairwise disjoint open intervals (x_j, x_{j-1}), $j = 1, \dots, n$, contains a root of f_n. That is n distinct real roots of a polynomial of degree n, so by the factor theorem these are all of them, each simple. Hence every root of f_n is real, and in fact

all n roots are real, simple and negative, one in each interval $(-2^{2j-n}, -2^{2j-2-n})$.

For $n = 1, 2$ the claim was checked directly. □

Layer 1: WHAT

Block 1. Read the exponent rather than the coefficient: $c_k = 2^{Q(k)}$ with $Q(k) = k(n-k)$ concave quadratic of second difference -2, equivalently $c_k^2 = 4c_{k-1}c_{k+1}$ exactly.

Block 2. Decide the certificate before doing any algebra: for a degree n polynomial that will not factor, "all roots real" is proved by exhibiting n sign changes and counting.

Block 3. Choose the test points so that the algebra collapses. Testing at $x = -2^t$ adds kt to the exponent, which only translates the vertex of the parabola; choose $t = 2j - n$ to park the vertex on the integer $k = j$.

Block 4. Evaluate. Every term becomes $\pm 2^{j^2-(k-j)^2}$, so after dividing by the largest term the whole problem becomes one universal sum $T_j = \sum(-1)^m 2^{-m^2}$ truncated at both ends.

Block 5. Estimate, and meet the threshold face on: the peak term 1 is exactly cancelled by its two neighbours, because $2 \cdot 2^{-1} = 1$. The sign is therefore decided by the $m = \pm 2$ terms, which is why $n \ge 3$ is needed and why $n = 2$ really does have a double root.

Block 6. Halve the work with the reflection $T_j = T_{n-j}$, so only $2j \le n$ needs estimating.

Block 7. Intermediate value theorem plus the factor theorem: n sign changes give n distinct real roots, and a degree n polynomial has no others.

Juxtaposition. The nominal route is: expand, spot the palindrome, substitute $y = x + 1/x$, get a polynomial of degree $\lfloor n/2 \rfloor$ in y, and now try to prove that all of *its* roots are real and of modulus at least 2. You have replaced one real rootedness problem by a harder one and lost the clean coefficient structure. The bifurcation point is the sentence "I will not look for the roots, I will look for the signs", taken the moment you notice you cannot factor. Everything after that is bookkeeping.

Layer 2: HOW

Block 1. **Cue.** Coefficients that are all powers of a single base, with an exponent that is visibly a quadratic in the index. **Why natural.** When coefficients are $b^{Q(k)}$, sums and ratios of coefficients are governed by differences of Q, not by Q itself. Computing the second difference of Q is therefore the cheapest possible probe, and it lands exactly on the log concavity ratio that controls real rootedness. **Link to the next block.** Knowing the ratio is exactly 4 tells you two things at once: real rootedness is plausible (this is the Hutchinson threshold), and any estimate you attempt will be tight rather than comfortable.

Block 2. **Cue.** "Show that all the roots are real", with no value asked for. **Why natural.** There are only three elementary certificates for real rootedness: exhibit the factorisation, realise the polynomial as a characteristic polynomial of a real symmetric matrix or a member of an orthogonal polynomial family, or exhibit enough sign changes. The first two need extra structure that is not on offer here, so the third is forced. This is elimination, not inspiration. **Link to the next block.** The certificate demands $n + 1$ test points. The rest of the problem is the choice of those points.

Block 3. **Cue.** A free parameter (which points?) meeting a coefficient family that is a power of two. **Why natural.** Choose the unknown to make the algebra trivial, not to make the geometry pretty. Substituting $x = -2^t$ replaces the exponent $k(n-k)$ by $k(n-k) + kt$, which is the same downward parabola in k with vertex at $(n+t)/2$. Since the terms are largest near the vertex and you want a clean dominant term, you want the vertex on an integer: $t = 2j - n$. Nothing here is inspired; it is completing the square in the exponent, which you would do to any quadratic. **Link to the next block.** Once the vertex is at $k = j$, the exponent is $j^2 - (k-j)^2$ and the whole family of $n+1$ evaluations is one sum in disguise.

Block 4. **Cue.** A sum whose terms all share the factor 2^{j^2} and whose signs alternate with k. **Why natural.** Normalise by the largest term before estimating anything. Dividing by $(-1)^j 2^{j^2}$ removes both j and n from the summand and leaves $\sum_m (-1)^m 2^{-m^2}$, with n and j surviving only in the truncation limits. A quantity that depends on the data only through its limits of summation is a quantity you can estimate once and reuse. **Link to the next block.** The estimate now needs only the shape of $g(m) = 2^{-m^2}$: positive, even, strictly decreasing away from 0, and dropping fast.

Block 5. **Cue.** $g(0) = 1$ and $2g(1) = 1$: the two neighbours cancel the peak exactly. **Why natural.** This is the promised threshold showing up in person. It is not bad luck; it is the identity $c_k^2 = 4c_{k-1}c_{k+1}$ read at the test point, and it means that the three central terms are the local quadratic $c_{k-1} + c_k y + c_{k+1} y^2$ evaluated at its own double root. When the leading estimate vanishes identically, the standard move is to go one term further out, and $2g(2) = 2^{-3}$ is the first surviving contribution. **Link to the next block.** Because the rescue comes from $m = \pm 2$, you need those indices to exist, which is exactly the condition $n \ge 3$; and $n \le 2$ must be checked by hand, where indeed f_2 has a repeated root.

Block 6. **Cue.** The truncation limits $-j$ and $n-j$ are symmetric under $j \mapsto n-j$, and the summand is even. **Why natural.** Symmetry of the data must be used before, not after, the estimating. Here it is free: one line of reindexing removes half the cases and, as a bonus, it re-derives the palindromic symmetry of f_n without any polynomial manipulation. **Link to the next block.** With $2j \le n$ assumed, the tail R_j starts at $m = j+1$ and is small compared with u_j except in the single case $j = 1$, which you then handle on its own.

Block 7. **Cue.** n sign changes in hand for a polynomial of degree n. **Why natural.** The intermediate value theorem produces roots; the factor theorem caps their number. Together they upgrade "at least n real roots" to "exactly n real roots, all simple, and no complex ones", which is strictly stronger than what was asked and costs no extra ink. **Link to the next block.** Nothing follows; state the interval for each root, since you have it for free and it shows the grader the roots are distinct.

Layer 3: WHY

The mathematical truth underneath is that real rootedness of a polynomial with positive coefficients is a statement about how strongly log concave the coefficient sequence is, and the threshold is the number 4 because $c_k^2 - 4c_{k-1}c_{k+1}$ is the discriminant of the local quadratic $c_{k-1} + c_k y + c_{k+1}y^2$. If the coefficients decay fast enough on both sides of any given index, then near the point where the kth term dominates, the polynomial behaves like that quadratic, and a quadratic with nonnegative discriminant has a real root. Hutchinson's theorem is the honest global version of this local picture. This problem is the extremal case: the discriminant is zero for every k, every local quadratic is a perfect square, and so the polynomial is as close to failing as a real rooted polynomial can be. That is precisely why the two neighbours cancel the peak exactly at each test point, and why the whole proof hangs on a term of size 2^{-4} rather than a term of size 1.

The discernment mechanism is a two step filter. Step one: when asked to prove a qualitative property of roots, list the certificates for that property and cross off the ones the given data cannot supply. For real rootedness the list is short, so this step is fast and decisive. Step two: when a certificate needs free parameters (here, the test points), choose the parameters to make the given structure degenerate, not to make the numbers small. The structure here is a parabola in the exponent, and a parabola degenerates when you slide its vertex onto a lattice point; that is what $x = -2^{2j-n}$ does. Train the second step by taking any coefficient family of the form $b^{Q(k)}$ and asking, before anything else, what substitution makes Q symmetric about an integer.

The examiners nudged in three ways. They wrote the coefficient as $2^{k(n-k)}$ rather than as a number, which is an instruction to read the exponent. They chose base 2, so that $2 \cdot 2^{-1} = 1$ produces exact cancellation rather than approximate cancellation, forcing you to be honest about the next order term instead of hand waving an inequality. And they chose $k(n-k)$ symmetric in $k \leftrightarrow n-k$, which hands you the reflection that halves the case analysis. Any base $b > 2$ in place of 2 makes the problem strictly easier, because then $2b^{-1} < 1$ and the peak term survives on its own.

Revolving concepts

Log concavity and the Hutchinson threshold. A positive sequence (c_k) is log concave if $c_k^2 \ge c_{k-1}c_{k+1}$. The relevant strengthening here is $c_k^2 \ge 4c_{k-1}c_{k+1}$: Hutchinson (1923) proved that this forces all zeros of $\sum c_k x^k$ to be real and negative, and Kurtz proved that strict inequality forces them also to be simple. Our sequence achieves equality everywhere, which is the extremal case. See Book 1, field: Polynomials, topic: real rootedness criteria.

Newton's inequalities. If $\sum_k a_k x^k$ of degree n has all real roots then $p_k^2 \ge p_{k-1}p_{k+1}$ where $p_k = a_k / \binom{n}{k}$. Necessary only. Useful for disproving real rootedness, never for proving it. See Book 1, field: Inequalities, topic: symmetric functions.

Eneström and Kakeya. If $0 < a_0 \le a_1 \le \cdots \le a_n$ then every complex root of $\sum a_k x^k$ has modulus at most 1; rescaling gives the annulus $r \le |z| \le R$ with $r = \min_k a_{k-1}/a_k$ and $R = \max_k a_{k-1}/a_k$ for any positive coefficients. Here $a_{k-1}/a_k = 2^{2k-n-1}$, so every root lies in $2^{1-n} \le |z| \le 2^{n-1}$, consistent with the intervals we produced. This is the same lemma used in the Elkies solution to 2014 A5, so install it once and bill it twice. See Book 1, field: Polynomials, topic: root location.

Palindromic polynomials. $c_k = c_{n-k}$ is equivalent to $x^n f(1/x) = f(x)$, which pairs each root z with $1/z$ and lets you substitute $y = x + 1/x$ when n is even. In our proof this symmetry appears as the identity $T_j = T_{n-j}$ and as the pairing $x_j \leftrightarrow x_{n-j}$ of test points. See Book 1, field: Polynomials, topic: reciprocal equations.

Alternating sums with rapidly decreasing terms. If $t_1 > t_2 > \cdots > t_N > 0$ then $\sum_{i=1}^{N} (-1)^{i-1} t_i$ lies strictly between $t_1 - t_2$ and t_1. That two sided bound, not merely the one sided Leibniz bound, is what makes both u_j and R_j controllable. See Book 1, field: Sequences and recurrences, topic: alternating series estimates.

Gaussian binomials and partial theta. The Gaussian binomial $\binom{n}{k}_q$ has degree exactly $k(n-k)$ in q, so $\sum_k 2^{k(n-k)} x^k$ is the leading exponent shadow of $\sum_k \binom{n}{k}_2 x^k$. Equally, the substitution $x = 2^{-n} y$ turns our polynomial into $\sum_{k=0}^{n} 2^{-k^2} y^k$, a truncation of the partial theta series $\sum_{k \ge 0} q^{k^2} y^k$ at $q = 1/2$. Recognising the normalised form is what tells you the answer cannot depend on n except through truncation. See Book 1, field: Generating functions, topic: q series.

The recursion, generalised. Since $2^{k(n-k)} = 2^{k(n-1-k)} \cdot 2^k$, we get $f_n(x) = f_{n-1}(2x) + x^n$, and by palindromy also $f_n(x) = 1 + x^n f_{n-1}(2/x)$. The general statement worth carrying: if $c_k^{(n)} = b^{\,Q(k,n)}$ with $Q(k,n) - Q(k,n-1) = \lambda k$ for a constant λ, then $f_n(x) = f_{n-1}(b^\lambda x) + c_n^{(n)} x^n$. The solution method for such a family is never to iterate the recursion but to use it as a consistency check on evaluations: it says $f_n(x_j) = f_{n-1}(2x_j) + x_j^n$ where $2x_j = -2^{2j-(n-1)}$ is again a test point for $n-1$, so the sign patterns for consecutive n are compatible. The same pattern (coefficient recursion becomes a dilation of the argument) recurs in every problem whose coefficients are q powers, including the Rogers and Szegő polynomials and every q binomial identity.

Circuit Bank

- **WHEN** you must prove every root of a degree n polynomial is real and you cannot factor it **DO** hunt for $n+1$ points at which the sign alternates, then invoke the intermediate value theorem and the factor theorem **BECAUSE** sign changes are the only elementary certificate that is both available without extra structure and strong enough to force all roots real

- **WHEN** coefficients have the form $b^{Q(k)}$ with Q a quadratic in the index **DO** test at $x = -b^t$ and complete the square in the exponent, choosing t so that the vertex sits on an integer **BECAUSE** multiplying by x^k adds a linear function of k to the exponent, which translates the parabola without changing its shape, so you may place its peak wherever you like

- **WHEN** a sum has one visibly dominant term **DO** divide through by that term before estimating anything **BECAUSE** normalising removes the parameters from the summand and leaves them only in the limits of summation, so one estimate serves every case

- **WHEN** the coefficients satisfy $c_k^2 = 4c_{k-1}c_{k+1}$ exactly **DO** expect the leading estimate to vanish identically and plan to use the next term out **BECAUSE** four is the discriminant threshold of the local quadratic $c_{k-1} + c_k y + c_{k+1} y^2$, so equality means that quadratic is a perfect square and its value at the double root is zero

- **WHEN** the data are symmetric under $k \mapsto n - k$ **DO** reindex to reduce to $2k \le n$ before estimating **BECAUSE** a symmetry used at the start halves the case analysis, whereas a symmetry noticed at the end saves nothing

Backtesting

1. First useful cue: the coefficient is written as a power of two with a quadratic exponent, so the object to analyse is the exponent $k(n-k)$, not the coefficient.
2. Method the expression suggested: exhibit n sign changes at test points chosen to complete the square in the exponent, namely $x = -2^{2j-n}$.
3. Where you would hesitate, and the thought to reinforce: at the moment the three central terms cancel to zero and it looks as though the method has failed. Reinforce this: an exact cancellation at the leading order is information, not failure, and it is exactly what the identity $c_k^2 = 4c_{k-1}c_{k+1}$ predicted. Go one term further out and continue.
4. The trap the question sets: $n = 2$ gives a genuine repeated root, so any argument claiming strict sign alternation for all n is false. The small cases are not decoration; they are where the threshold bites.
5. What makes you recognise it faster next time: the reflex of computing $c_k^2/(c_{k-1}c_{k+1})$ the instant you see positive coefficients plus a real rootedness claim. If the answer is a clean constant, the problem is a log concavity problem and the test points will be geometric.
6. The reusable decision rule: to prove real rootedness, choose test points that make one term dominate; to choose them, complete the square in the exponent of the coefficient.

Mirror drills

1. Show that all roots of $\sum_{k=0}^{n} 3^{k(n-k)}x^k$ are real, for every $n \geq 1$. *Answer:* the same test points $x_j = -3^{2j-n}$ give $\sum_m (-1)^m 3^{-m^2}$; now $2 \cdot 3^{-1} < 1$, so the peak term already dominates and $T_j \geq 1 - 2/3 - 2/3^4 - \cdots > 0$ with no threshold case and no need for $n \geq 3$. Base 2 was the only hard base.
2. Prove that $q_n(y) = \sum_{k=0}^{n} 2^{-k^2}y^k$ has all roots real and negative. *Answer:* $q_n(y) = f_n(2^{-n}y)$, so this is the same statement after a dilation; the test points become $y = -2^{2j}$.
3. Locate all roots of $\sum_{k=0}^{n} 2^{k(n-k)}x^k$ inside an annulus using only the coefficients. *Answer:* $a_{k-1}/a_k = 2^{2k-n-1}$ for $k = 1, \ldots, n$, so the Eneström and Kakeya corollary gives $2^{1-n} \leq |z| \leq 2^{n-1}$; compare with the intervals $(-2^{2j-n}, -2^{2j-2-n})$ produced by the sign argument.

12.11 B5. Parity of centralisers decides a matrix game

In the 75th annual Putnam Games, participants compete at mathematical games. Patniss and Keeta play a game in which they take turns choosing an element from the group of invertible $n \times n$ matrices with entries in the field $\mathbb{Z}/p\mathbb{Z}$ of integers modulo p, where n is a fixed positive integer and p is a fixed prime number. The rules of the game are:

(1) A player cannot choose an element that has been chosen by either player on any previous turn.

(2) A player can only choose an element that commutes with all previously chosen elements.

(3) A player who cannot choose an element on his or her turn loses the game.

Patniss takes the first turn. Which player has a winning strategy? (Your answer may depend on n and p.)

Read it out loud

Read the rules as algebra, not as a game. Rule (2) says that the set S of elements chosen so far is a commuting set, and that the legal moves are exactly the elements commuting with everything in S. That set of elements has a name: the centraliser $Z(S)$, and it is a subgroup. Rule (1) says you may not repeat. So the position is a set S, the move set is $Z(S) \setminus S$, and since every element of S commutes with every element of S we always have $S \subseteq Z(S)$. The game therefore ends exactly when $S = Z(S)$.

That last sentence is the whole problem, and you should have it inside thirty seconds. It says the total number of moves in a completed game is $|S| = |Z(S)|$, the order of a subgroup. This is a normal play game, so the loser is whoever faces an empty move set, which means the winner is decided by the parity of that group order and by nothing else. You do not need to know good moves from bad moves. You need to know which parities are reachable.

The fields wired in are finite group theory (centralisers, Lagrange, Cauchy), linear algebra over a finite field, and the small piece of combinatorial game theory that says a normal play game is decided by the parity of its length when that length is forced. What is really being tested is whether you will reach for Sprague and Grundy out of habit, or whether you will notice that this game has no independent components to add up and that its length is an invariant.

The first useful thing to write down after that is the observation that decides everything: $Z(S)$ shrinks as S grows, and each new centraliser is a subgroup of the previous one, so by Lagrange the orders divide each other. Parity is therefore a one way street. Once even, always even.

Approaches, ranked worst to best

1. **Play the small cases by hand.** *Cue:* "your answer may depend on n and p" invites experiments. *Circuit:* compute, then guess. $|GL_1(\mathbb{Z}/3\mathbb{Z})| = 2$ and $|GL_2(\mathbb{Z}/3\mathbb{Z})| = 48$; the second is already unplayable by hand and the third is out of the question. Ranked last as a proof method. Ranked first as a five minute sanity check: $n = 1$, $p = 2$ gives the trivial group, Patniss takes the identity and wins, which already tells you the answer is not "Keeta always".

2. **Sprague and Grundy.** *Cue:* an impartial normal play game. *Circuit:* compute Nim values of positions. The standard circuit, and here it misfires. Grundy theory earns its keep when a position splits into independent components whose values are added; this position is a single commuting set with no decomposition, and the position space is the set of all commuting subsets of a group of order roughly p^{n^2}. Recognising that a familiar circuit does not apply is itself a skill, and the tell is the absence of any sum structure.

3. **Pairing strategy for odd p.** *Cue:* the scalar matrix $-I$ is central and has order two. *Circuit:* answer every move g with a fixed involution applied to it, here $-g$. Excellent and almost free: it wins the odd case outright with no theory beyond the observation that $-g$ commutes with whatever g commutes with. It ranks below the winner only because it gives no purchase at all on $p = 2$, where no such universal involution exists.

4. **Parity of the centraliser chain.** *Cue:* the move set is a subgroup and the game ends when $S = Z(S)$. *Circuit:* count the length of the game instead of searching it. The winner. The length of a completed game is the order of the terminal subgroup; centralisers only shrink; subgroup orders only divide; therefore the parity gets locked as soon as either a chosen element has even order or some centraliser has odd order. This reduces the whole problem to a single question about the group: does some element have a centraliser of odd order?

The ideal solution

Let $G = GL_n(\mathbb{Z}/p\mathbb{Z})$, a finite group, and for a subset $S \subseteq G$ write

$$Z(S) = \{h \in G : hg = gh \text{ for all } g \in S\},$$

the centraliser of S, which is a subgroup of G (it is the intersection over $g \in S$ of the subgroups $Z(\{g\})$). Write S_t for the set of the first t chosen elements, so $S_0 = \emptyset$ and $Z(S_0) = G$.

Lemma 12.11.1. *The game terminates, and if it lasts N moves then $S_N = Z(S_N)$; in particular $N = |Z(S_N)|$ is the order of a subgroup of G.*

Proof. Each move removes one element from the finite set G, so the game terminates. By rule (2), any two chosen elements commute, so every element of S_t commutes with all of S_t, that is, $S_t \subseteq Z(S_t)$. By rules (1) and (2) the legal moves at position S_t are precisely the elements of $Z(S_t) \setminus S_t$. Hence the game ends at S_N if and only if $Z(S_N) \subseteq S_N$, which together with $S_N \subseteq Z(S_N)$ gives $S_N = Z(S_N)$. Finally $N = |S_N|$. □

Lemma 12.11.2. *If $S \subseteq S'$ then $Z(S') \leq Z(S)$, so $|Z(S')|$ divides $|Z(S)|$. Consequently, in any play of the game:*

(a) if $|Z(S_t)|$ is odd for some t, then N is odd;

(b) if some chosen element has even order, then N is even.

Proof. The inclusion is immediate from the definition, and the divisibility is Lagrange's theorem. For (a), $Z(S_N) \leq Z(S_t)$, so $N = |Z(S_N)|$ divides an odd number. For (b), if $g \in S_t$ has even order then $g \in S_N \subseteq Z(S_N)$, so $\operatorname{ord}(g)$ divides $N = |Z(S_N)|$ by Lagrange, and N is even. □

Proposition 12.11.3. *Patniss has a winning strategy if and only if there exists $g \in G$ with $|Z(\{g\})|$ odd.*

Proof. Since the players alternate with Patniss first, the Nth and final move is made by Patniss exactly when N is odd, and then Keeta is the player who cannot move. So Patniss wins if and only if N is odd.

Suppose such a g exists. Patniss opens with g. By Lemma 2(a) applied at $t = 1$, N is odd whatever either player does afterwards, so Patniss wins.

Suppose instead that $|Z(\{g\})|$ is even for every $g \in G$, and let g be Patniss's opening move. By Cauchy's theorem, the group $Z(\{g\})$ contains an element h of order 2. If $h \neq g$ then h is a legal reply for Keeta, and after it Lemma 2(b) forces N to be even. If $h = g$ then g itself has order 2 and Lemma 2(b) already forces N to be even; note that then $N = |Z(S_N)|$ is even and hence at least 2, so Keeta does have a legal reply and no special care is needed. Either way N is even and Keeta wins. □

Case p odd. The scalar matrix $-I$ lies in the centre of G, and $-I \neq I$ because $p > 2$, so $-I$ has order 2 and lies in $Z(\{g\})$ for every g. By Lagrange, $|Z(\{g\})|$ is even for every g, so by the Proposition Keeta wins. Explicitly, Keeta may answer every move g with $-g$: this commutes with everything that g commutes with because $-I$ is central, it is distinct from g because $2g = 0$ would force $g = 0$, and it is unchosen because the chosen set is stable under $x \mapsto -x$ after each of Keeta's replies.

Case $p = 2$. We exhibit g with $|Z(\{g\})|$ odd. Let $\mathbb{F}_{2^n}$ be the field with 2^n elements. As an $\mathbb{F}_2$ vector space it has dimension n, so choosing an $\mathbb{F}_2$ basis identifies it with the space of column vectors $\mathbb{F}_2^n$ and identifies $\mathbb{F}_2$ linear bijections of $\mathbb{F}_{2^n}$ with elements of G. The multiplicative group $\mathbb{F}_{2^n}^\times$ is cyclic; let α be a generator, and let $g \in G$ be the map $v \mapsto \alpha v$, which is $\mathbb{F}_2$ linear and bijective.

Suppose $h \in G$ commutes with g. Then $h(\alpha v) = \alpha h(v)$ for all v, and iterating gives $h(\alpha^i v) = \alpha^i h(v)$ for all $i \geq 0$; also $h(0 \cdot v) = 0 = 0 \cdot h(v)$. Every element of $\mathbb{F}_{2^n}$ is either 0 or a power of α, so $h(cv) = c\,h(v)$ for all $c \in \mathbb{F}_{2^n}$ and all v. Taking $v = 1$ gives $h(c) = c\,h(1)$ for all c, that is, h is multiplication by $\beta := h(1)$, and $\beta \neq 0$ since h is invertible. Conversely every such multiplication commutes with g. Hence

$$Z(\{g\}) \cong \mathbb{F}_{2^n}^\times, \qquad |Z(\{g\})| = 2^n - 1,$$

which is odd. By the Proposition, Patniss wins.

Patniss wins if $p = 2$; Keeta wins if $p > 2$; in both cases for every n.

Remark 12.11.4. Once $Z(S)$ is abelian the rest of the game is forced: every remaining element of $Z(S)$ commutes with every other, so play continues until all of them are used. With the g above, $Z(\{g\})$ is abelian and the game lasts exactly $2^n - 1$ moves. For $n = 1$, $p = 2$ the group is trivial, $2^1 - 1 = 1$, and Patniss wins by taking the identity.

Remark 12.11.5. The construction is not what separates $p = 2$ from odd p. The same g exists over any $\mathbb{F}_p$ and gives $|Z(\{g\})| = p^n - 1$. What separates the cases is only that $p^n - 1$ is odd precisely when $p = 2$. It is recorded in the official solution, and we do not prove it here, that for $p = 2$ the elements with centraliser of odd order are exactly those with n distinct eigenvalues in an algebraic closure; anything else fixes a nontrivial unipotent or a copy of $GL_k(\mathbb{F}_{2^d})$ with $k > 1$ inside its centraliser, and both have even order.

Layer 1: WHAT

Block 1. Translate the rules: position is the chosen set S, move set is $Z(S) \setminus S$.

Block 2. Rule (2) forces $S \subseteq Z(S)$; the chosen set is a commuting set sitting inside its own centraliser.

Block 3. Therefore the game ends exactly at $S = Z(S)$, so the length of a completed game is the order of a subgroup.

Block 4. Centralisers shrink as S grows and orders divide by Lagrange, so parity is a one way street: even stays even.

Block 5. Convert to a group question: Patniss wins if and only if some element has a centraliser of odd order, with Cauchy's theorem supplying the involution in the converse direction.

Block 6. Odd p: the centre contains the involution $-I$, so every centraliser has even order; Keeta wins.

Block 7. $p = 2$: realise $\mathbb{F}_2^n$ as the field $\mathbb{F}_{2^n}$ and take g to be multiplication by a generator of $\mathbb{F}_{2^n}^\times$; anything commuting with g is $\mathbb{F}_{2^n}$ linear, hence multiplication by a scalar, so $|Z(\{g\})| = 2^n - 1$ is odd and Patniss wins.

Juxtaposition. The nominal route treats this as a game: enumerate positions, look for a pairing or a mirroring strategy, try Grundy values, try to find "good" first moves by hand in $GL_2(\mathbb{Z}/2\mathbb{Z})$. It is not wrong so much as unbounded; there are far too many commuting subsets. The bifurcation point is one sentence: *stop asking which moves are good and ask how long the game is*. Once you ask

that, the terminal condition $S = Z(S)$ appears immediately, and with it a group order, and with it Lagrange.

Layer 2: HOW

Block 1. **Cue.** A rule of the form "you may only choose something compatible with everything already chosen". **Why natural.** Any such rule defines the move set as a closure operation applied to the current position. Naming that operation is the first move in every problem of this type, because a named operation has theorems attached, whereas an unnamed rule has none. Here the operation is the centraliser, and its first theorem is that it is a subgroup. **Link to the next block.** A move set that is a subgroup has an order, and orders have parity, so the game is now measurable.

Block 2. **Cue.** Every pair of chosen elements commutes, by rule (2) applied to whichever was chosen later. **Why natural.** This is the step people skip. The rule as written is asymmetric (the new element commutes with the old ones), and you must notice that it therefore makes the whole chosen set mutually commuting, so that $S \subseteq Z(S)$. Without this containment the terminal condition is not an equation and the count does not close. **Link to the next block.** With $S \subseteq Z(S)$ always true, the only way the move set can be empty is $S = Z(S)$.

Block 3. **Cue.** The game ends when the move set is empty. **Why natural.** Emptiness of $Z(S) \setminus S$ combined with $S \subseteq Z(S)$ is an equality of sets, not merely an inequality of sizes, and an equality of sets converts a dynamic quantity (the number of moves played) into a static one (the order of a subgroup). Converting a process into an invariant is the standard way to defeat a game whose state space is too large to search. **Link to the next block.** The number N of moves is now $|Z(S_N)|$, and normal play means Patniss wins if and only if N is odd.

Block 4. **Cue.** A nested chain $G = Z(S_0) \geq Z(S_1) \geq \cdots$ of subgroups. **Why natural.** Lagrange is the only tool needed: each order divides the previous, so an odd order can never become even and an even order can never become odd. Parity, unlike size, is monotone along the chain. This is why you never have to analyse the middle of the game. **Link to the next block.** So the parity of N is decided at the moment when the chain first becomes committed, and the first move is already such a moment if it makes the centraliser odd.

Block 5. **Cue.** "Even order" needs to be converted into a concrete element that a player can actually choose. **Why natural.** Cauchy's theorem is the standard bridge from a divisibility statement about $|H|$ to the existence of an element of order 2 in H. Keeta does not need a strategy for the whole game, she needs one element whose presence in S locks the parity for good, and an involution is exactly that. **Link to the next block.** The criterion is now purely about G: does some element have a centraliser of odd order? Answer it separately for odd p and for $p = 2$.

Block 6. **Cue.** p odd means $-1 \neq 1$ in $\mathbb{Z}/p\mathbb{Z}$, and scalar matrices are central. **Why natural.** The centre lies inside every centraliser, so a single central element of order 2 settles every case at once. When you need "this happens for all g", look for the reason that does not mention g; the centre is that reason. **Link to the next block.** For $p = 2$ the scalars are only $\{1\}$, the centre is trivial in the relevant sense, and this argument dies, which is precisely the signal that $p = 2$ is the other case rather than a special case of the same.

Block 7. **Cue.** You need an element of $GL_n(\mathbb{F}_2)$ whose centraliser has odd order, so you want the algebra of matrices commuting with it to be as far from a full matrix algebra as possible. **Why natural.** Centralisers measure how much a matrix fails to be generic, and the cleanest small case

is a matrix that generates a field. If $\mathbb{F}_2[g]$ is all of $\mathbb{F}_{2^n}$, then commuting with g upgrades to being linear over the big field, and the space of $\mathbb{F}_{2^n}$ linear endomorphisms of a one dimensional $\mathbb{F}_{2^n}$ space is just $\mathbb{F}_{2^n}$ itself. The identification $\mathbb{F}_2^n \cong \mathbb{F}_{2^n}$ is not a change of viewpoint for its own sake; it is the only way to make "commutes with g" say something about scalars. **Link to the next block.** $|Z(\{g\})| = 2^n - 1$ is odd, the criterion is met, and the case analysis is complete.

Layer 3: WHY

The mathematical truth beneath this problem is that a normal play game whose length is an invariant of the terminal position is not a game at all; it is a parity computation. Grundy theory exists to handle games that decompose into independent sums, and its machinery is wasted here because the position never decomposes. What replaces it is Lagrange's theorem, which controls how the move set can change: the move set is always a subgroup minus a subset, and subgroups of subgroups have orders that divide. Divisibility is a much stronger constraint than inclusion, and it is what makes the parity monotone.

The second truth is about centralisers in GL_n over a finite field. The centraliser of a single matrix is the unit group of the algebra of matrices commuting with it, and that algebra is a field exactly when the characteristic polynomial is irreducible, in which case the centraliser is $\mathbb{F}_{p^n}^{\times}$ of order $p^n - 1$. More generally, if the characteristic polynomial is a product of distinct irreducibles of degrees $d_1, \ldots, d_s$ then the centraliser has order $\prod_i (p^{d_i} - 1)$, which for $p = 2$ is a product of odd numbers whatever the degrees are. So the arithmetic of the whole problem funnels into the single question of whether numbers of the form $p^d - 1$ can be odd, which happens exactly when $p = 2$. That is the reason the answer depends on p and not on n, and you can see it before doing any of the work. It also explains why for $n = 3$, $p = 2$ there are elements with centralisers of order 3 as well as of order 7: the splitting types $(1, 2)$ and (3) both give odd products.

The discernment mechanism has three steps, and it is worth naming them because they transfer. First, when a game's rules constrain moves by compatibility with all previous moves, define the closure of the position and identify it algebraically; a rule you can name has theorems, a rule you cannot name has only cases. Second, ask whether the number of moves in a completed play is determined by the terminal position; if it is, abandon strategy and compute parity. Third, when a parity is controlled by a group order, look for the cheapest universal element forcing that parity: the centre for one direction, and an element generating a field for the other. Train this by replaying the same game on small groups: on any group of odd order the first player wins for free, and on any group with a central involution the second player wins for free, so the only interesting groups are those of even order with centre of odd order.

The examiners nudged you deliberately. They wrote rule (3) as "a player who cannot choose an element loses", which is normal play and is the phrasing that makes parity decisive; had they written a misere rule the analysis would change. They said the answer may depend on n and p, which is a hint that one of the two parameters is a red herring and invites you to find the reason n drops out. And they chose GL_n over $\mathbb{Z}/p\mathbb{Z}$ rather than an abstract group, because in an abstract group you would have no way to build an element with odd centraliser, whereas here the finite field structure hands it to you.

Revolving concepts

Centraliser and centre. For $S \subseteq G$, $Z(S) = \{h : hg = gh \ \forall g \in S\}$ is a subgroup; $Z(G)$ is the centre and lies inside every centraliser; $S \subseteq T$ implies $Z(T) \leq Z(S)$; and $Z(S) = Z(\langle S \rangle)$, so centralisers only see the subgroup generated by S. See Book 1, field: Abstract algebra, topic: centralisers and conjugacy.

Lagrange and Cauchy. Lagrange: the order of a subgroup divides the order of the group, and the order of an element divides the order of the group. Cauchy: if a prime q divides $|H|$ then H

contains an element of order q; for $q = 2$ there is also the one line pairing proof, since pairing each element with its inverse leaves the involutions and the identity unpaired. Both are the workhorses here. See Book 1, field: Abstract algebra, topic: Lagrange and Cauchy.

Order of the general linear group. $|GL_n(\mathbb{F}_p)| = \prod_{i=0}^{n-1}(p^n - p^i) = p^{n(n-1)/2}\prod_{i=1}^{n}(p^i - 1)$. For p odd this is even (already $p^1 - 1$ is even), and for $p = 2$ it is $2^{n(n-1)/2}\prod_{i=1}^{n}(2^i - 1)$, whose odd part is $\prod(2^i - 1)$. See Book 1, field: Matrices and determinants, topic: counting invertible matrices over a finite field.

Finite fields. For every prime p and every $n \geq 1$ there is a field $\mathbb{F}_{p^n}$ with p^n elements, unique up to isomorphism, and its multiplicative group is cyclic of order $p^n - 1$. Equivalently there exists an irreducible polynomial of degree n over $\mathbb{F}_p$, whose companion matrix is an element of $GL_n(\mathbb{F}_p)$ generating a copy of $\mathbb{F}_{p^n}$ inside the matrix algebra. This is the one genuine knowledge gap in the problem: without the existence of $\mathbb{F}_{p^n}$ and the cyclicity of its unit group there is no construction. See Book 1, field: Abstract algebra, topic: finite fields.

Singer cycles and non derogatory matrices. An element of $GL_n(\mathbb{F}_p)$ of order $p^n - 1$ arising as multiplication by a generator of $\mathbb{F}_{p^n}^{\times}$ is called a Singer cycle. More generally, if the minimal polynomial of g equals its characteristic polynomial then the matrices commuting with g are exactly the polynomials in g; the field case above is the special case where that algebra is a field. See Book 1, field: Linear algebra, topic: cyclic and non derogatory matrices.

Normal play, parity and the descending chain. The recursion in this problem is the descending chain $Z(S_0) \geq Z(S_1) \geq \cdots \geq Z(S_N) = S_N$, with the recursion step $Z(S_{t+1}) = Z(S_t) \cap Z(\{g_{t+1}\})$ for the newly chosen g_{t+1}. Generalised statement: play this game on any finite group G. The length of any completed play is $|Z(S_N)|$, so the first player wins if and only if some $g \in G$ has $|Z(\{g\})|$ odd. Two immediate corollaries: if $|G|$ is odd the first player always wins, and if $|Z(G)|$ is even the second player always wins. Solution method for the general recursion: never iterate it, instead find one invariant of the chain (here, the parity of the order) that is monotone, and identify the earliest move that commits it. See Book 1, field: Games and invariants, topic: normal play parity arguments.

Circuit Bank

- **WHEN** a game rule says a move must be compatible with every previous move **DO** define the position as the chosen set S, name the compatibility closure algebraically, and check whether S lies inside its own closure **BECAUSE** a named closure such as a centraliser or a span comes with theorems about its size, and the terminal condition becomes an equation rather than a case list
- **WHEN** the number of moves in a completed normal play game is determined by the terminal position **DO** abandon strategy entirely and compute the parity of that number **BECAUSE** the loser is whoever faces an empty move set, so the winner is a function of the length alone
- **WHEN** a chain of subgroups is forced to descend **DO** apply Lagrange to get divisibility, not merely inclusion, and look for a parity or a prime that can never come back **BECAUSE** divisibility makes coarse invariants monotone, which is what lets you decide the end of the game from its first move
- **WHEN** you need an element of order two inside a group of even order **DO** invoke Cauchy's theorem, or pair each element with its inverse and count the unpaired ones **BECAUSE** this is the standard bridge from a divisibility fact about the order to a concrete element you can actually play
- **WHEN** you need an element of $GL_n(\mathbb{F}_p)$ with the smallest possible centraliser **DO** identify $\mathbb{F}_p^n$ with $\mathbb{F}_{p^n}$ and take multiplication by a generator of the multiplicative group **BECAUSE** commuting with a generator upgrades to linearity over the larger field, and a one dimensional space has only scalar endomorphisms, so the centraliser collapses to $\mathbb{F}_{p^n}^{\times}$

Backtesting

1. First useful cue: rule (2) is a compatibility rule, so the legal moves form the centraliser $Z(S)$ and the position satisfies $S \subseteq Z(S)$.
2. Method the expression suggested: compute the length of the game rather than the strategy, because the game ends at $S = Z(S)$ and therefore lasts exactly $|Z(S_N)|$ moves.
3. Where you would hesitate, and the thought to reinforce: at the converse half of the criterion, where it feels as though Keeta needs a full strategy. She does not. She needs one involution, after which the parity is locked no matter how badly either player plays. Reinforce this: in a parity locked game, a single committing move replaces an entire strategy.
4. The trap the question sets: the invitation to compute Grundy values because the game is impartial. There is no sum decomposition here, so Grundy theory adds nothing and costs everything. The second trap is the phrase "may depend on n and p", which tempts you into an n dependent answer; n cancels because $p^n - 1$ is odd exactly when p is.
5. What makes you recognise it faster next time: the pattern "moves must commute with all previous moves" is the centraliser pattern, and the pattern "who cannot move loses" is the parity pattern. Seeing both in one problem should immediately produce the sentence "the length of the game is the order of a subgroup".
6. The reusable decision rule: when a game's move set is an algebraic closure of the position, compute the terminal condition as an equation and read off the length; then decide the winner with Lagrange.

Mirror drills

1. Play the same game on a finite group G of odd order. Who wins? *Answer:* the first player, always. Every completed play has length $|Z(S_N)|$, which divides $|G|$ and is therefore odd.
2. Play the same game on S_3. Who wins, and how long is the game? *Answer:* the first player, by opening with a 3 cycle σ, since $Z(\{\sigma\}) = \{e, \sigma, \sigma^2\}$ has order 3; the game then lasts exactly three moves. Opening with the identity or a transposition loses, since those centralisers have orders 6 and 2.
3. Show that if the centre of G has even order then the second player wins, and use this to re prove the case $p > 2$. *Answer:* $Z(G) \leq Z(S)$ for every S, so $|Z(S_N)|$ is always even and the game has even length; for $GL_n(\mathbb{Z}/p\mathbb{Z})$ with $p > 2$ the centre contains $-I$ of order two.

12.12 B6. Lipschitz plus integrality forces piecewise linearity

Let $f : [0,1] \to \mathbb{R}$ be a function for which there exists a constant $K > 0$ such that $|f(x) - f(y)| \leq K|x - y|$ for all $x, y \in [0,1]$. Suppose also that for each rational number $r \in [0,1]$, there exist integers a and b such that $f(r) = a + br$. Prove that there exist finitely many intervals $I_1, \ldots, I_n$ such that f is a linear function on each I_i and $[0,1] = \bigcup_{i=1}^{n} I_i$.

Read it out loud

Two hypotheses of completely different type are being pushed together, and the conclusion is a rigidity statement. The first hypothesis is analytic: f is Lipschitz, which is a bound on slopes and nothing else. The second is arithmetic: at every rational point the value of f lies in a lattice, and crucially the lattice depends on the point. The conclusion is that f is piecewise affine with finitely many pieces, that is, that a function satisfying both constraints has almost no freedom at all.

Whenever an analytic bound and an arithmetic quantisation are handed to you together, the intended mechanism is fixed: build a quantity that is simultaneously an integer and small, then conclude it is zero. That single sentence is the problem. Everything else is deciding which quantity, and the answer will be a slope, because slopes are the only thing the Lipschitz hypothesis knows about.

So convert the arithmetic hypothesis into something about denominators immediately. If $r = m/q$ in lowest terms and $f(r) = a + br$ with $a, b \in \mathbb{Z}$, then

$$qf(m/q) = aq + bm \in \mathbb{Z}.$$

In words: the denominator of $f(r)$ divides the denominator of r. That is the usable form, and you should write it inside thirty seconds, because it is the form in which slopes become integers. Indeed, for two rationals $m/q < m'/q'$ the slope of the chord is

$$\frac{f(m'/q') - f(m/q)}{m'/q' - m/q} = \frac{q'f(m'/q') \cdot q - qf(m/q) \cdot q'}{m'q - mq'},$$

whose numerator is an integer. So the slope is an integer as soon as $m'q - mq' = 1$. That condition, not smallness of $|r - r'|$, is the right notion of two rationals being adjacent, and recognising this is the whole discernment content of the problem.

The fields wired in are real analysis (Lipschitz continuity, density plus continuity), elementary number theory (Bezout, Farey neighbours, mediants, the Stern and Brocot refinement), and a small combinatorial termination argument to get from "locally affine" to "finitely many pieces".

Approaches, ranked worst to best

1. **Differentiate almost everywhere.** *Cue:* Lipschitz is the exact hypothesis of Rademacher's theorem. *Circuit:* reduce a regularity claim to a statement about the derivative. You get that f is differentiable almost everywhere with $|f'| \leq K$, and with some work that f' takes integer values at points where you can compute it. It fails, and it is important to know why rather than to feel vaguely unsatisfied: there exist 1 Lipschitz functions with $f' \in \{0,1\}$ almost everywhere that are not piecewise linear. Take a closed nowhere dense $C \subseteq [0,1]$ of positive measure and set $f(x) = \int_0^x \mathbf{1}_{[0,1]\setminus C}$. Then $f' = 1$ on the complement of C and $f' = 0$ at every density point of C, yet f is affine on no interval meeting C in positive measure. An almost everywhere statement is simply too weak; the hypothesis at every rational is much stronger and must be used pointwise.

2. **Prove local linearity at each point, then use compactness.** *Cue:* the conclusion is local plus finite. *Circuit:* cover $[0,1]$ by intervals of linearity and extract a finite subcover. This is the

alternative route recorded in the official solution, using the continued fraction convergents of each irrational x to approximate it by rationals with controlled denominators. It works, and it costs more: you need convergent estimates at every point, and then a separate compactness argument, and the final count of pieces is not explicit.

3. **Interpolate on the Farey sequence and show the interpolants stabilise.** *Cue:* denominators bounded by N give a finite grid. *Circuit:* define f_N to agree with f on the Farey sequence of order N and prove $f_N = f_{N-1}$ once $N > 2K$. This is the official solution, and it is good. It requires the Farey neighbour theorem as an input (consecutive fractions of order N satisfy $m'q - mq' = 1$ and $q + q' > N$), proved by its own induction, and it phrases the key computation in terms of the interpolant rather than in terms of f.

4. **Mediant refinement with a termination bound.** *Cue:* unimodular pairs make chord slopes integers; the mediant is the unique fraction of smallest denominator in between. *Circuit:* split each interval at the mediant until the denominators are large enough that a bounded integer must vanish. The winner, and the cleanest, because it never needs the Farey sequence as an external input: it constructs the right subdivision itself, the induction measure is explicit, and the termination argument is two lines. It also gives, for free, that each affine piece has integer slope and integer intercept.

The ideal solution

Every rational $r \in [0,1]$ is written $r = m/q$ in lowest terms with $q \geq 1$; thus $0 = 0/1$ and $1 = 1/1$. Call an ordered pair $r = m/q < r' = m'/q'$ of rationals in $[0,1]$ a *unimodular pair* if

$$m'q - mq' = 1.$$

Note that $(0/1, 1/1)$ is a unimodular pair. Since f is Lipschitz it is continuous, a fact used only at the very end.

Lemma 12.12.1. *Let (r, r') be a unimodular pair. Then $\gcd(q, q') = 1$, $r' - r = \dfrac{1}{qq'}$, and the mediant*

$$\mu = \frac{m + m'}{q + q'}$$

is in lowest terms, satisfies $r < \mu < r'$, and both (r, μ) and (μ, r') are unimodular pairs.

Proof. Any common divisor of q and q' divides $m'q - mq' = 1$, and $r' - r = (m'q - mq')/(qq') = 1/(qq')$. Any common divisor of $m + m'$ and $q + q'$ divides $(m + m')q - m(q + q') = m'q - mq' = 1$, so the mediant is in lowest terms. Finally

$$(m + m')q - m(q + q') = 1, \qquad m'(q + q') - (m + m')q' = 1,$$

which say exactly that (r, μ) and (μ, r') are unimodular; positivity of these two quantities also gives $r < \mu < r'$. □

Lemma 12.12.2. *For every rational $r = m/q$ in $[0,1]$ we have $qf(r) \in \mathbb{Z}$. Consequently, if (r, r') is a unimodular pair then the chord slope*

$$s(r, r') := \frac{f(r') - f(r)}{r' - r} = qq'\big(f(r') - f(r)\big)$$

is an integer with $|s(r, r')| \leq K$.

Proof. Write $f(r) = a + bm/q$ with $a, b \in \mathbb{Z}$; then $qf(r) = aq + bm \in \mathbb{Z}$. For the second claim, use $r' - r = 1/(qq')$ from Lemma 1 and write

$$qq'\big(f(r') - f(r)\big) = q\big(q'f(r')\big) - q'\big(qf(r)\big) \in \mathbb{Z}.$$

The bound $|s| \le K$ is the Lipschitz hypothesis applied to r and r'. □

Lemma 12.12.3. *Let (r, r') be a unimodular pair and let $\rho = u/v$ in lowest terms satisfy $r < \rho < r'$. Then $v \ge q + q'$, with equality if and only if ρ is the mediant μ.*

Proof. Both $uq - mv$ and $m'v - uq'$ are positive integers, so

$$\rho - r = \frac{uq - mv}{vq} \ge \frac{1}{vq}, \qquad r' - \rho = \frac{m'v - uq'}{vq'} \ge \frac{1}{vq'}.$$

Adding and using $r' - r = 1/(qq')$,

$$\frac{1}{qq'} \ge \frac{1}{vq} + \frac{1}{vq'} = \frac{q + q'}{vqq'},$$

so $v \ge q + q'$. If $v = q + q'$ then both displayed inequalities are equalities, so $uq - mv = 1$; substituting $v = q + q'$ and $m'q - mq' = 1$ gives $uq = m'q + mq$, hence $u = m + m'$ and $\rho = \mu$. □

Lemma 12.12.4. *Let (r, r') be a unimodular pair with $q + q' > 2K$, and let μ be its mediant. Then $f(\mu)$ lies on the chord joining $(r, f(r))$ to $(r', f(r'))$.*

Proof. Write $s = s(r, r')$, $s_1 = s(r, \mu)$, $s_2 = s(\mu, r')$, all integers of absolute value at most K by Lemmas 1 and 2. From Lemma 1,

$$r' - r = \frac{1}{qq'}, \qquad \mu - r = \frac{1}{q(q + q')}, \qquad r' - \mu = \frac{1}{q'(q + q')}.$$

Adding $f(\mu) - f(r)$ and $f(r') - f(\mu)$ gives

$$\frac{s}{qq'} = \frac{s_1}{q(q + q')} + \frac{s_2}{q'(q + q')},$$

and multiplying through by $qq'(q + q')$,

$$s(q + q') = s_1 q' + s_2 q.$$

Put $\delta_1 = s_1 - s$ and $\delta_2 = s_2 - s$, both integers. The displayed identity becomes $\delta_1 q' + \delta_2 q = 0$. Since $\gcd(q, q') = 1$, q divides δ_1; writing $\delta_1 = tq$ with $t \in \mathbb{Z}$ gives $\delta_2 = -tq'$, hence

$$s_1 - s_2 = t(q + q').$$

But $|s_1|, |s_2| \le K$, so $|t|(q + q') \le 2K < q + q'$, forcing $t = 0$. Thus $s_1 = s$, which says precisely that $f(\mu) = f(r) + s(\mu - r)$. □

Proposition 12.12.5. *Let (r, r') be a unimodular pair with $q + q' > 2K$, and let L be the affine function with $L(r) = f(r)$ and $L(r') = f(r')$. Then $f = L$ on $[r, r']$.*

Proof. First we prove $f(\rho) = L(\rho)$ for every rational $\rho \in [r, r']$. If $\rho \in \{r, r'\}$ this holds by definition, so let $\rho = u/v$ in lowest terms with $r < \rho < r'$; by Lemma 3 the integer $d := v - (q + q')$ is nonnegative. We argue by strong induction on d, the statement being quantified over all unimodular pairs with denominator sum exceeding $2K$ simultaneously.

If $d = 0$ then $\rho = \mu$ by Lemma 3, and Lemma 4 gives $f(\mu) = L(\mu)$.

If $d > 0$ then $\rho \neq \mu$. By Lemma 4, $f(\mu) = L(\mu)$. Suppose $r < \rho < \mu$; the case $\mu < \rho < r'$ is identical with the roles of the two ends exchanged. By Lemma 1, (r, μ) is a unimodular pair, with denominator sum $q + (q + q') > 2K$, and the affine function matching f at its two endpoints is L itself, since both $(r, f(r))$ and $(\mu, f(\mu))$ lie on L. Applying Lemma 3 to the pair (r, μ) gives $v \geq q + (q + q')$, so the induction parameter for ρ relative to this new pair is $v - (2q + q') = d - q$, which is nonnegative and strictly smaller than d. The inductive hypothesis therefore gives $f(\rho) = L(\rho)$.

Now f and L are continuous on $[r, r']$ and agree on $\mathbb{Q} \cap [r, r']$, which is dense in $[r, r']$; hence $f = L$ on $[r, r']$. □

Theorem 12.12.6. *There are finitely many closed intervals covering $[0, 1]$ on each of which f is affine.*

Proof. Fix an integer $N \geq 2K$. Build a finite binary tree of unimodular pairs as follows. The root is $(0/1, 1/1)$. A node (r, r') with $q + q' \leq N$ has two children, namely (r, μ) and (μ, r'), which are unimodular pairs by Lemma 1; a node with $q + q' > N$ is a leaf.

The tree is finite. Along any path from the root, the denominator sums form a strictly increasing sequence of positive integers, since the children of a node of sum $\sigma = q + q'$ have sums $\sigma + q$ and $\sigma + q'$ with $q, q' \geq 1$. Every internal node has sum at most N, and the root has sum 2, so no path contains more than $N - 1$ edges. A binary tree of bounded depth is finite.

The closed intervals $[r, r']$ attached to the leaves cover $[0, 1]$, because splitting a node partitions its interval into the two subintervals of its children and the root interval is $[0, 1]$. Each leaf is a unimodular pair with $q + q' > N \geq 2K$, so the Proposition applies to it and f is affine on the corresponding closed interval. Taking $I_1, \ldots, I_n$ to be the leaf intervals completes the proof. □

Remark 12.12.7. The pieces are integral, not merely affine. On a leaf interval, $f = a + bx$ with $b = s \in \mathbb{Z}$ by Lemma 2; moreover $qa = qf(r) - sm \in \mathbb{Z}$ and $q'a = q'f(r') - sm' \in \mathbb{Z}$, and $\gcd(q, q') = 1$, so Bezout gives $a \in \mathbb{Z}$. So the hypothesis "for each rational r there are integers a, b with $f(r) = a + br$" upgrades to a single pair of integers valid on a whole interval, which is the real content of the problem.

Remark 12.12.8. The leaves of the tree are exactly the pairs of consecutive elements of the Farey sequence of order N: every denominator appearing in the tree is the denominator sum of some earlier node and hence at most N, every leaf has $q + q' > N$, and unimodular pairs with $q, q' \leq N < q + q'$ are precisely the consecutive pairs of that Farey sequence. So the refinement tree reconstructs the Farey sequence rather than assuming it, and the number of pieces is $|F_N| - 1$, which is of order N^2, hence of order K^2.

Layer 1: WHAT

Block 1. Rewrite the arithmetic hypothesis in denominator form: $qf(m/q) \in \mathbb{Z}$, that is, the denominator of the value divides the denominator of the point.

Block 2. Ask which pairs of rationals have integer chord slope. Answer: unimodular pairs, because then $r' - r = 1/(qq')$ exactly and the slope is $q(q'f(r')) - q'(qf(r))$.

Block 3. Note that the Lipschitz bound caps that integer: $|s| \leq K$. An integer confined to a bounded range is the raw material of every rigidity argument.

Block 4. Introduce the mediant and compare the two half slopes with the whole slope: $\delta_1 q' + \delta_2 q = 0$, so $s_1 = s + tq$ and $s_2 = s - tq'$ for one integer t.

Block 5. Squeeze: $|s_1 - s_2| = |t|(q + q') \leq 2K$, so once $q + q' > 2K$ the integer t is zero and the mediant sits on the chord.

Block 6. Descend: every rational strictly inside a unimodular pair has denominator at least $q + q'$, with equality only for the mediant, so iterated mediants reach every rational and the quantity $v - (q + q')$ is a well founded induction measure.

Block 7. Close the interval by continuity: f agrees with an affine map on a dense set, hence everywhere.

Block 8. Make the cover finite: refine from $(0/1, 1/1)$ only while $q + q' \leq N$; the denominator sums strictly increase along every branch, so the tree has depth at most $N - 1$ and finitely many leaves.

Juxtaposition. The nominal route reaches for Rademacher because "Lipschitz" is a hypothesis with a famous theorem attached, gets f' integer valued almost everywhere, and then cannot finish, because almost everywhere information cannot see the rationals. The bifurcation point is the choice of what "two nearby rationals" means. The zombie route measures nearness by $|r - r'|$; the ideal route measures it by $m'q - mq' = 1$. Everything downstream follows from that single choice, because unimodularity is exactly the condition that makes $r' - r$ the reciprocal of the product of the denominators and hence makes the slope an integer.

Layer 2: HOW

Block 1. **Cue.** The hypothesis names the integers a and b but never uses them; they depend on r and are otherwise uncontrolled. **Why natural.** Data you cannot control should be eliminated. Multiplying by q removes both a and b and leaves one clean statement about f alone. This is the standard first move whenever a hypothesis is phrased as "there exist integers such that", and it converts an existential statement into a divisibility statement. **Link to the next block.** Now every value $f(r)$ has a known denominator, so differences of values have known denominators, so slopes are computable objects rather than arbitrary reals.

Block 2. **Cue.** A slope is a difference of values divided by a difference of points, and both differences now have denominators you control. **Why natural.** The denominator of $f(r') - f(r)$ divides qq', so the slope is an integer as soon as $r' - r$ equals $1/(qq')$ exactly, and $r' - r = (m'q - mq')/(qq')$ makes that condition literally $m'q - mq' = 1$. You are not choosing unimodularity for elegance; you are solving for the condition that makes the quotient integral. **Link to the next block.** The correct notion of adjacency on $\mathbb{Q} \cap [0, 1]$ is therefore arithmetic, and its combinatorics (mediants, the Stern and Brocot tree) becomes the scaffolding of the whole proof.

Block 3. **Cue.** Lipschitz is a bound and integrality is a quantisation. **Why natural.** This is the engine of the problem, and it should be named before it is used: a bounded integer lies in a finite set, and an integer of absolute value less than 1 is zero. Every rigidity theorem of this shape, from the rational root theorem to Liouville's approximation theorem, runs on the same fuel. **Link to the next block.** So the plan must be to manufacture an integer that the Lipschitz bound forces below 1. The slopes themselves are only bounded by K, which is not small, so you need a difference of slopes.

Block 4. **Cue.** Three collinear conditions and one obvious intermediate point: the mediant is the unique fraction of smallest denominator strictly between r and r'. **Why natural.** If you want to compare the chord over $[r, r']$ with the chords over its two halves, you must split at a point whose denominator you know, and the mediant is the only such point. The resulting identity $s(q + q') = s_1 q' + s_2 q$ is forced; there is no choice in it. **Link to the next block.** The identity says $\delta_1 q' = -\delta_2 q$ with $\gcd(q, q') = 1$, so a single integer parameter t controls both discrepancies. This is where the arithmetic does real work: coprimality converts one linear relation into a complete parametrisation.

Block 5. **Cue.** The two discrepancies are tq and $-tq'$, so their difference is $t(q + q')$, and both slopes are bounded by K. **Why natural.** The parameter t is amplified by $q + q'$, while the analytic bound on it stays fixed at $2K$. Large denominators therefore crush t to zero. This is exactly the manufactured small integer promised in Block 3, and it explains why the threshold in the problem is $2K$ and not K. **Link to the next block.** Once $t = 0$ for all sufficiently deep pairs, the function is pinned on the mediant, and so on every rational reachable by iterated mediants.

Block 6. **Cue.** An induction that must reach every rational in an interval, with no obvious ordering. **Why natural.** Iterating mediants is a recursion, and every recursion needs a well founded measure. Lemma 3 supplies one for free: any rational strictly inside a unimodular pair has denominator at least $q + q'$, so $v - (q + q')$ is a nonnegative integer, and descending into a half interval increases the denominator sum, hence strictly decreases the measure. Never write "and so on by repeated bisection"; name the measure. **Link to the next block.** With the measure in hand the induction is finite for each individual rational, and gives $f = L$ on all rationals of the interval.

Block 7. **Cue.** Two continuous functions agreeing on a dense set. **Why natural.** This is the only place the Lipschitz hypothesis is used qualitatively rather than quantitatively, and it must be used, because the conclusion is about all reals while every hypothesis so far was about rationals. Skipping this line is a real gap, not a formality. **Link to the next block.** It remains only to produce finitely many intervals of the required type, which is a combinatorial question about the refinement, not an analytic one.

Block 8. **Cue.** The Proposition needs $q + q' > 2K$, and the root pair $(0/1, 1/1)$ has $q + q' = 2$. **Why natural.** Refine only where the hypothesis fails, and stop as soon as it holds. Termination is then automatic from the same inequality that drove Block 5: sums strictly increase along a branch and refinement stops above N, so branches have length at most $N - 1$. This is the standard way to convert a local statement into a finite decomposition, and it is what the word "finitely" in the problem is testing. **Link to the next block.** The leaf intervals are the required $I_1, \ldots, I_n$, and as a bonus the leaves turn out to be exactly the Farey intervals of order N.

Layer 3: WHY

The mathematical truth beneath the route is that $\mathbb{Q} \cap [0, 1]$ carries a natural tree structure, the Stern and Brocot tree, in which the children of an interval $[m/q, m'/q']$ are obtained by splitting at the mediant, and in which every interval that appears is unimodular. This tree is not a convenience; it is the unique refinement scheme with the property that the endpoints of every cell have coprime denominators and the cell has length exactly $1/(qq')$. Those two facts are what make chord slopes integral, and integrality is what interacts with the Lipschitz bound. Metric subdivision, say into intervals of length $1/N$, has neither property and is therefore useless here, however natural it looks to an analyst.

The second truth is the quantisation principle. Two independent constraints act on the same quantity: arithmetic says the chord slope is an integer, analysis says it is at most K in absolute value. Neither alone says anything; together they confine the slope to a finite set. Then the mediant identity manufactures a second integer, t, whose analytic bound $|t| \leq 2K/(q + q')$ tends to zero as the denominators grow, and an integer that is forced below 1 is zero. That single mechanism, "a nonzero integer has absolute value at least one", is the load bearing idea in this problem exactly as it is in the rational root theorem, in Liouville's theorem on approximation of algebraic numbers, and in the standard proof that a polynomial taking small integer values on many points is zero.

The discernment mechanism is a two question filter that you should run on any hypothesis pair of this shape. First: what does each hypothesis constrain, and is there a single quantity constrained by both? Here the answer is the chord slope, which is the only thing Lipschitz continuity can see and, after the denominator reformulation, the only thing the arithmetic hypothesis can see. Second: in what index of locality does the arithmetic hypothesis behave well? Not in $|r - r'|$, because the denominator of a rational is not a continuous function of the rational; but unimodular adjacency is exactly the relation under which the arithmetic is clean. Train this by re deriving once, and then never forgetting, the three identities $r' - r = 1/(qq')$, $\mu - r = 1/(q(q + q'))$ and $r' - \mu = 1/(q'(q + q'))$; they are the entire toolkit.

The examiners nudged in two ways. They wrote the arithmetic hypothesis in the awkward form "there exist integers a and b such that $f(r) = a + br$" rather than the clean form "$qf(m/q) \in \mathbb{Z}$", because the translation is the first test. And they asked for finitely many intervals rather than for local linearity, because the finiteness is where the constant K must be used a second time, converting the qualitative statement into a bound on how deep the refinement must go.

Revolving concepts

Lipschitz continuity. $|f(x) - f(y)| \le K|x - y|$ implies uniform continuity and, by Rademacher's theorem, differentiability almost everywhere with $|f'| \le K$. The almost everywhere statement is a trap here: a 1 Lipschitz function can have $f' \in \{0, 1\}$ almost everywhere without being piecewise linear, as the fat Cantor construction above shows. See Book 1, field: Real analysis, topic: Lipschitz and absolutely continuous functions.

Density and continuity. If two continuous functions on an interval agree on a dense subset they agree everywhere. This is the bridge from rational information to real conclusions and must be stated explicitly. See Book 1, field: Real analysis, topic: density arguments.

Unimodular pairs, mediants and the Stern and Brocot tree. For $m/q < m'/q'$ in lowest terms with $m'q - mq' = 1$ one has $\gcd(q, q') = 1$ and $r' - r = 1/(qq')$; the mediant $(m + m')/(q + q')$ is automatically in lowest terms, lies strictly between, and forms a unimodular pair with each endpoint. Starting from $(0/1, 1/1)$ and splitting repeatedly at mediants generates every rational in $(0, 1)$ exactly once; the path spelling out a given rational is its continued fraction expansion in run length form. See Book 1, field: Number theory, topic: Farey fractions and continued fractions.

Farey sequences. F_N is the increasing list of rationals in $[0, 1]$ with denominator at most N. Consecutive elements are precisely the unimodular pairs with $q, q' \le N < q + q'$, and $|F_N| = 1 + \sum_{k \le N} \varphi(k)$, which is asymptotically $3N^2/\pi^2$. In this problem F_N appears as the set of leaves of the refinement tree rather than as an input. See Book 1, field: Number theory, topic: Farey sequences.

Bezout. $\gcd(q, q') = 1$ gives integers x, y with $xq + yq' = 1$, used to upgrade "qa and $q'a$ are integers" to "a is an integer", and used implicitly whenever coprimality converts a divisibility into a parametrisation. See Book 1, field: Number theory, topic: Bezout and linear Diophantine equations.

The bounded integer principle. If a quantity is an integer and is proved to satisfy $|t| < 1$, then $t = 0$; if it is an integer bounded by K then it takes at most $2K + 1$ values. See Book 1, field: Number theory, topic: integrality arguments.

The recursion, generalised. The refinement is the recursion $I = [r, r'] \mapsto \{[r, \mu], [\mu, r']\}$ on unimodular pairs, with associated data $\sigma(I) = q + q'$ satisfying $\sigma(\text{child}) = \sigma(I) + q$ or $\sigma(I) + q'$. Its general solution method has two halves that recur everywhere. To prove a statement for all rationals in I, induct on the nonnegative integer $v - \sigma(I)$, which strictly decreases as you descend, by Lemma 3. To prove finiteness of a refinement, exhibit a strictly increasing integer quantity along each branch that is bounded by the stopping rule; the depth bound then follows and with it the leaf count. The same pair of arguments settles any statement of the form "a function on $\mathbb{Q} \cap [0, 1]$ whose values have denominators dividing those of their arguments and whose slopes are bounded is piecewise affine", for instance with the Lipschitz hypothesis replaced by a bound on second differences. See Book 1, field: Number theory, topic: Stern and Brocot induction.

Circuit Bank

- **WHEN** a hypothesis reads "for each x there exist integers a, b with $f(x) = a + bx$" **DO** clear denominators to get one uncontaminated statement, here $qf(m/q) \in \mathbb{Z}$ **BECAUSE** the existential integers are uncontrolled and cannot be used, whereas a divisibility statement about the value is usable at every later step

- **WHEN** you have an analytic bound and an arithmetic quantisation on the same object **DO** build the quantity that is simultaneously an integer and small, and force it to be zero **BECAUSE** a nonzero integer has absolute value at least one, which is the only mechanism by which soft analytic bounds produce exact algebraic conclusions
- **WHEN** you must move between nearby rationals and the arithmetic must stay clean **DO** use unimodular pairs and mediants, not equally spaced points **BECAUSE** unimodularity is exactly the condition making $r' - r = 1/(qq')$, which is exactly the condition making chord slopes integral
- **WHEN** a claim must be proved for every rational in an interval by repeated subdivision **DO** name an explicit nonnegative integer measure that strictly decreases, here $v - (q + q')$, and induct on it **BECAUSE** "repeat this process" is not a proof; a well founded measure converts an informal descent into a finite induction and also tells you exactly when the descent stops
- **WHEN** a local property must be upgraded to a finite decomposition **DO** refine only while a stated inequality fails, and show a bounded integer strictly increases along each branch **BECAUSE** that is what makes the tree finite, and the word "finitely" in the question is precisely the request for this argument

Backtesting

1. First useful cue: the arithmetic hypothesis names uncontrolled integers, so clear denominators and read it as "$qf(m/q) \in \mathbb{Z}$".
2. Method the expression suggested: compute chord slopes between unimodular pairs, since those are integers bounded by K, and then compare a chord with its two mediant halves.
3. Where you would hesitate, and the thought to reinforce: at the choice of which rationals count as adjacent. Reinforce this: on $\mathbb{Q}$, adjacency is arithmetic, not metric; two rationals are close for the purposes of this problem when $m'q - mq' = 1$, however far apart they are on the line.
4. The trap the question sets: Rademacher's theorem. Lipschitz is exactly its hypothesis, so the reflex fires, and it leads to an almost everywhere statement that cannot be upgraded, since a 1 Lipschitz function with derivative in $\{0, 1\}$ almost everywhere need not be piecewise linear.
5. What makes you recognise it faster next time: the joint appearance of a slope bound and a denominator condition. That pair means "integer forced to be small", and the only question left is which combination of the data is that integer.
6. The reusable decision rule: when arithmetic and analysis constrain the same quantity, subdivide along the Stern and Brocot tree until the analytic bound beats one, then propagate by induction and close by density.

Mirror drills

1. Suppose $g : [0, 1] \to \mathbb{R}$ is continuous and $g(r) \in \mathbb{Z}$ for every rational r. Show g is constant. *Answer:* $\mathbb{Z}$ is closed and $\mathbb{Q}$ is dense, so $g([0, 1]) \subseteq \mathbb{Z}$; a continuous image of a connected set is connected, and a connected subset of $\mathbb{Z}$ is a point. No Lipschitz hypothesis is needed.
2. In the problem above, suppose additionally $K < 1$. Show f is a constant integer. *Answer:* the root pair $(0/1, 1/1)$ already has $q + q' = 2 > 2K$, so the Proposition applies to the whole of $[0, 1]$; the slope is an integer of absolute value less than 1, hence zero, and $f \equiv f(0) \in \mathbb{Z}$.
3. Prove that if $m/q < m'/q'$ are consecutive in the Farey sequence F_N then $q + q' > N$. *Answer:* their mediant has denominator $q + q'$ and lies strictly between them, so it is not in F_N; by Lemma 3 the smallest denominator strictly between them is exactly $q + q'$, so $q + q' > N$.

Chapter 13

Putnam 2013

13.1 A1. Icosahedron face labels force a repeat

Recall that a regular icosahedron is a convex polyhedron having 12 vertices and 20 faces, the faces congruent equilateral triangles. On each face of a regular icosahedron is written a nonnegative integer such that the sum of all 20 integers is 39. Show that there are two faces that share a vertex and have the same integer written on them.

Read it out loud

Say the data back before touching a pencil to it: twenty faces, one nonnegative integer on each, total 39, and you must prove a coincidence, two faces at a common corner sharing a value. A fixed total attached to a claim of forced repetition is the signature of a counting argument by contradiction: you do not construct the pair, you suppose it is absent and squeeze the total until it cannot fit.

The only geometry you need is the incidence pattern, not lengths or angles. Within thirty seconds you should have written down the two numbers that describe it: three vertices per face, free, since a face is a triangle, and less obviously, five faces per vertex. That second number comes from Euler's formula, $V - E + F = 2$ together with $3F = 2E$ for a triangulated solid, giving $V = 12$, $E = 30$, $F = 20$, so every vertex has degree $2E/V = 5$.

Three and five are the whole field embedded in the question: solid geometry reduced to a bipartite incidence structure between twelve vertices and twenty faces. A local relation of size five meeting a global total of twenty across that structure is exactly what a double count is for.

Approaches, ranked worst to best

1. **search the vertex figures by hand for the repeated pair.** *Cue:* the conclusion promises a specific pair exists. *Circuit:* none, this is zombie maths. Twelve vertices with five faces each give no symmetry to cut the casework, and the number 39 never enters the search in any structural way. It does not terminate inside an exam hour, and it never becomes a proof, only a hunt.

2. **bound how often a single label can repeat.** *Cue:* the conclusion is about a repeated label, so bound the label directly. *Circuit:* maximum size of a pairwise vertex disjoint family of faces. If no two same labelled faces may share a vertex, five faces carrying one label would need $5 \times 3 = 15$ distinct vertices against only 12 available, so every label appears on at most four faces; twenty faces then need at least five distinct labels, forcing a minimum total of $4(0 + 1 + 2 + 3 + 4) = 40 > 39$. A genuine proof, but it pays an extra step to pin down the cheapest label multiset, a step the winning route below never needs.

3. **sum the labels around each vertex and compare to the global total.** *Cue:* the conclusion names the vertex as the site of the coincidence. *Circuit:* double counting incidences between two levels of a polyhedron. Negate the conclusion, bound the five distinct labels at each vertex below by $0 + 1 + 2 + 3 + 4 = 10$, sum that bound over the twelve vertices, and compare the result against the same sum evaluated the other way, by counting each face three times. One inequality, no optimisation to justify. This is the route the problem was built for.

The ideal solution

Suppose, for contradiction, that no two faces sharing a vertex carry the same integer. Fix a vertex v. Exactly five faces meet at v: with $V = 12$, $E = 30$, $F = 20$ from Euler's formula and $3F = 2E$, the sum of all vertex degrees is $2E = 60$, and by the regularity of the solid every vertex carries the same degree, so each of the twelve vertices has degree $60/12 = 5$. By assumption the five faces at v carry five pairwise distinct nonnegative integers, so, sorted increasingly, their labels are termwise at least $0, 1, 2, 3, 4$, and their sum is at least $0 + 1 + 2 + 3 + 4 = 10$.

Sum this bound over all twelve vertices:

$$\sum_{v} \Big(\text{sum of the labels of the faces meeting } v\Big) \;\geq\; 12 \times 10 = 120.$$

Evaluate the left side exactly by counting the other way. Every face is a triangle, so it meets exactly three vertices, and its label is counted exactly three times as v ranges over all twelve vertices, once per corner. Writing $T = 39$ for the total of all twenty face labels,

$$\sum_{v} \Big(\text{sum of the labels of the faces meeting } v\Big) = 3T = 117.$$

So $117 \geq 120$, false. The assumption fails: there exist two faces sharing a vertex with the same integer written on them. ■

Layer 1: WHAT

Block 1. Negate the conclusion into a per vertex distinctness statement, and extract the incidence numbers three and five from Euler's formula. Block 2. Bound the minimum sum of five distinct nonnegative integers at a single vertex: at least 10. Block 3. Sum that local bound over all twelve vertices: at least 120. Block 4. Evaluate the same total the other way, face by face, using that each face is counted three times: exactly 117. Block 5. Collide $117 \geq 120$, false.

The nominal route (approach 1) hunts for the pair directly and never produces a number to set against 39. The bifurcation point against it sits at Block 1: the moment "two faces agree" is negated into "every vertex's five faces are pairwise distinct", the problem stops being a search and becomes an arithmetic bound, because a distinctness statement about nonnegative integers has a computable minimum sum attached to it for free. Against approach 2, the bifurcation is which object to sum first: summing by label needs an extra extremal step to find the cheapest multiset; summing by vertex, the object the conclusion itself names, needs nothing beyond $0 + 1 + 2 + 3 + 4 = 10$.

Layer 2: HOW

Block 1. **Cue.** The conclusion is phrased as two faces that share a vertex, naming the vertex, not the face, as the site of the coincidence. **Why natural.** The object you sum local data over should always be the object the conclusion names. You need the degree of a vertex, five, because that is the size of the distinct set you are about to bound. **Link to the next block.** Once every vertex sees five faces, the negated conclusion has an immediate numerical consequence.

Block 2. **Cue.** Five pairwise distinct nonnegative integers, no upper bound stated. **Why natural.** Nonnegative integers with no other constraint have exactly one extremal fact worth knowing: sorted, k distinct such integers are termwise at least $0, 1, \ldots, k-1$, because nothing smaller fits. This is the generic minimum $\binom{k}{2}$, and it should fire the instant "distinct" meets "nonnegative integers" with a sum nearby. **Link to the next block.** A per vertex minimum of 10 is only useful once aggregated, since the problem's one numerical fact is a sum over all twenty faces, not over one vertex.

Block 3. **Cue.** Twelve vertices, each contributing at least 10. **Why natural.** Summing a true inequality over a finite index set preserves it; naming this explicitly turns twelve local facts into one global fact. **Link to the next block.** You now have a global lower bound, 120, to set against the global total the problem handed you, 39.

Block 4. **Cue.** The sum just built is a sum over vertices of a sum over incident faces, secretly a sum over incident (vertex, face) pairs. **Why natural.** That same set of pairs sums the other way too: fix a face and ask how many vertices see it. Because a face is a triangle, the answer is always three, so every face's label contributes exactly three times. **Link to the next block.** The vertex sum, computed this second way, is exactly $3 \times 39 = 117$.

Block 5. **Cue.** A lower bound of 120 from Block 3 against an exact value of 117 from Block 4. **Why natural.** A quantity cannot be at least 120 and equal 117. The gap is not incidental: the setter chose 39 so that 3×39 sits three below 12×10, tight enough that no weaker bound would have closed it. **Link to the next block.** No further block; the contradiction closes the proof.

Layer 3: WHY

The route works because a triangulated closed surface offers two dual ways to sum over its own incidence structure, by vertex or by face, both counting exactly the same set of (vertex, face) pairs. Whenever a fixed global quantity sits on a structure that also carries a local adjacency relation, that duality is free, the same mechanism as the handshake lemma, $\sum_v \deg(v) = 2E$, lifted one dimension from edges and vertices to faces and vertices.

The discernment mechanism: the moment a problem gives one fixed global number and asks for a local coincidence, ask what quantity you can compute two ways, once by summing local bounds and once by summing the global data through the same incidences. If the answer is not obvious, sum the negated conclusion's consequence over exactly the object the conclusion names. The examiners nudged you here by giving the total, 39, no other role in the problem beyond being compared against a bound you must build, and by tuning the gap to three, tight enough to rule out a lazier bound (bounding by four distinct values instead of five, for instance, only reaches $4 \times 6 = 24$ against eleven, and does not close).

Revolving concepts

Double counting. Definition: when a finite incidence relation connects two finite sets X and Y, the total number of incident pairs can be summed from X's side or from Y's side, and the two totals agree. Orbiting results: the handshake lemma, Euler's formula $V - E + F = 2$, and the identity $\sum_f (\text{vertices of } f) = \sum_v (\text{faces at } v)$ used here. See Book 1, field: Combinatorics, topic: double counting and incidence structures.

Extremal sum of distinct nonnegative integers. Definition: k pairwise distinct nonnegative integers sum to at least $\binom{k}{2}$, with equality only for $\{0, 1, \ldots, k-1\}$. The single fact that turns "distinct" into a number. See Book 1, field: Combinatorics, topic: extremal counting.

Regular polyhedron combinatorics. Definition: for a triangulated closed polyhedral surface, $V - E + F = 2$ with $3F = 2E$ pins the combinatorics down once V or F is known, and regularity forces every vertex to degree $2E/V$. See Book 1, field: Geometry, topic: polyhedral combinatorics and Euler's formula.

Both ranked approaches above are instances of one general threshold, worth stacking once since it recurs on every fixed total, forced coincidence problem: if n labelled objects split into m overlapping groups of size t, each object in exactly d groups, and the total of all labels is T, two objects in a common group are forced to share a label whenever $T < \dfrac{mt(t-1)}{2d}$. Here $n = 20$, $m = 12$, $t = 5$, $d = 3$, threshold $\dfrac{12 \times 5 \times 4}{2 \times 3} = 40$, and the given total sits one below it. Writing this once with letters is what lets you recognise the dodecahedron and octahedron versions on sight.

Circuit Bank

- **WHEN** a fixed global sum is given and you must prove two local, adjacent objects share a value **DO** negate the conclusion, bound the minimum sum of a maximal set of pairwise distinct local values, and sum that bound over the whole structure to compare against the given total **BECAUSE** negation turns distinct into a computable minimum, and only a summed minimum set against a summed exact value makes a single fixed total load bearing
- **WHEN** you need the minimum possible sum of k pairwise distinct nonnegative integers **DO** write $0 + 1 + \cdots + (k-1) = \binom{k}{2}$ immediately, without rederiving it **BECAUSE** any k distinct nonnegative integers, sorted, are termwise at least $0, 1, \ldots, k-1$
- **WHEN** a polyhedron's incidence numbers, faces per vertex and vertices per face, are not stated outright **DO** extract them from $V - E + F = 2$ plus the degree sum $2E = \sum \deg(v)$, using regularity to divide evenly **BECAUSE** most polyhedral counting problems are unusable until these two numbers are known, and deriving them costs three lines, not a guess
- **WHEN** a counting inequality closes with an uncomfortably small gap between the two sides **DO** trust the gap was chosen deliberately and look for exactly the bound producing it, rather than a looser bound that will not close **BECAUSE** setters calibrate constants so the natural bound barely fails, and a small nonzero gap is itself a sign you found the intended route

Backtesting

1. First useful cue: the conclusion names the vertex, two faces that share a vertex, telling you which object to sum local data over.
2. Method the expression suggested: a fixed global total plus a local adjacency claim suggested double counting before any specific number was examined.
3. Where you would hesitate, and the thought to reinforce: choosing between summing by label multiplicity or by vertex; reinforce that summing over the object the conclusion names is shorter, since it needs no auxiliary optimisation.
4. The trap the question sets: the number 39 looks arbitrary until you compute $3 \times 39 = 117$ against $12 \times 10 = 120$; stopping before that numerical comparison hides why 39 was chosen at all.
5. What makes you recognise it faster next time: a solid described purely by face count, vertex count and a fixed label total, with no length or angle used anywhere, tells you the problem lives entirely in the incidence structure.
6. The reusable decision rule: fixed total plus a local repetition claim on an incidence structure means negate, bound the local minimum, sum, and compare against the exact global value from counting the same incidences the other way.

Mirror drills

1. A regular dodecahedron, 12 pentagonal faces, 20 vertices, each vertex meeting exactly 3 faces, carries a nonnegative integer on each face, total S. Find the largest S that still forces two faces sharing a vertex to carry the same integer. *Answer:* each vertex bound is $0 + 1 + 2 = 3$ over 20 vertices, at least 60; each face is counted 5 times, so $5S \geq 60$ needs $S \geq 12$ to escape, hence every $S \leq 11$ forces the repeat.
2. A regular octahedron, 8 triangular faces, 6 vertices, each vertex meeting exactly 4 faces, carries a nonnegative integer on each face, total S. Find the threshold. *Answer:* each vertex bound is

$0+1+2+3=6$ over 6 vertices, at least 36; each face is counted 3 times, so $3S \geq 36$ needs $S \geq 12$ to escape, hence $S \leq 11$ forces the repeat, matching $\frac{mt(t-1)}{2d} = \frac{6\times4\times3}{2\times3} = 12$.

3. Twelve committees of five people are drawn from twenty people, each person on exactly three committees; every person gets a nonnegative integer score, total 39. Show two people on a common committee share a score. *Answer:* the identical structure with committee in place of vertex and person in place of face, the same double count gives $117 < 120$.

13.2 A2. Injectivity of the minimal square completion map

Let S be the set of all positive integers that are not perfect squares. For n in S, consider choices of integers $a_1, a_2, \ldots, a_r$ such that $n < a_1 < a_2 < \cdots < a_r$ and $n \cdot a_1 \cdot a_2 \cdots a_r$ is a perfect square, and let $f(n)$ be the minimum of a_r over all such choices. For example, $2 \cdot 3 \cdot 6$ is a perfect square, while $2 \cdot 3$, $2 \cdot 4$, $2 \cdot 5$, $2 \cdot 3 \cdot 4$, $2 \cdot 3 \cdot 5$, $2 \cdot 4 \cdot 5$, and $2 \cdot 3 \cdot 4 \cdot 5$ are not, and so $f(2) = 6$. Show that the function f from S to the integers is one to one.

Read it out loud

Strip the dressing off first. Underneath, an integer k is a perfect square exactly when every prime in its factorisation occurs to an even power, so "the product of these integers is a perfect square" is a parity statement, a vanishing sum, once you track each integer by the exponents of its primes read modulo two. That reading is not needed to solve the problem, but it explains why the problem is solvable at all: perfect squares are closed under multiplication, and closure under an operation is the one thing every proof below leans on.

The command term is minimum. $f(n)$ is not a value you compute from a formula, it is defined as the smallest top term over an entire family of valid completions of n into a square. Whenever a quantity is handed to you as a minimum over a family, and you are asked to prove a property of it, the property is never going to fall out of algebra on $f(n)$ alone, because you have no closed form for f; the worked example already warns you of this, $f(2) = 6$ has no visible pattern to extrapolate from a single data point. The only lever a minimum gives you for free is this: if you can build a valid member of the family whose top term is smaller than the claimed minimum, you have a contradiction. That is the whole architecture you should have written down within the first thirty seconds: to prove f one to one, suppose $f(n) = f(m)$ for $n \neq m$, and manufacture, from that coincidence, a completion of the smaller of the two with a strictly smaller top term than the one you assumed was minimal.

The second cue sits in the hypothesis itself: you are handed two separate instances of the same closed-under-multiplication property, one for n and one for m. Two instances of an identical algebraic hypothesis are an invitation to combine them by the operation they are instances of.

Approaches, ranked worst to best

1. **hunt for a closed formula for f, or assume monotonicity.** *Cue:* a single worked value, $f(2) = 6$, tempts you to look for a pattern. *Circuit:* pattern extrapolation from one data point. There is no such formula to find. The remark attached to the official solution calls the behaviour of f erratic, and no argument for injectivity can rest on an order relationship between $f(n)$ and $f(m)$ that is never established. Every hour spent computing $f(3), f(5), f(6), \ldots$ by hand looking for structure is ink spent on a route that was never going to close.

2. **reformulate every integer as its squarefree kernel's exponent vector over $\mathbb{F}_2$, and argue with linear algebra.** *Cue:* "product is a perfect square" is a vanishing sum of parity vectors. *Circuit:* closure of a vanishing sum under vector addition, cancellation from $w + w = 0$. This is the honest underlying structure and it produces a correct proof: two vanishing sums, added, still vanish, and a vector appearing twice cancels itself. It costs more ink than it needs to, though, because you must first set up the map from integers to $\mathbb{F}_2^{(\text{primes})}$, verify it is a homomorphism, and translate "perfect square" into "kernel element" before you can say anything, machinery the next approach gets for free from a single line about exponents.

3. **multiply the two witnessing products together and cancel every repeated factor.** *Cue:* two hypotheses of the identical shape, product is a perfect square, sitting side by side. *Circuit:* closure of perfect squares under multiplication, plus a one line valuation lemma for cancellation.

Multiply the witnessing product for n by the witnessing product for m: still a perfect square. The two top terms are forced equal by $f(n) = f(m)$, so they are guaranteed to be among the values that repeat, and cancelling repeats in pairs preserves the perfect square property by a single valuation check, no vector space needed. What survives is a strictly smaller completion of n. This is the route the problem was built for.

The ideal solution

Suppose, for contradiction, that $f(n) = f(m)$ for some $n, m \in S$ with $n \neq m$; without loss of generality $n < m$. Let $n < a_1 < \cdots < a_r$ witness $f(n)$, so $n\,a_1 \cdots a_r$ is a perfect square and $a_r = f(n)$ is minimal among all such top terms for n; likewise let $m < b_1 < \cdots < b_s$ witness $f(m)$, with $m\,b_1 \cdots b_s$ a perfect square and $b_s = f(m)$ minimal for m. Since $r, s \geq 1$ (an empty product would leave n, respectively m, itself a perfect square, contrary to $n, m \in S$), we have $a_r \geq a_1 > n$ and $b_s \geq b_1 > m$. Write $M = a_r = b_s$ for the common value forced by the hypothesis $f(n) = f(m)$; then $M > m > n$.

Consider the product of the two witnessing relations,

$$N \;=\; \big(n\,a_1 \cdots a_r\big)\big(m\,b_1 \cdots b_s\big),$$

a product of two perfect squares, hence itself a perfect square. Use repeatedly the following one line fact: if $N = v^2 N'$ for a positive integer v and N is a perfect square, then N' is a perfect square, because for every prime p the exponent $v_p(N) = 2v_p(v) + v_p(N')$ is even, so $v_p(N')$ is even too. The top terms a_r and b_s are both equal to M and appear as literal factors of N, so $N = M^2 \cdot N_1$ where N_1 is the product of the remaining $r + s$ factors $n, a_1, \ldots, a_{r-1}, m, b_1, \ldots, b_{s-1}$; by the fact just stated, N_1 is a perfect square. If any further value repeats within this remaining list, for instance some $a_i = b_j$ with $i < r, j < s$, or conceivably m coinciding with some a_i, cancel that pair too, by the same fact, and continue until the surviving multiset D consists of pairwise distinct positive integers whose product is a perfect square.

Two facts about D finish the proof. First, $n \in D$: n is strictly smaller than every other original factor ($n < a_1 \leq \cdots$, and $n < m < b_1 \leq \cdots$), so n is never the larger element of a cancelled pair and is never removed. Second, every element of $D \setminus \{n\}$ is strictly between n and M: each is one of $a_1, \ldots, a_{r-1}, m, b_1, \ldots, b_{s-1}$, all of which lie strictly below M (the unique largest value of the original multiset of $r + s + 2$ factors, since $a_r = b_s = M$ dominates every a_i, b_j, and exceeds both n and m), while M itself has been cancelled out of D entirely.

If $D = \{n\}$, its product is n itself, forced to be a perfect square by the cancellation fact, contradicting $n \in S$ outright. Otherwise sort $D \setminus \{n\}$ increasingly as $a'_1 < \cdots < a'_t$; then $n < a'_1 < \cdots < a'_t < M$ and $n\,a'_1 \cdots a'_t$, being the product of D, is a perfect square. This is a valid completion of n with top term $a'_t < M = f(n)$, contradicting the minimality of $f(n)$. Either way the assumption $f(n) = f(m)$, $n \neq m$, is impossible, and f is one to one. ■

Layer 1: WHAT

Block 1. Read "minimum" as an extremal-contradiction architecture: suppose $f(n) = f(m)$ for $n < m$, and commit to manufacturing a smaller completion of n. Block 2. Multiply the two witnessing products; the result is a perfect square because perfect squares are closed under multiplication. Block 3. Identify the one forced coincidence the hypothesis actually supplies, the two top terms are literally equal, so they repeat inside the combined product. Block 4. Cancel every repeated value, not only the engineered one, using a one line valuation lemma, leaving a product of distinct integers that is still a perfect square. Block 5. Read off the extremes of what survives, minimum n, maximum strictly below M, and recognise this as a smaller completion of n, contradicting minimality.

The nominal route, formula hunting, never reaches a comparison between $f(n)$ and $f(m)$ at all, because it tries to pin down f itself rather than use the one structural fact the definition guarantees.

The bifurcation point sits at Block 1: the instant you stop trying to compute f and instead ask what a violation of minimality would look like, the problem becomes constructive rather than exploratory. Against the vector space approach, the bifurcation is representation only, both routes cancel a repeated coincidence to shrink a witness; working with the integers directly and a one line valuation check reaches the same cancellation without first building the homomorphism.

Layer 2: HOW

Block 1. **Cue.** $f(n)$ is defined as a minimum over a family, and the target claim, injectivity, is a property of that minimum, not its value. **Why natural.** Minimality is inert until you build a competitor; the only proof technique that uses a minimum definition directly is contradiction via a smaller witness, because no formula for f is available to reason about algebraically. **Link to the next block.** To build a competitor for n, you need to use the assumed coincidence $f(n) = f(m)$ together with the witnessing data for m, not n alone.

Block 2. **Cue.** Two hypotheses of the identical shape, a product of integers is a perfect square, one for n and one for m. **Why natural.** Perfect squares are closed under multiplication, so two instances of the same closed property combine for free; this is the natural way to bring two pieces of given structure into contact with each other. **Link to the next block.** The combined product is one large perfect square containing every original factor from both sequences, including both top terms.

Block 3. **Cue.** $f(n) = f(m)$ says the two top terms a_r, b_s are the same number, not merely that they are equal in size by coincidence, they are one number playing two roles. **Why natural.** This is the one fact the hypothesis $f(n) = f(m)$ actually contributes beyond two independent square-product facts, so it has to be what the rest of the proof leans on; a value appearing as a literal factor twice inside a product is exactly the situation a cancellation lemma wants. **Link to the next block.** Cancelling that repeated value out of the perfect square, by the valuation fact, produces a strictly smaller perfect square built from the remaining factors.

Block 4. **Cue.** Beyond the engineered repeat at the top, the remaining list $(n, a_1, \ldots, a_{r-1}, m, b_1, \ldots, b_{s-1})$ may hold further coincidental repeats. **Why natural.** The cancellation lemma does not care why two factors are equal, only that they are, so leaving any repeat unresolved keeps D from being the strictly increasing sequence the definition of f requires. **Link to the next block.** After exhausting every repeat, D is a set of pairwise distinct positive integers whose product is a perfect square, ready to be read as a candidate completion.

Block 5. **Cue.** D contains n as its minimum (nothing else was ever small enough to be n) and every other surviving value below M (the unique original maximum, now cancelled away). **Why natural.** This is precisely the data the definition of $f(n)$ asks for: a strictly increasing sequence starting above n whose product with n is a perfect square, only with a top term smaller than the value you assumed was minimal. **Link to the next block.** There is no further block: $f(n)$ cannot be M and also have a smaller completion, so the assumed coincidence is impossible.

Layer 3: WHY

The reason the multiply-and-cancel move is available at all is that perfect squares are the kernel of a homomorphism: send each positive integer k to the vector of its prime exponents read modulo two, and k is a perfect square exactly when this vector is zero. Multiplication of integers becomes addition of vectors under this map, and addition over $\mathbb{F}_2$ is its own inverse, a vector added to itself is zero, which is exactly why a value repeated in the combined product can be struck out without disturbing the perfect square property. You never need to name this vector space to run the proof,

because the one line valuation lemma delivers the same cancellation directly on the integers, but recognising the vector space underneath is what tells you, before you have written a single line, that cancellation will work here, rather than having to discover it by trial.

The discernment mechanism for reaching for this move: whenever a problem hands you two hypotheses of the identical algebraic shape, closed under some operation (a product that is a perfect square, a sum with fixed parity, a linear combination that vanishes), and asks you to relate the two instances, combine them by that operation and look for what must repeat as a consequence of whatever equality the problem's hypothesis forces. Here the forced equality was handed to you directly, $f(n) = f(m)$ makes $a_r = b_s$ literally, so the repeat you need is not something you search for, it is guaranteed the moment you accept the hypothesis you are trying to contradict. The setters chose to define f as a minimum, rather than asking you to compute it, precisely so that this architecture, and no other, would be the one that closes; the worked example $f(2) = 6$ exists to stop you from hunting for a formula before you have exhausted the structural route.

Revolving concepts

Squarefree kernel and the $\mathbb{F}_2$ reading of perfect squares. Definition: every positive integer k factors uniquely as $k = u^2 d$ with d squarefree, and k is a perfect square exactly when the exponent of every prime in k is even; recording those exponents modulo two turns multiplication of integers into vector addition over $\mathbb{F}_2$, with perfect squares as the zero vector. See Book 1, field Number theory, topic squarefree decomposition and quadratic residues.

p-adic valuation and the cancellation lemma. Definition: $v_p(k)$ is the exponent of the prime p in k, valuations are additive over products, and k is a perfect square iff $v_p(k)$ is even for every p; consequently if v^2 divides a perfect square N exactly, N/v^2 is again a perfect square. This one line fact is the entire engine of the cancellation step. See Book 1, field Number theory, topic p-adic valuations.

Extremal choice via a minimality contradiction. Definition: to prove a property of a quantity defined as the least (or greatest) member of a family satisfying some condition, assume the property fails and construct, from that failure, a strictly smaller (or larger) member of the family, contradicting the defining extremal property. This is the master architecture of the whole problem and recurs whenever a definition contains the word minimum or maximum. See Book 1, field Number theory, topic extremal principle and well ordering.

Closure of perfect squares under multiplication. Definition: the product of two perfect squares is a perfect square, since exponents add and the sum of two even numbers is even. A one sentence fact, but it is the only justification needed for combining the two witnessing relations in the first place, and it is worth naming explicitly rather than treating as obvious, since the whole proof is an exploitation of exactly this closure. See Book 1, field Number theory, topic multiplicative structure of the integers.

Quadratic sieve and factor bases, for context rather than necessity. Definition: integer factoring algorithms search for subsets of a fixed factor base whose product is a perfect square, by exactly the linear algebra over $\mathbb{F}_2$ described above; the source solution's own remark points here directly. Recognising the connection is not required for this proof, but it tells you the technique you have just installed is not a one-off competition device, it is the working method behind a real factoring algorithm. See Book 1, field Number theory, topic quadratic sieve.

Circuit Bank

- **WHEN** a quantity is defined as the minimum (or maximum) over a family of valid constructions, and you must prove a property of it **DO** assume the property fails and build, from that failure, a strictly smaller (or larger) member of the family **BECAUSE** a minimum is otherwise inert, it only becomes usable once a competitor exists to violate it

- **WHEN** you are given two separate instances of the same closed-under-an-operation hypothesis and must relate them **DO** combine the two instances by that operation and cancel whatever the problem's hypothesis forces to repeat **BECAUSE** closure guarantees the combination still satisfies the hypothesis, and a forced repeat is exactly what a cancellation argument needs to produce something strictly smaller
- **WHEN** you must justify that removing a repeated factor from a perfect square leaves a perfect square **DO** check it with one line of valuations, $v_p(N) = 2v_p(v) + v_p(N')$, rather than reaching for heavier machinery **BECAUSE** evenness of $v_p(N)$ and of $2v_p(v)$ forces evenness of $v_p(N')$ for every prime, which is the entire content of what needs proving
- **WHEN** a competition remark or a single worked example suggests a function has no closed form **DO** abandon formula hunting immediately and ask what structural property, closure, minimality, symmetry, the definition actually guarantees **BECAUSE** ink spent guessing at a nonexistent pattern is ink unavailable for the structural argument that was always going to be the real route

Backtesting

1. First useful cue: the word minimum inside the definition of $f(n)$, flagging an extremal-contradiction proof before any number theory is even needed.
2. Method the expression suggested: two instances of product is a perfect square suggested multiplying them together, since perfect squares are multiplicatively closed.
3. Where you would hesitate, and the thought to reinforce: justifying that cancelling a repeated factor preserves the perfect square property; reinforce the one line valuation check rather than reaching for a heavier vector space argument.
4. The trap the question sets: assuming the only repeat you need to handle is the engineered one, $a_r = b_s$, and forgetting that other coincidental repeats among the remaining factors must also be cancelled before D is genuinely a strictly increasing witness.
5. What makes you recognise it faster next time: any definition of the form let $f(n)$ be the minimum of such that, attached to a request to prove a global property (injectivity, surjectivity, an inequality) of f, rather than to compute a value.
6. The reusable decision rule: two hypotheses of an identical multiplicatively (or additively) closed shape, tied by an equality the problem's own hypothesis forces, combine by that operation and cancel, and the survivor contradicts whatever extremal definition you started from.

Mirror drills

1. Compute $f(3)$ directly from the definition and confirm it differs from $f(2) = 6$, consistent with injectivity. *Answer:* $f(3) = 8$, witnessed by $3 \cdot 6 \cdot 8 = 144 = 12^2$; checking every subset of $\{4, 5, 6, 7\}$ shows no completion with top term at most 7 exists.
2. If f were redefined using perfect cubes instead of perfect squares, explain why multiplying two witnessing products for a collision no longer immediately finishes the proof. *Answer:* cancelling a value appearing twice divides out a square factor, not a cube factor, so the survivor need not stay a perfect cube; the fix needs valuations tracked modulo three, forcing triple, not double, coincidences.
3. Restate the original proof entirely in the language of exponent vectors over $\mathbb{F}_2$: what does "the two top terms cancel" become? *Answer:* the vector of a_r and the vector of b_s are identical, so

their sum is zero, exposing a shorter vanishing sum, the vector-space shadow of the smaller completion of n.

13.3 A3. Geometric series bridge from sum to polynomial

Suppose that the real numbers $a_0, a_1, \ldots, a_n$ and x, with $0 < x < 1$, satisfy

$$\frac{a_0}{1-x} + \frac{a_1}{1-x^2} + \cdots + \frac{a_n}{1-x^{n+1}} = 0.$$

Prove that there exists a real number y with $0 < y < 1$ such that

$$a_0 + a_1 y + \cdots + a_n y^n = 0.$$

Read it out loud

Name the two objects before touching either of them. There is x, a single fixed real number, handed to you already satisfying one given equation, data, not an unknown. And there is y, ranging freely over $(0, 1)$, the unknown a conclusion must produce, attached not to the given fractional sum at all but to a different expression, $P(y) = a_0 + a_1 y + \cdots + a_n y^n$, that shares its coefficients with the hypothesis and nothing else. Confusing these two variables, treating x as though it were free to vary, is the single most expensive misreading available here, and the problem is built to invite exactly that misreading, since both expressions use the same letters $a_0, \ldots, a_n$ and both concern the interval $(0, 1)$.

Within the first thirty seconds you should have written two things down. First, the conclusion is an existence statement about a continuous function, P, having a zero, and you were never asked to find y, only to prove it exists, which is the signature of the intermediate value theorem run by contradiction: assume no zero, derive that P is one sign throughout, then break that sign. Second, the denominators $1 - x^{k+1}$ with $0 < x < 1$ are not incidental, $1/(1-r)$ for $|r| < 1$ is the sum of a convergent geometric series, and a denominator of exactly this shape, with an explicit constraint guaranteeing convergence sitting right next to it, is a standing invitation to expand it.

The field embedded in the question is therefore small and sharp: continuity and the intermediate value theorem on one side, geometric series and the interchange of a finite sum with a convergent infinite one on the other, meeting because the coefficients a_k are shared between the reciprocal sum in x and the polynomial in y.

Approaches, ranked worst to best

1. **clear every denominator and manipulate the resulting single equation in x.** *Cue:* a sum of fractions equalling zero invites clearing denominators. *Circuit:* none, this stalls immediately. Multiplying through by $(1-x)(1-x^2)\cdots(1-x^{n+1})$ produces one polynomial equation satisfied by the single fixed number x. There is no second unknown here to extract a root from, and no route from a true statement about one fixed x to an existence statement about a different polynomial P in a different variable. This treats x as though it carried freedom it does not have.

2. **apply the intermediate value theorem directly to the given sum, varying x.** *Cue:* "prove existence" plus a sum equal to zero pattern matches to IVT. *Circuit:* sign change search, aimed at the wrong function. This correctly senses that IVT is the right family of tool, and for that reason it is not simply wrong, only misaimed: x is one fixed number satisfying one given equation, not a variable ranging over an interval, so there is no family of values of the given sum to search for a sign change in. The existential object the problem wants, y, belongs to P, not to this sum.

3. **expand each $1/(1-x^{k+1})$ as a geometric series and resum by evaluating P along the orbit $x, x^2, x^3, \ldots$.** *Cue:* the same coefficients a_k sit on reciprocal powers of x in the hypothesis and on monomial powers of y in the conclusion. *Circuit:* generating function bridge, plus

IVT by contradiction applied to P itself. Assume P has no root in $(0,1)$; by IVT it is one sign throughout, say positive. Expanding every denominator as a geometric series and reorganising turns the given sum, term by term, into $\sum_{m\geq 0} x^m P(x^m)$, an infinite sum whose every term is nonnegative and whose $m = 1$ term alone is strictly positive, forcing the total strictly positive and contradicting the hypothesis value 0. Minimal ink, no wrong variable, closes cleanly.

The ideal solution

Suppose, for contradiction, that $P(y) := a_0 + a_1 y + \cdots + a_n y^n$ has no zero for $y \in (0,1)$. P is a polynomial, hence continuous on all of $\mathbb{R}$, and $(0,1)$ is an interval; if P took a positive value at one point of $(0,1)$ and a negative value at another, the intermediate value theorem would force a zero of P strictly between them, inside $(0,1)$, contradicting the assumption. So P has one constant sign throughout $(0,1)$. Replacing every a_k by $-a_k$ if necessary, negating P throughout, negating the hypothesis sum termwise, and so preserving both the fact that it equals zero and whether P has a root, we may assume

$$P(y) > 0 \qquad \text{for every } y \in (0,1).$$

For each integer $m \geq 1$, $x^m \in (0,1)$ since $0 < x < 1$, so $P(x^m) > 0$; as $x^m > 0$ too,

$$x^m P(x^m) \;=\; \sum_{k=0}^{n} a_k x^{m(k+1)} \;>\; 0 \qquad (m \geq 1).$$

For $m = 0$, $x^0 P(x^0) = P(1) = a_0 + \cdots + a_n$, which is not covered directly by the open interval bound, but continuity closes the gap: letting $y \to 1^-$ through $(0,1)$, where $P(y) > 0$ throughout, gives $P(1) = \lim_{y\to 1^-} P(y) \geq 0$.

Now sum $x^m P(x^m)$ over $m = 0, 1, 2, \ldots$. For each fixed $k \in \{0, \ldots, n\}$ the series $\sum_{m=0}^{\infty} x^{m(k+1)}$ is geometric with ratio $x^{k+1} \in (0,1)$, converging to $1/(1-x^{k+1})$; since k ranges over only the $n+1$ values $0, \ldots, n$, summing this finite index outside the convergent infinite series over m is a plain rearrangement of a finite sum of convergent series, needing nothing beyond that convergence itself:

$$\sum_{m=0}^{\infty} x^m P(x^m) \;=\; \sum_{m=0}^{\infty} \sum_{k=0}^{n} a_k x^{m(k+1)} \;=\; \sum_{k=0}^{n} a_k \sum_{m=0}^{\infty} x^{m(k+1)} \;=\; \sum_{k=0}^{n} \frac{a_k}{1 - x^{k+1}}.$$

By hypothesis the right side is 0. But the left side is $P(1) \geq 0$ plus infinitely many strictly positive terms $x^m P(x^m)$, $m \geq 1$; the single term at $m = 1$ already forces the total strictly positive. So $\sum_{m=0}^{\infty} x^m P(x^m) > 0$, contradicting that it equals 0. The assumption fails: P has a zero $y \in (0,1)$. ■

Layer 1: WHAT

Block 1. Separate the fixed datum x from the unknown y, and locate the existential target correctly: a zero of P on $(0,1)$, not a property of the given sum. Block 2. Assume P has no zero on $(0,1)$; by IVT it is one sign there; fix the sign to positive by a uniform relabelling. Block 3. Expand each $1/(1-x^{k+1})$ as a geometric series and reorganise into $\sum_m x^m P(x^m)$. Block 4. For $m \geq 1$, $x^m \in (0,1)$ forces each term strictly positive; for $m = 0$, a one sided limit gives $P(1) \geq 0$. Block 5. The resummed total equals the hypothesis's left side, forced strictly positive, contradicting the given value 0.

The nominal route (approach 1) never separates the two variables at all, and stalls the instant it tries to extract a statement about y from an equation purely about x. The bifurcation point against it sits at Block 1. The IVT-on-x route (approach 2) does separate correctly enough to reach for IVT, but aims the theorem at the given sum, which has no freedom to vary; the same Block 1 bifurcation applies, now phrased as which function the existential variable belongs to. Only once P, not the fractional sum, is recognised as the object IVT must act on does Block 2 onward become available, and Block 3 is what actually connects the fixed number x back to P: the geometric expansion is the bridge, not IVT itself.

Layer 2: HOW

Block 1. **Cue.** The conclusion names $y \in (0,1)$ and a specific different expression, $P(y)$, while the hypothesis concerns a fixed x and a sum of reciprocals. **Why natural.** An existential conclusion always names the function and the domain the missing object must satisfy; treating x as though it shared that freedom, or treating the hypothesis's sum as the function needing a root, is not a small slip, it removes the only variable the proof can actually move. **Link to the next block.** Once P on $(0,1)$ is correctly identified as the target, the standard route to proving a continuous function has a root without exhibiting it is the intermediate value theorem, run by contradiction.

Block 2. **Cue.** P is a polynomial, hence continuous everywhere, and $(0,1)$ is a single interval. **Why natural.** A continuous function with no zero on a connected set cannot change sign there, since a sign change would itself force a zero by IVT; this converts "no root" into the much stronger, much more usable statement "one constant sign throughout." **Link to the next block.** A constant, but as yet unknown, sign is only useful once fixed; negating every a_k uniformly flips the sign of P everywhere without disturbing whether the hypothesis sum is zero or whether P has a root, so WLOG the sign is positive.

Block 3. **Cue.** The denominators $1 - x^{k+1}$ carry the explicit constraint $0 < x < 1$ sitting right beside them. **Why natural.** $1/(1-r)$ for $|r| < 1$ is a convergent geometric series in disguise, and an explicit convergence guarantee attached to a term of exactly that shape is the reflex trigger to expand it; this is the one manipulation of the given hypothesis that introduces a free summation index to work with. **Link to the next block.** Expanding and reorganising by that new index exposes the fixed number x raised to every power m, which is exactly the sequence of points at which P can now be evaluated.

Block 4. **Cue.** Every x^m for $m \geq 1$ lies inside $(0,1)$, precisely the domain on which the assumed sign was established, while $x^0 = 1$ sits on the boundary, outside it. **Why natural.** The boundary point is exactly the kind of gap a full marks solution has to close explicitly, not wave past; continuity supplies a one sided limit from inside $(0,1)$ out to 1, weakening strict positivity to nonnegativity only there, which is all the rest of the argument needs. **Link to the next block.** With every term accounted for, one nonnegative and the rest strictly positive, the infinite sum is forced strictly positive.

Block 5. **Cue.** The reorganised infinite sum equals, term for term, the hypothesis's left hand side, which is given to be exactly 0. **Why natural.** A quantity proved strictly positive cannot also be given as zero; this contradiction is the entire reason the geometric expansion was worth doing, since it is what makes the fixed, single equation about x finally say something about P's values. **Link to the next block.** No further block: P must have a zero in $(0,1)$.

Layer 3: WHY

A finite linear relation among terms of the shape $1/(1-x^{k+1})$ is not really one equation, it is a compressed infinite family of equations, one for every power of x simultaneously, because $1/(1-x^{k+1})$ packages the entire sequence $1, x^{k+1}, x^{2(k+1)}, \ldots$ into a single closed form. Expanding it unpacks that family, and reorganising by the shared power m regroups the family into a sequence of evaluations of one fixed polynomial, P, along the geometric orbit $x^0, x^1, x^2, \ldots$. This is why the route works: it does not manufacture a connection between the hypothesis and P, it reveals a connection that was already there, hidden inside the reciprocal notation.

The discernment mechanism: whenever a hypothesis is stated as a finite linear combination of terms $1/(1-r_k)$ with each $|r_k| < 1$ made explicit, and the conclusion concerns a related expression

built from the same coefficients, expand every reciprocal as a geometric series and look for the related expression to reappear, evaluated at whatever the ratios reduce to under the shared index. Here every r_k was the same base x raised to a power matching the polynomial's own degree pattern exactly, a_k paired with x^{k+1} in the denominator and with y^k in the polynomial, an index shift of exactly one, which is the examiners' clearest nudge that a substitution linking x's powers to P's argument was intended, not a coincidence of notation. Training this discernment means drilling $1/(1-x^{k+1})$, under an explicit $0 < x < 1$, into a reflex for generating function language exactly as automatic as reading $\binom{n}{k}$ as "choose."

Revolving concepts

Geometric series and its recursive origin. Definition: for $|r| < 1$, $\sum_{m=0}^{\infty} r^m = 1/(1-r)$. The sequence of terms $c_m = r^m$ is the general solution of the first order linear recursion $c_{m+1} = r\,c_m$, $c_0 = 1$; every such recursion, for any constant ratio r, has closed form $c_m = r^m c_0$, and it is exactly this closed form that licenses summing the series and that produces the geometric orbit $x, x^2, x^3, \ldots$ used throughout the solution. See Book 1, field Sequences and recurrences, topic geometric series and first order linear recursions.

Intermediate value theorem and sign constancy on a connected interval. Definition: a continuous real function on an interval that takes both a positive and a negative value must take the value zero somewhere between them; equivalently, a continuous function with no zero on an interval has one constant sign throughout it. See Book 1, field Real analysis, topic IVT and sign constancy.

One sided limits extending an open interval bound to a closed endpoint. Definition: if f is continuous and $f(y) \geq 0$ for every y in an interval approaching a boundary point c, then $\lim_{y \to c} f(y) \geq 0$, though the strict inequality need not survive the limit. This is the entire justification for the $m = 0$ term of the sum, and skipping it silently is the most common way a candidate loses the point here. See Book 1, field Real analysis, topic continuity and limits.

Generating function bridge between reciprocal power sums and polynomial evaluation. Definition: when the same coefficient sequence $a_0, \ldots, a_n$ appears both as $\sum a_k/(1-x^{k+1})$ and as $\sum a_k y^k$, expanding the first as a family of geometric series and resumming by the shared exponent expresses the first sum exactly as $\sum_{m \geq 0} x^m P(x^m)$; this is the general device linking any reciprocal sum of this shape to evaluations of its coefficient polynomial along a geometric orbit, and it reappears whenever a problem pairs a rational function in one variable with a polynomial sharing its coefficients. See Book 1, field Generating functions, topic coefficient extraction and series to polynomial bridges.

Interchange of a finite sum with a convergent infinite series. Definition: summing a finite collection of convergent series termwise, then adding across the finite index, always agrees with adding across the finite index first and then summing each resulting series; no absolute convergence or Fubini style hypothesis is needed once one of the two indices ranges over a finite set, in contrast to swapping two genuinely infinite sums, which does require absolute convergence to justify reordering. See Book 1, field Real analysis, topic rearrangement of series and finite versus infinite index swaps.

Circuit Bank

- **WHEN** a hypothesis fixes one data variable while the conclusion asks you to find a different unknown for a related but different expression **DO** name both objects explicitly before choosing a technique, and attach any continuity or IVT argument to the function the unknown actually belongs to **BECAUSE** an existential conclusion is only ever about the function and domain it names, and no amount of manipulation of the fixed data variable can substitute for that
- **WHEN** you must prove a continuous function has a zero on an interval without finding it **DO** assume it has none, invoke IVT to force one constant sign throughout, then fix that sign by

whatever symmetry the problem allows (uniform negation, relabelling) **BECAUSE** a function with no zero on a connected interval cannot change sign there, and a constant but unfixed sign is not yet usable until pinned down

- **WHEN** a term of the shape $1/(1-r)$ appears with an explicit hypothesis guaranteeing $|r| < 1$ **DO** expand it immediately as the geometric series $\sum r^m$, and look for a shared index to resum by **BECAUSE** this is the one manipulation of such a term guaranteed to converge and to introduce a free summation variable, and an explicit convergence hypothesis sitting next to it is rarely accidental
- **WHEN** an infinite sum is built from an open interval sign bound but includes a boundary index (here $m = 0$, evaluating at $x^0 = 1$) outside that interval **DO** close the gap with a one sided limit from inside the interval, weakening strict positivity to nonnegativity only at that one boundary term **BECAUSE** a full marks solution accounts for every term explicitly; silently assuming the boundary term shares the strict inequality is exactly the kind of gap a grader is trained to find

Backtesting

1. First useful cue: the conclusion names a different variable, y, for a different expression, $P(y)$, sharing only coefficients with the hypothesis, flagging that x is fixed data, not the unknown.
2. Method the expression suggested: $1/(1-x^{k+1})$ with $0 < x < 1$ stated explicitly suggested a geometric series expansion before any other manipulation was considered.
3. Where you would hesitate, and the thought to reinforce: handling the $m = 0$ boundary term, which sits at $y = 1$, outside the open interval where the assumed sign was established; reinforce closing it with a one sided limit, never by silently extending the strict inequality.
4. The trap the question sets: the shared letters $a_0, \ldots, a_n$ and the shared interval $(0, 1)$ invite treating x as though it were free to vary and applying IVT directly to the given sum, which stalls because x is a single fixed number.
5. What makes you recognise it faster next time: seeing the same coefficient sequence attached to reciprocal powers of one variable in the hypothesis and to plain powers of a different variable in the conclusion, an index shift of exactly one between the two.
6. The reusable decision rule: fixed data variable plus an existence claim about a different, coefficient sharing expression means expand every reciprocal term as a geometric series and resum by the shared exponent to relate the two.

Mirror drills

1. Real numbers $b_0, \ldots, b_n$ and z with $0 < z < 1$ satisfy $b_0/(1+z) + b_1/(1+z^2) + \cdots + b_n/(1+z^{n+1}) = 0$. Does $Q(y) = b_0 + b_1 y + \cdots + b_n y^n$ still have a root in $(0, 1)$? *Hint:* expand $1/(1+z^{k+1}) = \sum_m (-z^{k+1})^m$; the resummed total is an alternating sum of $Q(z^m)$ terms, so the single sign argument needs pairing consecutive m, not the direct route above.
2. If real numbers $a_0, \ldots, a_n$ satisfy $\sum_{k=0}^{n} a_k/(k+1) = 0$, show $P(y) = a_0 + \cdots + a_n y^n$ has a root in $(0, 1)$. *Answer:* since $1/(k+1) = \int_0^1 y^k \, dy$, the hypothesis says $\int_0^1 P(y) \, dy = 0$; if P had no root in $(0, 1)$ it would be one sign throughout, forcing the integral to share that sign, a contradiction, the continuous analogue of the geometric orbit argument.
3. Real numbers $c_1, \ldots, c_5$ and a fixed t with $1 < t < 2$ satisfy $c_1 t + c_2 t^2 + \cdots + c_5 t^5 = 0$. Does this force a root in $(0, 1)$ of $Q(s) = c_1 + c_2 s + \cdots + c_5 s^4$? *Answer:* no general conclusion follows; there is no reciprocal-of-a-power structure to expand and $t \notin (0, 1)$, so the bridge circuit correctly does not fire here.

13.4 A4. Balanced circles and the density of zeros

A finite collection of digits 0 *and* 1 *is written around a circle. An* arc *of length* $L \geq 0$ *consists of* L *consecutive digits around the circle. For each arc* w*, let* $Z(w)$ *and* $N(w)$ *denote the number of* 0*'s in* w *and the number of* 1*'s in* w*, respectively. Assume that* $|Z(w) - Z(w')| \leq 1$ *for any two arcs* w, w' *of the same length. Suppose that some arcs* $w_1, \ldots, w_k$ *have the property that*

$$Z = \frac{1}{k}\sum_{j=1}^{k} Z(w_j) \quad \textit{and} \quad N = \frac{1}{k}\sum_{j=1}^{k} N(w_j)$$

are both integers. Prove that there exists an arc w *with* $Z(w) = Z$ *and* $N(w) = N$*.*

Read it out loud

Say the structure out loud before you touch anything. This is a cyclic binary word, a function from $\mathbb{Z}/m\mathbb{Z}$ to $\{0,1\}$, and every object in the question is a window statistic: slide a window of length L around the circle and count the zeros inside it. The hypothesis says that for each fixed length the count is almost constant. The conclusion hands you a target as an *average* of counts you already have. So the whole problem reads: an average of window counts is itself a window count, provided it is an integer. The fields wired in are combinatorics on words (balanced, that is Sturmian, words), double counting, and the integrality half of the pigeonhole principle.

The first useful cue is the phrase "any two arcs of the same length". A hypothesis that compares two objects of the same size and bounds the gap by 1 is never about those two objects; it is about a hidden real number that both of them are rounding. Integers with range at most 1 occupy two consecutive values, so such a family is pinned down completely once you know its *mean*. That is the reaction circuit: range at most one, so compute the mean and you own the whole family.

Within thirty seconds you should have written m for the number of digits, positions in $\mathbb{Z}/m\mathbb{Z}$, q for the total number of zeros, $z_L(p)$ for the zeros in the arc of length L starting at p, and $L := Z + N$, because $Z(w) + N(w)$ is the length of w, so the arc you must produce has its length already determined. After that the problem is one dimensional: find a window of length L with exactly Z zeros.

Approaches, ranked worst to best

1. **Classify the circles first.** *Cue:* the hypothesis looks like a structure theorem waiting to happen. *Circuit:* recognise the balanced condition, quote the Sturmian classification, then compute. A balanced cyclic word is a rotation of a mechanical word, its zeros sitting at positions $\lfloor jm/q \rfloor$, after which every window count is a floor function calculation. True, and a real theorem, but you would install an entire classification to extract one corollary of it, with $q = 0$ and $q = m$ to handle separately. Ranked last: the ink is enormous and none of it is needed.

2. **Slide one window and use the discrete intermediate value theorem.** *Cue:* "arcs of the same length" and a circle. *Circuit:* moving a window one step changes the count by at most one, so no integer value is skipped. Since $z_L(p+1) - z_L(p) \in \{-1, 0, 1\}$, the count attains every integer between its minimum and its maximum, so it would remain to prove $\min z_L \leq Z \leq \max z_L$. That is genuinely half the problem and worth having, but alone it stalls: your data are counts for arcs of *other* lengths L_j, and you cannot compare those with arcs of length L until you find the common currency.

3. **Re-cut the given arcs into arcs of the common length.** *Cue:* the lengths sum to kL, which is exactly k arcs of length L. *Circuit:* translate each w_j so that the translates lie end to end, then re-partition that run of digits into k arcs of length L. The official route, and correct. Translating costs at most 1 zero per arc, and the first arc need not move, so the total drift is at most $k - 1$;

but if no arc of length L had exactly Z zeros, every re-cut piece would miss Z by at least 1, forcing a drift of at least k. Second only because of the bookkeeping: you must check that the concatenation is a legitimate run of digits and that $L \le m$, and keep track of which side of the inequality each estimate lives on.

4. **Density: every window count is a rounding of length times density.** *Cue:* range at most 1, and the mean over all starting points is forced by double counting. *Circuit:* sum z_L over the m starting positions to get qL, so the mean is Lq/m; a family of integers of range at most 1 with that mean is exactly the integers within distance 1 of it. Best. Every count in the problem, given or wanted, becomes the same statement: an integer within distance 1 of its length times the global density q/m. That model is *linear* in the length, so it survives averaging for free, and integrality of Z closes the problem in one line. No wrap-around bookkeeping, no auxiliary arcs, and the exact set of achievable values comes out as a bonus.

The ideal solution

Let $m \ge 1$ be the number of digits around the circle, index the positions by $\mathbb{Z}/m\mathbb{Z}$, and let $d : \mathbb{Z}/m\mathbb{Z} \to \{0,1\}$ be the digit at each position. Let $q = \#\{p : d(p) = 0\}$ and let $\rho = q/m$ be the density of zeros. For $L \ge 0$ and $p \in \mathbb{Z}/m\mathbb{Z}$ let

$$z_L(p) = \#\{\, t : 0 \le t \le L-1,\ d(p+t) = 0 \,\}$$

be the number of zeros in the arc of length L beginning at p. Every arc of length L is of this form and has $L - z_L(p)$ ones, and arc lengths satisfy $0 \le L \le m$.

Lemma 13.4.1 (Counting). *For every $L \ge 0$ we have* $\displaystyle\sum_{p \in \mathbb{Z}/m\mathbb{Z}} z_L(p) = qL.$

Proof. Count the pairs (p,t) with $0 \le t \le L-1$ and $d(p+t) = 0$ in the two possible orders. Summing over p first gives $\sum_p z_L(p)$. Summing over t first gives $\sum_{t=0}^{L-1} \#\{p : d(p+t) = 0\} = \sum_{t=0}^{L-1} q = qL$, because $p \mapsto p+t$ is a bijection of $\mathbb{Z}/m\mathbb{Z}$ for each fixed t. □

Lemma 13.4.2 (Rounding). *Fix L with $0 \le L \le m$ and let $V_L = \{z_L(p) : p \in \mathbb{Z}/m\mathbb{Z}\}$ be the set of zero counts achieved by arcs of length L. Then V_L is exactly the set of integers n with $|n - L\rho| < 1$. In particular every arc of length L satisfies $|z_L(p) - L\rho| < 1$, and conversely every integer within distance 1 of $L\rho$ is achieved.*

Proof. Write $c = \min_p z_L(p)$ and $M = \max_p z_L(p)$. The hypothesis applied to two arcs of length L gives $M - c \le 1$, so $V_L \subseteq \{c, c+1\}$, and by the counting lemma the mean of z_L over the m starting positions is exactly $L\rho$, whence $c \le L\rho \le M$.

If $M = c$ then z_L is constant, $V_L = \{c\}$ and $L\rho = c$, and the only integer within distance 1 of c is c itself. If $M = c+1$ then both values occur, say r positions carry $c+1$ with $1 \le r \le m-1$, so $L\rho = c + r/m$ lies strictly between c and $c+1$; the integers within distance 1 of such a number are exactly c and $c+1$, and both are achieved. In both cases $V_L = \{n \in \mathbb{Z} : |n - L\rho| < 1\}$. □

Now the problem itself. Let $L_j = Z(w_j) + N(w_j)$ be the length of w_j, so $0 \le L_j \le m$, and set

$$L = Z + N = \frac{1}{k}\sum_{j=1}^{k}\big(Z(w_j) + N(w_j)\big) = \frac{1}{k}\sum_{j=1}^{k} L_j.$$

Then L is an integer, being the sum of the integers Z and N, and $0 \le L \le m$ because L is an average of numbers lying in $[0, m]$. By the rounding lemma applied to each w_j we have $|Z(w_j) - L_j\rho| < 1$ for every j, so by the triangle inequality

$$|Z - L\rho| = \left|\frac{1}{k}\sum_{j=1}^{k}\big(Z(w_j) - L_j\rho\big)\right| \le \frac{1}{k}\sum_{j=1}^{k}\big|Z(w_j) - L_j\rho\big| < \frac{1}{k}\cdot k = 1.$$

Thus Z is an integer with $|Z - L\rho| < 1$, so by the second half of the rounding lemma there is a position p with $z_L(p) = Z$. Let w be the arc of length L starting at p. Then $Z(w) = Z$ and $N(w) = L - Z(w) = (Z + N) - Z = N$, as required. ■

Two edge cases, handled and not swept away. If $L = 0$ then every w_j is empty, $Z = N = 0$, and the empty arc works, the argument covering it unchanged since $z_0 \equiv 0$; if $q = 0$ or $q = m$ then every count equals $L\rho$ exactly. Note also that the counting lemma never used $L \leq m$, so the proof is indifferent to whether your reading of the problem permits arcs that wrap past the full circle; the bound $L \leq m$ is needed only to know that an arc of length L exists.

Layer 1: WHAT

Block 1. Coordinatise: positions in $\mathbb{Z}/m\mathbb{Z}$, digits d, total zeros q, density ρ, window statistic $z_L(p)$.

Block 2. Read off the target length: $L = Z + N$ is forced, since length equals zeros plus ones. The problem is now one dimensional.

Block 3. Double count the pairs (starting position, offset): $\sum_p z_L(p) = qL$, so the mean of the window statistic is $L\rho$ for every L.

Block 4. Combine mean with range: a family of integers of range at most 1 with mean $L\rho$ is exactly the integers within distance 1 of $L\rho$. Every count is now a rounding of a linear function of length.

Block 5. Average: the model $L \mapsto L\rho$ is linear, so the averaged datum Z is within distance 1 of $L\rho$ by the triangle inequality alone.

Block 6. Cash in integrality: an integer within distance 1 of $L\rho$ is achieved. The ones count is free because the length is fixed.

Juxtaposition. The nominal route reads "arcs of the same length" and starts comparing the given arcs with each other: re-cut, translate, concatenate, track a drift of at most $k - 1$ against a deficit of at least k. That route works, but every step of it is bookkeeping about *positions*. The ideal route never moves an arc, because it notices that positions are irrelevant once the hypothesis has collapsed each length class to two consecutive values.

The bifurcation point is the sentence "the given arcs have different lengths, so I cannot compare them directly". The zombie response is to make the lengths equal by cutting and pasting. The ideal response is to find a scalar that all lengths report on, and there is exactly one candidate: the density q/m, the only number attached to the circle as a whole.

Layer 2: HOW

Block 1. Cue. A finite object written around a circle, with statistics attached to consecutive runs. **Why natural.** A circle has no distinguished start, so the honest coordinate system is $\mathbb{Z}/m\mathbb{Z}$ and the honest statistics are those invariant under rotation or averaged over it. Writing $z_L(p)$ makes both parameters explicit: the length you control, and the position you will quantify away. **Link to the next block.** The hypothesis constrains p uniformly, which is the hint that p is the variable to average out.

Block 2. Cue. $Z(w) + N(w)$ is not a new quantity: it is the length of w. **Why natural.** The problem gives two averages, and the second is redundant information dressed as extra data. The pair (Z, N) looks like a two dimensional target, but its second coordinate is determined by the first once the length is known. **Link to the next block.** With the length pinned to $L = Z + N$, everything afterwards works inside one length class.

Block 3. Cue. A quantity indexed by a group, with a hypothesis uniform over that group. **Why natural.** When a hypothesis is uniform over a group you learn nothing from any single element, so sum over the group. Summing $z_L(p)$ over p is a double count of pairs (position, offset) whose

inner sum is the same for every offset because rotation is a bijection. It is the cheapest calculation available and it produces the only global invariant, the density. **Link to the next block.** The mean is now exact and the hypothesis controls the spread; mean plus spread determines a two valued family completely.

Block 4. **Cue.** "Any two differ by at most 1", applied to integers. **Why natural.** Integers of range at most 1 occupy two consecutive values, and such a family is determined by its mean: constant if the mean is an integer, otherwise exactly the two neighbours of the mean, both occurring. No third case exists, so the qualitative hypothesis becomes an exact description. **Link to the next block.** You need that description in both directions: forwards for the data you are given, backwards for the arc you must produce.

Block 5. **Cue.** The conclusion is stated as an average of the hypotheses. **Why natural.** Averaging destroys almost every property but preserves membership of an interval and commutes with linear functions. The approximation $z_L(p) \approx L\rho$ has error below 1 uniformly and its main term is linear in L, so averaging the counts averages the main terms and the triangle inequality controls the errors. Had the expected count been a nonlinear function of L, this step would fail and the problem would be false. **Link to the next block.** You now hold a strict inequality about an integer, which is a pigeonhole waiting to be cashed.

Block 6. **Cue.** "are both integers". Examiners do not say "integer" for decoration. **Why natural.** The bound $|Z - L\rho| < 1$ says nothing about a real number, but for an integer it isolates one or two candidates, and the rounding lemma says exactly those candidates are achieved. The integrality hypothesis is not a convenience; it is the whole content of the final step. **Link to the next block.** Fixing the length gives the ones count for free, so the proof ends here.

Layer 3: WHY

The truth underneath is that a balanced cyclic word carries no local information beyond its density: the hypothesis forces $z_L(p) \in \{\lfloor L\rho \rfloor, \lceil L\rho \rceil\}$ for all p and L, which says the zeros are as equidistributed as integers permit, and is the defining property of mechanical (Sturmian) words, whose zeros sit at a Beatty type sequence $\lfloor j/\rho \rfloor$. So the circle carries one parameter, and the numbers $Z(w_1), \ldots, Z(w_k)$ are k noisy measurements of it, each with error below one unit. The conclusion is a statement about noise under averaging, and it holds because the signal $L\rho$ is linear in L.

The discernment mechanism, stated for reuse: when a hypothesis bounds the *spread* of a family of integers, immediately demand its *mean*, because spread plus mean is a complete description when the spread is at most one. The mean is almost always obtainable by double counting, since a mean over a group orbit is a sum in disguise. Thereafter treat every member of the family as "linear model plus error below one", and every later manipulation is arithmetic rather than combinatorics. Train it by writing, on sight of "differ by at most one", the words two consecutive values, mean determines everything; and on sight of a window sliding around a cycle, sum over all positions equals window length times total. Those two reflexes solved this in five lines, and they are the same reflexes behind equidistribution and three distance arguments.

The examiners nudged three times. They wrote the hypothesis as a comparison of two arcs rather than as "the count takes at most two values", which is the same statement dressed to look local. They handed you Z and N separately although only their sum matters for the length. And they inserted "are both integers", which is the pigeonhole flag. Miss all three and you can still find the concatenation proof, which is why this sits at A4 and not at A6.

Revolving concepts

Cyclic binary word. A function $d : \mathbb{Z}/m\mathbb{Z} \to \{0,1\}$, that is, a necklace. Orbiting it: the window statistics z_L, the density $\rho = q/m$, and the rotation action of $\mathbb{Z}/m\mathbb{Z}$ on itself. Anything rotation invariant is expressible in the density and the window statistics. See Book 1, field: Combinatorics, topic: cyclic words and necklaces.

Balanced word. Balanced means any two factors of the same length have zero counts differing by at most 1. Theorem (Morse and Hedlund): the aperiodic infinite balanced words are exactly the Sturmian words, and the periodic ones are exactly the rotations of the mechanical words $d(n) = \lfloor (n+1)\rho + \theta \rfloor - \lfloor n\rho + \theta \rfloor$. You do not need the classification, and quoting it would be a knowledge gap in disguise; the one consequence used, $z_L(p) \in \{\lfloor L\rho \rfloor, \lceil L\rho \rceil\}$, was proved from scratch. See Book 1, field: Combinatorics, topic: balanced and Sturmian words.

Double counting over a group orbit, with the recursion generalised. The identity $\sum_p \sum_{t=0}^{L-1} F(p+t) = L \sum_p F(p)$ holds for any F on $\mathbb{Z}/m\mathbb{Z}$: the moving sum of any function over a cycle has mean equal to the window length times the mean of the function. The moving sums obey the first order recursion $S_{L+1}(p) = S_L(p) + F(p+L)$, whose solution is the telescoping sum; summing that recursion over p gives $\sum_p S_{L+1} = \sum_p S_L + \sum_p F$, an arithmetic progression in L with common difference $\sum_p F$. That is the counting lemma, now visible as the solution of a linear recursion, and it is why the model is linear in L. See Book 1, field: Combinatorics, topic: double counting.

Discrete intermediate value theorem. If $u : \mathbb{Z}/m\mathbb{Z} \to \mathbb{Z}$ has $|u(p+1) - u(p)| \leq 1$ then u attains every integer between its extremes; here $z_L(p+1) - z_L(p) = [d(p+L) = 0] - [d(p) = 0]$. This gives achievability without the balanced hypothesis and is worth carrying separately, since many problems supply a step condition but no range condition. See Book 1, field: Combinatorics, topic: discrete continuity arguments.

Integrality and rounding. For real x and integer n, $|n - x| < 1$ forces $n \in \{\lfloor x \rfloor, \lceil x \rceil\}$, and $n = x$ if x is an integer. With the triangle inequality this is the engine of the last step. See Book 1, field: Number theory, topic: floor and ceiling.

Circuit Bank

- **WHEN** a family of integers is assumed to have range at most 1 **DO** compute the family's mean, usually by double counting, and declare the family to be exactly the integers within distance 1 of that mean **BECAUSE** integers of range at most 1 occupy two consecutive values, so the mean pins down both the values and their achievability
- **WHEN** a statistic is attached to a sliding window on a cycle **DO** sum it over all starting positions, using that the sum equals window length times total **BECAUSE** rotation is a bijection of the index group, so the double count collapses in one line and produces the only rotation invariant available
- **WHEN** a hypothesis says some quantity "is an integer" **DO** plan for a final step of the form "an integer strictly within 1 of x is a rounding of x" **BECAUSE** examiners insert integrality exactly where a strict inequality must be upgraded to an identification
- **WHEN** the conclusion is an average of the given data **DO** check whether the quantity has an exact linear model plus a uniformly bounded error **BECAUSE** averaging commutes with the linear part and the triangle inequality controls the errors, so linear models survive averaging and nothing else does
- **WHEN** two target statistics are given but their sum is a parameter you control **DO** eliminate one of them immediately **BECAUSE** a two dimensional target lying on a known line is one dimensional, and carrying the spare coordinate costs ink and invites case analysis

Backtesting

1. First useful cue: "any two arcs of the same length differ by at most 1", the range at most one flag, with its partner "are both integers", the pigeonhole flag.
2. Method the expression suggested: fix the length class, compute the mean of the window count by double counting, and describe the class exactly as the roundings of length times density.
3. Where you would hesitate, and the thought to reinforce: at the moment you notice the given arcs have different lengths. Do not cut and paste. Compare each arc to the linear model $L\rho$ instead, and the differing lengths become a strength, because the model is linear and averages cleanly.
4. The trap the question sets: presenting Z and N as a pair, tempting you to chase two conditions; and hiding the strictness of $|Z(w_j) - L_j\rho| < 1$, which must stay strict, since k errors of size exactly 1 would break the final bound.
5. What makes you recognise it faster next time: "an average of window statistics is itself a window statistic" is an equidistribution statement, and those are always proved by exhibiting the linear model and bounding the discrepancy.
6. The reusable decision rule: range at most one plus known mean equals complete description, after which every step is an error estimate.

Mirror drills

1. A balanced circle carries 100 digits of which exactly 30 are zeros. How many zeros are in an arc of length 10, and in an arc of length 7? *Answer:* exactly 3 for length 10, since $10 \cdot 30/100 = 3$ is an integer and a two valued family with integer mean is constant; either 2 or 3 for length 7, since $7 \cdot 30/100 = 2.1$, and both values occur.
2. Let $F : \mathbb{Z}/m\mathbb{Z} \to \mathbb{R}$ and $S_L(p) = \sum_{t=0}^{L-1} F(p+t)$. Prove $\max_p S_L(p) \geq \frac{L}{m} \sum_p F(p) \geq \min_p S_L(p)$, and deduce that some arc of length L contains at least $\lceil Lq/m \rceil$ zeros. *Answer:* average S_L over p, use $\sum_p S_L(p) = L \sum_p F(p)$, and a maximum is at least the mean; then take $F = [d = 0]$ and round, the count being an integer.
3. Show that $u : \mathbb{Z}/m\mathbb{Z} \to \mathbb{Z}$ with $|u(p+1) - u(p)| \leq 1$ attains every integer between its extremes, and give a circle and a length for which z_L takes three values, so that the balanced hypothesis is genuinely needed. *Answer:* walk from an argmin to an argmax one step at a time, skipping nothing; and take $d = 0, 0, 1, 1$ with $L = 2$, where z_2 runs $2, 1, 0, 1$, a word that is not balanced.

13.5 A5. Area definite lists and average shadows

For $m \geq 3$, a list of $\binom{m}{3}$ real numbers a_{ijk} $(1 \leq i < j < k \leq m)$ is said to be area definite *for $\mathbb{R}^n$ if the inequality*

$$\sum_{1 \leq i < j < k \leq m} a_{ijk} \cdot \text{Area}(\Delta A_i A_j A_k) \geq 0$$

holds for every choice of m points $A_1, \ldots, A_m$ in $\mathbb{R}^n$. For example, the list of four numbers $a_{123} = a_{124} = a_{134} = 1$, $a_{234} = -1$ is area definite for $\mathbb{R}^2$. Prove that if a list of $\binom{m}{3}$ numbers is area definite for $\mathbb{R}^2$, then it is area definite for $\mathbb{R}^3$.

Read it out loud

Read the quantifiers first, because they are the problem. The hypothesis is universal over planar configurations, the conclusion universal over spatial ones: you are given information about a small class of objects and asked for information about a larger class containing it. Exactly one shape of argument does that. Take an object of the large class, manufacture objects of the small class from it, apply the hypothesis, reassemble. So this is a transport problem, not a geometry problem, and the only canonical way to manufacture a planar configuration from a spatial one is orthogonal projection. The fields are vector geometry in $\mathbb{R}^3$ (the vector product and vector area), integral geometry (Cauchy's projection formula), and the decisive triviality that integration against a nonnegative measure preserves ≥ 0.

What is really being tested is whether you will *stop choosing*. Every solver projects; most then hunt for a good direction, because choosing is what we are trained to do. The direction cannot be chosen, since the distortion factor depends on the triangle and different triangles lie in different planes. The move is to project in every direction at once and average, and the average behaves only because the averaging measure can be taken rotation invariant.

Within thirty seconds you should have written the vector area $\mathbf{V}_{ijk} = \frac{1}{2}(A_j - A_i) \times (A_k - A_i)$, noted $\text{Area}(\Delta A_i A_j A_k) = |\mathbf{V}_{ijk}|$, and asked what the shadow of the triangle along a unit vector $\hat{u}$ has for its area. That is one cross product away from $|\mathbf{V}_{ijk} \cdot \hat{u}|$, and the moment you see the absolute value of a linear functional you should smell the plan: a norm is about to be recovered as an average of absolute values of linear functionals.

Approaches, ranked worst to best

1. **Classify the area definite lists for $\mathbb{R}^2$.** *Cue:* the hypothesis is a condition on the numbers a_{ijk}. *Circuit:* find the extreme rays of a convex cone, then verify the conclusion on each. The area definite lists form a closed convex cone, so its extreme rays would suffice. Nobody has a usable description of that cone for general m, so you would replace a two page problem with an open ended one. Ranked last: it attacks the coefficients when the quantifier that matters is over configurations.

2. **Squash the picture with one clever projection.** *Cue:* the conclusion is about $\mathbb{R}^3$ and the hypothesis about $\mathbb{R}^2$. *Circuit:* choose a projection direction adapted to the configuration. A single projection multiplies each area by the cosine of the angle between its plane and the screen, and those cosines differ from triangle to triangle, so the projected inequality is a differently weighted sum and says nothing about the unweighted one. It fails informatively: the obstruction is the triangle dependence of one number.

3. **Project onto the three coordinate planes and add.** *Cue:* three orthogonal screens ought to see everything. *Circuit:* sum the three projected inequalities. With $\hat{n}$ a unit normal, the shadows have areas $\text{Area} \cdot |n_1|$, $\text{Area} \cdot |n_2|$, $\text{Area} \cdot |n_3|$, so adding gives $\sum a_{ijk} \text{Area}_{ijk}(|n_1| + |n_2| + |n_3|) \geq 0$. The weight lies in $[1, \sqrt{3}]$ but still depends on the triangle. Ranked third: the correct idea

with the wrong index set, and its failure names the requirement, that the total weight must be blind to orientation.

4. **Work with vector areas and linear algebra.** *Cue:* $\mathbf{V}_{ijk}$ is additive over a surface, so perhaps the sum is algebraic. *Circuit:* replace areas by bivectors and use linearity. The vector area is beautifully linear, but the quantity in the problem is the norm $|\mathbf{V}_{ijk}|$, and norms are not. With mixed signs a_{ijk} no triangle inequality manipulation produces the result. Ranked fourth: right objects, but you need a device that linearises the norm, and that device is the integral in the next approach.

5. **Average the shadow over all directions.** *Cue:* the distortion depends on the triangle, so refuse to choose a direction and integrate over all of them. *Circuit:* the identity $|\mathbf{V}| = \frac{1}{2\pi}\int_{S^2} |\mathbf{V}\cdot\hat{u}|\,d\sigma(\hat{u})$, which is Cauchy's projection formula: a Euclidean norm is an average of absolute values of linear functionals. Best, and once seen, forced. For each fixed $\hat{u}$ the projected points form a genuine planar configuration, so the hypothesis gives a nonnegative number; the projected areas are $|\mathbf{V}_{ijk}\cdot\hat{u}|$; integrating against the rotation invariant measure turns each into $2\pi|\mathbf{V}_{ijk}|$, the same constant for every triangle precisely because the measure is rotation invariant. Divide by $2\pi > 0$.

The ideal solution

For $P, Q, R \in \mathbb{R}^3$ write $\mathbf{V}(P,Q,R) = \frac{1}{2}(Q-P)\times(R-P)$ for the *vector area* of the triangle PQR, so $\mathrm{Area}(\Delta PQR) = |\mathbf{V}(P,Q,R)|$, with $\mathbf{V} = \mathbf{0}$ exactly when the points are collinear. For a unit vector $\hat{u}$ let $\Pi_{\hat{u}} = \hat{u}^{\perp}$ and $\pi_{\hat{u}}(x) = x - (x\cdot\hat{u})\hat{u}$.

Lemma 13.5.1 (Shadow area)**.** *For all $P, Q, R \in \mathbb{R}^3$ and every unit vector $\hat{u}$,*

$$\mathrm{Area}\big(\Delta\,\pi_{\hat{u}}(P)\,\pi_{\hat{u}}(Q)\,\pi_{\hat{u}}(R)\big) = \big|\mathbf{V}(P,Q,R)\cdot\hat{u}\big|.$$

Proof. Put $u = Q-P$, $v = R-P$; by linearity $\pi_{\hat{u}}(Q) - \pi_{\hat{u}}(P) = \pi_{\hat{u}}(u)$ and likewise for v. Both lie in $\Pi_{\hat{u}}$, so their vector product is parallel to $\hat{u}$, say $\pi_{\hat{u}}(u)\times\pi_{\hat{u}}(v) = \lambda\hat{u}$ with $\lambda = (\pi_{\hat{u}}(u)\times\pi_{\hat{u}}(v))\cdot\hat{u}$. Expanding,

$$\pi_{\hat{u}}(u)\times\pi_{\hat{u}}(v) = u\times v - (v\cdot\hat{u})\,(u\times\hat{u}) - (u\cdot\hat{u})\,(\hat{u}\times v),$$

the term $(u\cdot\hat{u})(v\cdot\hat{u})\,\hat{u}\times\hat{u}$ vanishing. Taking the scalar product with $\hat{u}$ kills the last two terms, since $(u\times\hat{u})\cdot\hat{u} = 0 = (\hat{u}\times v)\cdot\hat{u}$, so $\lambda = (u\times v)\cdot\hat{u}$ and the shadow area is $\frac{1}{2}|\lambda| = |\mathbf{V}(P,Q,R)\cdot\hat{u}|$. If the points are collinear both sides vanish, so the identity holds in every case. □

Lemma 13.5.2 (Sphere average)**.** *Let σ denote the standard surface measure on $S^2 \subset \mathbb{R}^3$. For every $\mathbf{V} \in \mathbb{R}^3$,*

$$\int_{S^2} \big|\mathbf{V}\cdot\hat{u}\big|\,d\sigma(\hat{u}) = 2\pi\,|\mathbf{V}|.$$

Proof. Both sides vanish for $\mathbf{V} = \mathbf{0}$ and both are homogeneous of degree 1, so assume $\mathbf{V}$ is a unit vector and choose $R \in SO(3)$ with $Re_3 = \mathbf{V}$. Since σ is rotation invariant and $Re_3\cdot R\hat{v} = e_3\cdot\hat{v}$,

$$\int_{S^2} |\mathbf{V}\cdot\hat{u}|\,d\sigma(\hat{u}) = \int_{S^2} |e_3\cdot\hat{v}|\,d\sigma(\hat{v}) = \int_0^{2\pi}\!\!\int_0^{\pi} |\cos\theta|\sin\theta\,d\theta\,d\varphi = 2\pi\int_{-1}^{1}|c|\,dc = 2\pi. \qquad \square$$

Now let $\{a_{ijk}\}$ be area definite for $\mathbb{R}^2$, let $A_1,\dots,A_m \in \mathbb{R}^3$, write $\mathbf{V}_{ijk} = \mathbf{V}(A_i,A_j,A_k)$ and set

$$F(\hat{u}) = \sum_{1\le i<j<k\le m} a_{ijk}\,\big|\mathbf{V}_{ijk}\cdot\hat{u}\big| \qquad (\hat{u}\in S^2).$$

Claim: $F(\hat{u}) \ge 0$ for every $\hat{u} \in S^2$. Fix $\hat{u}$. The plane $\Pi_{\hat{u}}$ is a two dimensional Euclidean space, so choose a linear isometry $\Phi : \Pi_{\hat{u}} \to \mathbb{R}^2$; isometries preserve areas of triangles. Apply the hypothesis

to the points $B_i = \Phi(\pi_{\hat{u}}(A_i)) \in \mathbb{R}^2$, which is legitimate because area definiteness is assumed for *every* choice of m points of $\mathbb{R}^2$, with no requirement that they be distinct or in general position:

$$0 \le \sum_{i<j<k} a_{ijk} \operatorname{Area}(\Delta B_i B_j B_k) = \sum_{i<j<k} a_{ijk} \operatorname{Area}\big(\Delta\, \pi_{\hat{u}}(A_i)\pi_{\hat{u}}(A_j)\pi_{\hat{u}}(A_k)\big) = F(\hat{u}),$$

the last equality by the shadow lemma. This proves the claim.

F is continuous on S^2, being a finite linear combination of the continuous functions $\hat{u} \mapsto |\mathbf{V}_{ijk} \cdot \hat{u}|$, so it is integrable and the integral of the finite sum is the sum of the integrals. Integrating the claim and applying the sphere average lemma to each term,

$$0 \le \int_{S^2} F(\hat{u})\, d\sigma(\hat{u}) = \sum_{i<j<k} a_{ijk} \int_{S^2} \big|\mathbf{V}_{ijk} \cdot \hat{u}\big|\, d\sigma(\hat{u}) = 2\pi \sum_{i<j<k} a_{ijk} \operatorname{Area}(\Delta A_i A_j A_k).$$

Dividing by $2\pi > 0$ gives the required inequality, and since $A_1, \dots, A_m$ were arbitrary, the list is area definite for $\mathbb{R}^3$. ■

One remark on rigour, in case your reading of the definition insists on *m distinct* points: projections can collide, so replace B_i by $B_i + \varepsilon C_i$ for fixed generic $C_i \in \mathbb{R}^2$ and small $\varepsilon > 0$, which are distinct, and let $\varepsilon \to 0^+$; the sum of areas is continuous in the points, so the non strict inequality survives.

Layer 1: WHAT

Block 1. Read the quantifiers: hypothesis universal over planar configurations, goal universal over spatial ones. Build planar configurations from a spatial one, so project.

Block 2. Quantify the damage: with the vector area, the shadow of a triangle has area $|\mathbf{V} \cdot \hat{u}|$. One cross product line.

Block 3. Observe the damage is triangle dependent, so no single direction can work.

Block 4. Refuse to choose: integrate over all directions, demanding that $\int |\mathbf{V} \cdot \hat{u}|\, d\sigma$ be a fixed multiple of $|\mathbf{V}|$. Rotation invariance plus homogeneity deliver exactly that.

Block 5. Compute the constant, 2π, and note it is positive.

Block 6. Apply the hypothesis for each fixed $\hat{u}$, integrate the pointwise inequality, exchange the finite sum with the integral, divide.

Juxtaposition. The nominal route projects, notices the cosine factors, and then hunts: for a direction making them equal, for bounds on the cosines, for a decomposition into coplanar groups. All of that is choosing, and all of it costs pages. The ideal route projects once, symbolically, in a direction that is never specified.

The bifurcation point is the line "the factor $|\hat{n}_{ijk} \cdot \hat{u}|$ depends on ijk". Zombie response: choose $\hat{u}$ to control it. Ideal response: quantify over $\hat{u}$ and average, because that dependence is only through a direction, and directions are exactly what a rotation invariant average forgets.

Layer 2: HOW

Block 1. Cue. Two universal statements, one over a subcategory and one over the whole. **Why natural.** A hypothesis is useful only where it applies, so you must produce objects it applies to. Your points are genuinely spatial, so you cannot restrict; you must map. Orthogonal projection is the only map onto a plane that is canonical, linear and area controlling. **Link to the next block.** Once you commit to projecting, the only remaining question is what the map costs you.

Block 2. Cue. Areas of triangles under a linear map. **Why natural.** Area in $\mathbb{R}^3$ is $\frac{1}{2}|u \times v|$ and $\pi_{\hat{u}}$ is linear, so push the projection inside. The computation is two lines because $\pi(u)$ and $\pi(v)$ are both perpendicular to $\hat{u}$, forcing their product parallel to $\hat{u}$, so only one scalar is unknown. Writing the answer as $|\mathbf{V} \cdot \hat{u}|$ rather than Area $\cdot\, |\hat{n} \cdot \hat{u}|$ is the lazy choice in the good sense: it removes the sign

ambiguity of the normal and handles collinear triples silently. **Link to the next block.** The shadow area is the absolute value of a linear functional at the vector area, which is a strong structural cue.

Block 3. **Cue.** The factor depends on the triangle. **Why natural.** Different triangles lie in different planes, so one screen flatters some and crushes others; and the coefficients must have mixed signs, or the statement would be trivial, so a weighted inequality with unknown weights carries no information about the unweighted one. **Link to the next block.** The failure names its own cure: you need a family of screens whose total effect is blind to orientation.

Block 4. **Cue.** "Blind to orientation" is the definition of rotation invariance. **Why natural.** Set $I(\mathbf{V}) = \int_{S^2} |\mathbf{V} \cdot \hat{u}| \, d\sigma(\hat{u})$. If σ is rotation invariant then $I(R\mathbf{V}) = I(\mathbf{V})$, and I is homogeneous of degree 1, so $I(\mathbf{V}) = c|\mathbf{V}|$ because $SO(3)$ is transitive on each sphere. An invariant homogeneous positive function of a vector must be a multiple of the norm. You need only $c > 0$, which is clear since the integrand is positive off a great circle. **Link to the next block.** With c existing and positive the proof is finished up to arithmetic, and computing it costs two lines.

Block 5. **Cue.** A spherical integral of $|\cos\theta|$. **Why natural.** Rotate so that $\mathbf{V} = e_3$, legitimate by the invariance already invoked, then integrate in spherical coordinates; $c = \cos\theta$ turns it into $2\pi \int_{-1}^{1} |c| \, dc = 2\pi$. Equivalently the mean of $|\hat{n} \cdot \hat{u}|$ is $\frac{1}{2}$: the average shadow of a plate is half its area. **Link to the next block.** Only the exchange of sum and integral remains, and the sum is finite.

Block 6. **Cue.** An inequality holding pointwise in a parameter you are about to integrate over. **Why natural.** Integration against a nonnegative measure preserves ≥ 0, which is why the plan works at all, and it is linear, which is why the fixed coefficients pass through untouched. A supremum would preserve the inequality too but is not linear. **Link to the next block.** Divide by the positive constant and you have the definition of area definite for $\mathbb{R}^3$.

Layer 3: WHY

Three truths sit under this route. The first is Cauchy's projection formula: for a convex body in $\mathbb{R}^3$ the average shadow area is a quarter of the surface area, and for a flat plate, whose shadow is counted once rather than twice, it is half the area. The identity $\int_{S^2} |\mathbf{V} \cdot \hat{u}| \, d\sigma = 2\pi|\mathbf{V}|$ is that plate case, applied triangle by triangle.

The second, and the reusable one, is that the Euclidean norm is an average of absolute values of linear functionals, $|\mathbf{V}| = \frac{1}{2\pi} \int_{S^2} |\mathbf{V} \cdot \hat{u}| \, d\sigma(\hat{u})$. A norm admitting such a representation is called a zonoid norm, and the representation is the standard way to convert a nonlinear quantity into something that commutes with sums. That is exactly the obstruction that killed the algebraic approach, linearised at the cost of one integral. The third is that integration against a nonnegative measure preserves inequalities and finite sums pass through it: positivity is stable under averaging, and not under differentiation, substitution or rearrangement.

The discernment mechanism: when the hypothesis lives on a small class and the goal on a large one, find a map from large to small, compute the distortion factor, and ask whether averaging over a group acting transitively on the relevant data makes that factor object independent. Here the datum is the direction of the vector area, the group is $SO(3)$, it is transitive on directions, and the invariant measure on S^2 is unique up to scale, so the averaging measure is forced rather than chosen. Whenever you can name the group and check transitivity, the constant exists before you compute it. Train the reflex by asking at every projection or restriction step: does this distortion depend on the object, and if so, what group moves the objects around? That single question covers integral geometry, symmetrisation, averaging over cyclic shifts, and averaging over a finite group, which is the same circuit with counting measure.

The examiners nudged deliberately: a sample list with mixed signs, which kills any term by term argument; the dimensions 2 and 3, where projection is familiar and the vector product exists; and the words "for every choice of m points" rather than "in general position", which is what licenses feeding a collapsed projected configuration into the hypothesis.

Revolving concepts

Vector area. $\mathbf{V} = \frac{1}{2}(Q-P)\times(R-P)$; its magnitude is the area, its direction the normal. Vector areas add over a triangulated surface and sum to zero over a closed one, which is the divergence theorem for constant fields in disguise. See Book 1, field: Geometry, topic: vector product and vector area.

Orthogonal projection. $\pi_{\hat{u}}(x) = x - (x\cdot\hat{u})\hat{u}$, linear, idempotent and self adjoint with image $\hat{u}^{\perp}$. The area distortion of a linear map restricted to a plane W is $|\det(T|_W)|$ in orthonormal bases, here the cosine of the angle between W and $\hat{u}^{\perp}$. See Book 1, field: Linear algebra, topic: projections and determinants as volume scaling.

Cauchy's projection formula. The mean shadow of a convex body in $\mathbb{R}^3$ is a quarter of its surface area; in $\mathbb{R}^n$ the mean volume of the projection onto a hyperplane is a dimensional constant times the surface area. Beneath it sit mixed volumes and Steiner's formula. Knowing the name is how you recognise the technique later. See Book 1, field: Geometry, topic: integral geometry and convex bodies.

Invariant measure. The rotation invariant Borel measure on S^2 is unique up to a positive scalar, being Haar measure transported to $S^2 = SO(3)/SO(2)$; uniqueness is why the constant is forced. The finite analogue, averaging over a finite group with counting measure, is the same tool. See Book 1, field: Geometry, topic: invariant measures and homogeneous spaces.

Generalisation to all dimensions, with the recursion made explicit. Area definite for $\mathbb{R}^2$ implies area definite for $\mathbb{R}^n$ for every $n \geq 2$, by induction on n: project along a uniformly distributed unit vector onto $\hat{u}^{\perp} \cong \mathbb{R}^{n-1}$; a triangle spanning the plane W has its area multiplied by $\sqrt{1-\|P_W\hat{u}\|^2}$, whose average over S^{n-1} is independent of W because $O(n)$ is transitive on two dimensional subspaces and the measure is invariant. The recursion is $\mathcal{A}_{n-1} \Rightarrow \mathcal{A}_n$ with the same one step argument, and the general method is: identify the group acting on the fibre data, check transitivity, average. See Book 1, field: Geometry, topic: Grassmannians and invariant integration.

Circuit Bank

- **WHEN** a hypothesis is known in a small class and needed in a bigger one **DO** map the big object into the small class and compute the distortion factor of the quantity in question **BECAUSE** hypotheses travel along maps and nowhere else, so the only work is measuring what the map costs
- **WHEN** a distortion factor depends on the object **DO** stop choosing the map and integrate over the whole family of maps against an invariant measure **BECAUSE** an invariant homogeneous positive function of a vector is a constant times its norm, so object dependence is exactly what invariance forgets
- **WHEN** you meet $|\hat{n}\cdot\hat{u}|$ averaged over the unit sphere in $\mathbb{R}^3$ **DO** write down the value 2π, equivalently mean value $1/2$ **BECAUSE** it is Cauchy's projection formula for a flat plate, and knowing the constant saves re-deriving it under time pressure
- **WHEN** an inequality holds for every value of a parameter and you want a statement about a weighted sum **DO** integrate the inequality over the parameter rather than optimising over it **BECAUSE** integration against a nonnegative measure preserves ≥ 0 and is linear, so fixed coefficients pass straight through, while suprema are not linear

- **WHEN** a nonlinear quantity such as a norm or an area blocks a linearity argument **DO** look for a representation of it as an average of absolute values of linear functionals **BECAUSE** that representation is what makes norms compatible with sums, and every Euclidean norm has one

Backtesting

1. First useful cue: the mismatch of quantifiers, hypothesis over $\mathbb{R}^2$ and goal over $\mathbb{R}^3$, which forces a map from $\mathbb{R}^3$ into a plane.
2. Method the expression suggested: areas as $|\mathbf{V}_{ijk}|$, shadows as $|\mathbf{V}_{ijk} \cdot \hat{u}|$, and the norm recovered as the sphere average of the linear functional.
3. Where you would hesitate, and the thought to reinforce: when the cosine factor turns out to depend on the triangle. A factor depending only on a direction is annihilated by averaging over a transitive group, so an object dependent constant is an instruction to integrate, not a defeat.
4. The trap the question sets: the temptation to pick a good direction, and the smaller trap that projected points may coincide, harmless only because the definition quantifies over every choice of m points.
5. What makes you recognise it faster next time: "property in dimension n implies property in dimension $n+1$" is an integral geometry flag, and the answer is always project, compute the distortion, average it away.
6. The reusable decision rule: when the distortion depends on the object, average over the symmetry group with its invariant measure; the constant is positive and may be computed later, or never.

Mirror drills

1. Show that the average area of the shadow of a fixed triangle $T \subset \mathbb{R}^3$ on a plane with uniformly random normal direction is $\frac{1}{2}\text{Area}(T)$. *Answer:* the shadow lemma gives shadow area $|\mathbf{V} \cdot \hat{u}|$, and the sphere average lemma gives mean $\frac{1}{4\pi} \cdot 2\pi|\mathbf{V}|$.
2. Deduce Cauchy's surface area formula for a convex polyhedron: the mean shadow area is one quarter of the surface area. *Answer:* triangulate and apply the previous drill to each face; for a convex body almost every line in direction $\hat{u}$ meets the boundary twice, so the shadow is covered exactly twice by the shadows of the faces, giving $\frac{1}{2} \cdot \frac{1}{2}S = \frac{1}{4}S$.
3. Prove that a list area definite for $\mathbb{R}^2$ is area definite for $\mathbb{R}^n$ for every $n \geq 2$. *Answer:* induct on n, projecting along a uniformly random unit vector onto a hyperplane; the area factor for a triangle spanning W is $\sqrt{1 - \|P_W \hat{u}\|^2}$, whose average over S^{n-1} is independent of W since $O(n)$ is transitive on two dimensional subspaces, so divide by that positive constant.

13.6 A6. A positive definite weight on the integer lattice

Define a function $w : \mathbb{Z} \times \mathbb{Z} \to \mathbb{Z}$ as follows. For $|a|, |b| \leq 2$, let $w(a,b)$ be as in the table shown; otherwise, let $w(a,b) = 0$.

$w(a,b)$	$b=-2$	$b=-1$	$b=0$	$b=1$	$b=2$
$a=-2$	-1	-2	2	-2	-1
$a=-1$	-2	4	-4	4	-2
$a=0$	2	-4	12	-4	2
$a=1$	-2	4	-4	4	-2
$a=2$	-1	-2	2	-2	-1

For every finite subset S of $\mathbb{Z} \times \mathbb{Z}$, define

$$A(S) = \sum_{(\mathbf{s},\mathbf{s}') \in S \times S} w(\mathbf{s} - \mathbf{s}').$$

Prove that if S is any finite nonempty subset of $\mathbb{Z} \times \mathbb{Z}$, then $A(S) > 0$. (For example, if $S = \{(0,1),(0,2),(2,0),(3,1)\}$, then the terms in $A(S)$ are $12, 12, 12, 12, 4, 4, 0, 0, 0, 0, -1, -1, -2, -2, -4, -4$.)

Read it out loud

Strip the table away and say what is left. You have a double sum over $S \times S$ whose summand depends only on the *difference* of the two indices. That single feature is the entire problem: a kernel depending only on $\mathbf{s} - \mathbf{s}'$ is translation invariant, the associated quadratic form is a convolution, and translation invariant operators on $\mathbb{Z}^2$ are diagonalised by the characters $\mathbf{u} \mapsto e^{i\langle \mathbf{u}, \theta \rangle}$. So the sentence to say out loud is: this is a Toeplitz quadratic form, and "is it positive?" is the question "is its symbol nonnegative?".

The fields are Fourier analysis on the lattice $\mathbb{Z}^2$ and its dual torus, trigonometric identities of Chebyshev type, and a two variable polynomial inequality on the square $[-1,1]^2$. The table is a smokescreen: all that matters is that it is supported on a 5×5 box, that it is symmetric under $a \mapsto -a$ and under $b \mapsto -b$, and that its entries were manufactured by expanding a nonnegative expression. Somebody chose a nonnegative function on the torus and printed its Fourier coefficients; your job is to run the construction in reverse.

What is tested is whether $w(\mathbf{s} - \mathbf{s}')$ triggers a circuit. If it does, this is thirty minutes of careful routine work. If it does not, you will spend two hours charging the negative entries against the 12s and you will fail, because the failure is structural: the entries sum to zero, so for large S the positive mass is cancelled almost exactly and $A(S)$ is governed by the boundary of S, not its size. Within thirty seconds write the generating function $f(\theta) = \sum_{\mathbf{u} \in S} e^{i\langle \mathbf{u}, \theta \rangle}$, the symbol $g(\theta) = \sum_{\mathbf{c}} w(\mathbf{c}) e^{i\langle \mathbf{c}, \theta \rangle}$, and the guess $A(S) = \mathcal{M}\left[|f|^2 g\right]$. Note also the word "nonempty" and the strict inequality: strictness will not come from the positivity argument, so plan a separate final step.

Approaches, ranked worst to best

1. **Induct on the size of S.** *Cue:* a statement about all finite sets. *Circuit:* add one point and control the increment. Adding $\mathbf{p}$ changes A by $12 + 2\sum_{\mathbf{s} \in S} w(\mathbf{p} - \mathbf{s})$. Take S containing the four neighbours $\mathbf{p} \pm (1,0)$, $\mathbf{p} \pm (0,1)$: the increment is $12 + 2(-4-4-4-4) = -20 < 0$. So A is not monotone and the induction has no hypothesis to run on. Ranked last, and worth killing in one line so that you stop believing in it.

2. **Local charging.** *Cue:* a big positive diagonal entry against small negative ones. *Circuit:* pay each negative term from a nearby positive one. The diagonal contributes $12|S|$ and you try to distribute it. For S an $n \times n$ box, $A(S) = 32(n-1)$ while $|S| = n^2$, so $A(S)/|S| \to 0$: the positivity is a boundary effect, invisible to any local and uniform argument. Instructive, because that computation tells you the form is degenerate in the direction of constants.

3. **Write w as an autocorrelation.** *Cue:* if $w = \varphi \star \tilde{\varphi}$ then $A(S) = \sum_{\mathbf{u}} \left| \sum_{\mathbf{s} \in S} \varphi(\mathbf{s} + \mathbf{u}) \right|^2 \geq 0$ automatically. *Circuit:* exhibit the quadratic form as a sum of squares in the data. The right kind of idea, since this is what positive semidefiniteness means concretely, but searching for φ is blind guesswork and no finitely supported φ exists here: in two variables a nonnegative trigonometric polynomial need not be a squared modulus, which is exactly the failure of the Fejer and Riesz theorem beyond one variable.

4. **Diagonalise the quadratic form as a matrix.** *Cue:* $A(S) = \mathbf{1}_S^{\mathsf{T}} W \mathbf{1}_S$ with $W_{\mathbf{uv}} = w(\mathbf{u} - \mathbf{v})$. *Circuit:* a symmetric matrix is positive definite iff its eigenvalues are positive. Right, and since the eigenvectors of a translation invariant matrix are the characters, this approach *is* the next one in linear algebra clothing. Ranked here only because stated this way it invites finite dimensional eigenvalue estimates such as Gershgorin, which fail: the diagonal entry is 12 against an absolute off diagonal row sum of 36.

5. **Fourier transform on $\mathbb{Z}^2$.** *Cue:* the summand depends only on $\mathbf{s} - \mathbf{s}'$. *Circuit:* a translation invariant kernel is a convolution, characters diagonalise it, and positivity of the form is nonnegativity of the symbol, the easy half of the Herglotz theorem. Best, and forced by the shape of the sum. Write $A(S)$ as the average of $|f|^2 g$ over the torus, compute $g = 16G(\cos s, \cos t)$ from the double symmetry of the table, prove $G \geq 0$ on $[-1,1]^2$ by pairing each negative monomial with the positive monomial that divides it, and take the strictness from the equality analysis, which the same identities hand you for free.

The ideal solution

Write $\theta = (s,t)$, $\langle \mathbf{u}, \theta \rangle = u_1 s + u_2 t$ for $\mathbf{u} \in \mathbb{Z}^2$, and $e_{\mathbf{u}}(\theta) = e^{i\langle \mathbf{u}, \theta \rangle}$. Let

$$\mathcal{M}[F] := \frac{1}{4\pi^2} \int_0^{2\pi} \int_0^{2\pi} F(s,t)\, ds\, dt.$$

The orthogonality relation $\mathcal{M}[e_{\mathbf{u}}] = 1$ if $\mathbf{u} = \mathbf{0}$ and 0 otherwise follows at once from $\int_0^{2\pi} e^{ins} ds = 0$ for $n \neq 0$. For a finite nonempty $S \subseteq \mathbb{Z}^2$ put

$$f(\theta) = \sum_{\mathbf{u} \in S} e_{\mathbf{u}}(\theta), \qquad g(\theta) = \sum_{\mathbf{c} \in \mathbb{Z}^2} w(\mathbf{c})\, e_{\mathbf{c}}(\theta),$$

the second sum being finite since w vanishes off the 5×5 box.

Step 1 (the form is the average of $|f|^2 g$). Since the coefficients of f are real, $\overline{f(\theta)} = \sum_{\mathbf{v} \in S} e_{-\mathbf{v}}(\theta)$, so $|f|^2 = \sum_{\mathbf{u},\mathbf{v} \in S} e_{\mathbf{u}-\mathbf{v}}$ and

$$\mathcal{M}\big[|f|^2 g\big] = \sum_{\mathbf{u},\mathbf{v} \in S} \sum_{\mathbf{c} \in \mathbb{Z}^2} w(\mathbf{c})\, \mathcal{M}\big[e_{\mathbf{u}-\mathbf{v}+\mathbf{c}}\big] = \sum_{\mathbf{u},\mathbf{v} \in S} w(\mathbf{v} - \mathbf{u}) = A(S),$$

the only surviving terms being those with $\mathbf{c} = \mathbf{v} - \mathbf{u}$. All sums are finite, so the interchanges are trivial. Taking $g \equiv 1$ in the same computation gives the fact needed at the end,

$$\mathcal{M}\big[|f|^2\big] = \#\{(\mathbf{u},\mathbf{v}) \in S \times S : \mathbf{u} = \mathbf{v}\} = |S|.$$

Step 2 (compute the symbol). The table satisfies $w(a,b) = w(-a,b) = w(a,-b)$, so grouping the 25 terms into the classes $(|a|,|b|)$ and using $e^{i\alpha} + e^{-i\alpha} = 2\cos\alpha$ gives, with $z = \cos s$ and $y = \cos t$,

$$\begin{aligned} g &= w(0,0) + 2w(1,0)\cos s + 2w(2,0)\cos 2s + 2w(0,1)\cos t + 2w(0,2)\cos 2t \\ &\quad + 4w(1,1)\cos s\cos t + 4w(1,2)\cos s\cos 2t + 4w(2,1)\cos 2s\cos t + 4w(2,2)\cos 2s\cos 2t \\ &= 12 - 8z + 4(2z^2-1) - 8y + 4(2y^2-1) + 16zy - 8z(2y^2-1) - 8y(2z^2-1) - 4(2z^2-1)(2y^2-1). \end{aligned}$$

The constants cancel as $12-4-4-4=0$, the terms in z alone as $-8z+8z=0$, likewise those in y, and collecting the rest gives

$$g(s,t)=16\,G(\cos s,\cos t),\qquad G(z,y)=z^2+y^2+zy-z^2y-zy^2-z^2y^2.$$

Step 3 ($G\geq 0$ on the square). Every negative monomial of G is a positive monomial multiplied by a factor of modulus at most 1, and all three carry a factor zy, so the grouping to use is decided by the sign of zy. For $z,y\in[-1,1]$ we have two identities, each verified by expanding:

$$\text{(i)}\qquad G(z,y)=zy(1-zy)+z^2(1-y)+y^2(1-z),$$
$$\text{(ii)}\qquad G(z,y)=(z+y)^2-zy(1+z)(1+y).$$

If $zy\geq 0$, use (i): each of zy, $1-zy$, $1-y$, $1-z$, z^2, y^2 is nonnegative. If $zy\leq 0$, use (ii): $(z+y)^2\geq 0$ while $-zy\geq 0$, $1+z\geq 0$, $1+y\geq 0$. Hence $g\geq 0$ everywhere on the torus, and by Step 1, $A(S)\geq 0$.

Step 4 (where G vanishes). The same identities give the equality cases at no extra cost. If $zy\geq 0$ and $G=0$, all three terms of (i) vanish: $z^2(1-y)=0$ gives $z=0$ or $y=1$, and $y^2(1-z)=0$ gives $y=0$ or $z=1$. If $z=0$ the second forces $y=0$; if instead $y=1$ then, as $y\neq 0$, the second forces $z=1$, and $zy(1-zy)=0$ holds. So the solutions are $(0,0)$ and $(1,1)$. If $zy\leq 0$ and $G=0$, then $(z+y)^2=0$ and $zy(1+z)(1+y)=0$; the first gives $y=-z$ and substituting into the second gives $z^2(1-z^2)=0$, so the solutions are $(0,0)$, $(1,-1)$ and $(-1,1)$.

Hence G vanishes on $[-1,1]^2$ exactly at $(0,0)$, $(1,1)$, $(1,-1)$, $(-1,1)$. Since $\cos s=0$ has two solutions in $[0,2\pi)$ while each of $\cos s=1$ and $\cos s=-1$ has one, the zero set $N=\{\theta\in[0,2\pi)^2:g(\theta)=0\}$ consists of exactly seven points, and in particular is finite.

Step 5 (strict positivity). Suppose $A(S)=0$. The function $|f|^2g$ is continuous and, by Step 3, nonnegative, with average $A(S)=0$; a continuous nonnegative function with vanishing integral is identically zero, so $|f|^2g\equiv 0$. For $\theta\notin N$ we have $g(\theta)>0$, hence $f(\theta)=0$; so f vanishes off a finite set and therefore, being continuous on a space where the complement of a finite set is dense, vanishes identically. But then $|S|=\mathcal{M}\big[|f|^2\big]=0$, contradicting nonemptiness. Therefore $A(S)>0$. ■

Two remarks worth banking. The argument never used that the coefficients of f are 0 or 1: replacing f by $\sum_{\mathbf{u}}c_{\mathbf{u}}e_{\mathbf{u}}$ for finitely supported $c:\mathbb{Z}^2\to\mathbb{C}$ proves that $\sum_{\mathbf{u},\mathbf{v}}c_{\mathbf{u}}\overline{c_{\mathbf{v}}}w(\mathbf{u}-\mathbf{v})>0$ whenever $c\not\equiv 0$, that is, w is a strictly positive definite function on $\mathbb{Z}^2$. And $A(S)$ is an integer, so in fact $A(S)\geq 1$; the true minimum is 12, attained by a single point, while the $n\times n$ box gives $A(S)=32(n-1)$ for $n\geq 2$, so no bound $A(S)\geq c|S|$ can hold. The reason is visible in the symbol: $g(0,0)=16G(1,1)=0$, the entries of the table summing to zero, so the form is degenerate on the trivial character and large sets are cheap.

Layer 1: WHAT

Block 1. Read the kernel: $w(\mathbf{s}-\mathbf{s}')$ depends only on the difference, so A is a translation invariant quadratic form, that is, a convolution.

Block 2. Diagonalise: characters diagonalise convolutions, so pass to the torus, $A(S)=\mathcal{M}\big[|f|^2g\big]$.

Block 3. Reduce: since $|f|^2\geq 0$, it suffices to prove $g\geq 0$ pointwise. The set S has now left the problem entirely.

Block 4. Compute g: the double symmetry converts exponentials into cosines, and $\cos 2\alpha=2\cos^2\alpha-1$ converts those into a polynomial $16G(z,y)$ on the square.

Block 5. Prove $G\geq 0$ on the square by pairing each negative monomial with a positive monomial it divides, splitting on the sign of zy because all three negative monomials carry that factor.

Block 6. Read the equality cases off the same identities: four points, hence a finite zero set on the torus.

Block 7. Upgrade to strict: a continuous nonnegative function of zero average vanishes identically, $g > 0$ off a finite set, so $f \equiv 0$, contradicting $\mathcal{M}\left[|f|^2\right] = |S| \geq 1$.

Juxtaposition. The nominal route sees sixteen terms in the worked example and a big 12 on the diagonal, and starts accounting: 12 per point, -4 per edge neighbour, $+4$ per diagonal neighbour. That is zombie maths of the purest kind, and the $n \times n$ box shows why it can never close, since the leading terms cancel identically and the truth lives on the boundary.

The bifurcation point is the very first line: how you read $w(\mathbf{s} - \mathbf{s}')$. Read as "a number attached to each pair", you go to accounting. Read as "the kernel depends only on the difference", you go to Fourier. The two routes never meet again.

Layer 2: HOW

Block 1. **Cue.** The summand is a function of $\mathbf{s} - \mathbf{s}'$ alone. **Why natural.** Difference kernels are exactly the kernels invariant under translating S, and a quadratic form invariant under a group action should be studied in a basis adapted to the group. For $\mathbb{Z}^2$ acting on itself, that basis is the characters, because translation multiplies each character by a scalar. This is the principle that diagonalises a circulant matrix, and it is not special to this problem: convolution becomes multiplication, always. **Link to the next block.** You now need the dictionary between a set and a function on the torus, which is the generating function.

Block 2. **Cue.** A sum over $S \times S$ of a difference kernel, plus a wish to see squares. **Why natural.** $\sum_{\mathbf{u},\mathbf{v} \in S} e_{\mathbf{u}-\mathbf{v}}$ is exactly $|f|^2$, the identity behind every "count pairs with a given difference" argument. Multiplying by g and averaging kills every character but the trivial one, selecting $\mathbf{c} = \mathbf{v} - \mathbf{u}$. Equivalently $A(S)$ is the constant coefficient of the Laurent polynomial $f(x,y)f(x^{-1},y^{-1})g(x,y)$, and averaging over the two unit circles is how one extracts a constant coefficient. **Link to the next block.** The factor $|f|^2$ is nonnegative whatever S is, so all the content has been pushed into g.

Block 3. **Cue.** A product of a nonnegative factor with an unknown one, integrated. **Why natural.** Proving $g \geq 0$ proves the theorem for all S simultaneously. This is why the Fourier route dominates every combinatorial route: it replaces infinitely many statements, one per S, by one statement about a fixed function of two real variables. The price is a two variable inequality, which is finite work. **Link to the next block.** So compute g, in a form you can actually test for nonnegativity.

Block 4. **Cue.** The table is symmetric in $a \mapsto -a$ and in $b \mapsto -b$. **Why natural.** Symmetry pairs the exponentials into cosines, so g is real valued, which it had better be if it is to be nonnegative; then $\cos 2\alpha = 2\cos^2 \alpha - 1$, the first nontrivial case of the Chebyshev recursion, turns everything into a polynomial in z and y. Crucially the substitution also records the constraint $z, y \in [-1, 1]$, which is not a technicality but the whole reason the inequality is true, since $G(2,2) = -20 < 0$. **Link to the next block.** You now need a polynomial inequality on a box, and boxes have canonical nonnegative atoms.

Block 5. **Cue.** A polynomial with a few negative monomials, to be shown nonnegative on $[-1,1]^2$. **Why natural.** On the square the manifestly nonnegative quantities are $1 \pm z$, $1 \pm y$, $1 - zy$, squares and their products, so any certificate is assembled from those. Write each negative monomial as a positive monomial times a factor known to lie in $[-1,1]$: $z^2 y = z^2 \cdot y$, $zy^2 = y^2 \cdot z$, $z^2y^2 = zy \cdot zy$. That produces (i) at once, valid whenever the leftover zy is nonnegative. When $zy \leq 0$ the term $zy(1 - zy)$ turns against you, so regroup: $z^2 + y^2 + zy = (z+y)^2 - zy$ is comfortable when $-zy \geq 0$, and the remaining $-zy(1 + z + y + zy)$ factors as $-zy(1+z)(1+y)$, which is (ii). Neither identity is a rabbit from a hat; each is the natural grouping in its regime. **Link to the next block.** Both identities are sums of products of nonnegative factors, so their equality cases are free.

Block 6. **Cue.** You proved ≥ 0 but the problem said > 0. **Why natural.** A sum of nonnegative terms vanishes only if every term does, so the zero set follows from two or three small equations in each regime. Do it now, while the identities are in front of you: the alternative, quoting that the zero set of a nonzero real analytic function has measure zero, is heavier machinery for a weaker conclusion. **Link to the next block.** A finite zero set makes the closing continuity argument elementary.

Block 7. **Cue.** Strict inequality from a nonstrict one, with an integral in hand. **Why natural.** A continuous nonnegative function with zero integral is identically zero; this is where the continuity of $|f|^2 g$ earns its keep. Then f vanishes off a finite set, hence everywhere, hence S is empty. The identity $\mathcal{M}\left[|f|^2\right] = |S|$ is Parseval, and it is the only place nonemptiness is used, exactly as it should be, since the statement is false for $S = \emptyset$. **Link to the next block.** Done; the remarks on integrality and the box are for the Circuit Bank, not the proof.

Layer 3: WHY

The governing truth is the Herglotz theorem, the $\mathbb{Z}^d$ case of Bochner's theorem: a function w on $\mathbb{Z}^d$ is positive definite exactly when it is the Fourier transform of a nonnegative measure on the torus, and for finitely supported w that measure has the symbol g as its density. This problem asks for the easy direction of that equivalence, applied to a w constructed by running the theorem backwards. Once you know the theorem exists the problem is not a puzzle: it is a Fourier transform and a polynomial inequality on a box.

Two subsidiary truths carry weight. Convolution operators are diagonalised by characters, which is why S can be eliminated at Step 3. And positivity on a semialgebraic set is certified by combinations of the defining inequalities: on $[-1,1]^2$ those are $1 \pm z \geq 0$ and $1 \pm y \geq 0$, so every certificate is a positive combination of products of these with squares. That is the systematic reason the two identities look as they do, and the reason a split on the sign of zy is the natural first attempt, since zy is the one product of atoms whose sign the square does not fix.

The discernment mechanism: whenever a quantity is a double sum over a set with a summand depending only on the difference of the indices, you are looking at $\mathcal{M}\left[|f|^2 g\right]$ in disguise, and the question about all sets collapses to a question about one function. The recognition cue is syntactic, not semantic; you need not understand what w means, only see the subtraction inside its argument. Train it by rewriting every "count the pairs at difference $\mathbf{d}$" problem as a constant coefficient extraction until the translation is automatic.

The examiners' nudges are clear once you know the answer. They printed a symmetric table so the symbol would be real; they chose entries summing to zero so that no crude size based bound could work; they gave a worked example with sixteen listed terms as bait for the accounting route; and they asked for a strict inequality, warning that the natural argument gives only ≥ 0. A6 status is honest here: without the Fourier circuit installed there is no reasonable route in, and the knowledge gap is real rather than a matter of ingenuity.

Revolving concepts

Characters and the dual torus. The characters of $\mathbb{Z}^d$ are $\mathbf{u} \mapsto e^{i\langle \mathbf{u}, \theta \rangle}$ for θ in $(\mathbb{R}/2\pi\mathbb{Z})^d$, and the orthogonality relation $\mathcal{M}[e_{\mathbf{u}}] = [\mathbf{u} = \mathbf{0}]$ is the whole computational content of the subject at this level. See Book 1, field: Discrete structures and graphs, topic: Fourier analysis on abelian groups.

Convolution and Toeplitz forms. A kernel $K(\mathbf{u}, \mathbf{v}) = w(\mathbf{u} - \mathbf{v})$ gives the form $\langle w * c, c \rangle$ with symbol $\hat{w} = g$, and the values of g are the eigenvalues of the operator. The finite one dimensional analogue is a circulant matrix, whose eigenvalues are the discrete Fourier transform of its first row. See Book 1, field: Matrices and determinants, topic: circulant and Toeplitz matrices.

Herglotz and Bochner. Positive definite on $\mathbb{Z}^d$ iff the Fourier transform is a nonnegative measure. Positive definite functions also arise as autocorrelations $\varphi \star \tilde{\varphi}$; in one variable Fejer and Riesz gives $g = |\varphi|^2$ for a trigonometric polynomial φ, but this fails in two or more variables, which is exactly why the autocorrelation approach has no chance here. See Book 1, field: Real analysis, topic: positive definite functions.

Chebyshev polynomials, with the recursion generalised. $\cos(n\alpha) = T_n(\cos\alpha)$ where $T_0 = 1$, $T_1 = z$ and $T_{n+1}(z) = 2zT_n(z) - T_{n-1}(z)$. Any trigonometric polynomial even in α is a polynomial in $\cos\alpha$, obtained by running that linear recursion, and the substitution automatically encodes $\cos\alpha \in [-1, 1]$; in several variables you run it once per variable, which is Step 2. Solving the recursion by its characteristic equation $\lambda^2 - 2z\lambda + 1 = 0$, whose roots are $e^{\pm i\alpha}$ with $z = \cos\alpha$, gives the closed form $T_n(z) = \cos(n \arccos z)$; every constant coefficient linear recursion is handled the same way. See Book 1, field: Polynomials, topic: Chebyshev polynomials.

Certificates of positivity on a box. To prove $P \geq 0$ on $[-1, 1]^2$, write P as a positive combination of products of squares with the atoms $1 - z$, $1 + z$, $1 - y$, $1 + y$; such a representation always exists for strictly positive P (Positivstellensatz), and finding one by hand means matching each negative monomial with a positive monomial that divides it. See Book 1, field: Inequalities, topic: sums of squares and positivity certificates.

From nonnegative to positive. If $F \geq 0$ is continuous on a compact space with $\int F = 0$ then $F \equiv 0$; combined with an explicit description of where one factor vanishes, this converts any "≥ 0" proof into a "> 0" proof. See Book 1, field: Real analysis, topic: vanishing integrals.

Circuit Bank

- **WHEN** a double sum over $S \times S$ has a summand depending only on $\mathbf{s} - \mathbf{s}'$ **DO** write it as $\mathcal{M}\left[|f|^2 g\right]$ with f the generating function of S and g the symbol of the kernel **BECAUSE** difference kernels are convolutions, characters diagonalise convolutions, and the set then disappears from the problem
- **WHEN** you must prove a quadratic form in an arbitrary finite set is nonnegative **DO** compute the symbol and prove it is nonnegative pointwise **BECAUSE** by Herglotz that condition is necessary and sufficient, so you are guaranteed not to be wasting effort
- **WHEN** a trigonometric polynomial is invariant under $s \mapsto -s$ and $t \mapsto -t$ **DO** substitute $z = \cos s$, $y = \cos t$ through the Chebyshev recursion and remember the constraint $z, y \in [-1, 1]$ **BECAUSE** the problem becomes a polynomial inequality on a box, and the box constraint is usually essential rather than cosmetic
- **WHEN** you must certify a polynomial is nonnegative on $[-1, 1]^2$ **DO** match each negative monomial with a positive monomial that divides it, and split on the sign of the one product whose sign is undetermined **BECAUSE** the certificate must be built from the atoms $1 \pm z$, $1 \pm y$ and squares, and this matching is the mechanical way to find it
- **WHEN** your argument yields ≥ 0 but the problem demands > 0 **DO** extract the equality cases from the certificate you already wrote, show the zero set is small, and use that a continuous nonnegative function of zero integral vanishes identically **BECAUSE** the equality analysis is free once the proof is a sum of nonnegative terms, and it is far cheaper than any analytic continuation argument

Backtesting

1. First useful cue: the subtraction inside $w(\mathbf{s} - \mathbf{s}')$, announcing a translation invariant kernel and therefore Fourier; secondary cues are the double symmetry of the table and its entries summing to zero.

2. Method the expression suggested: express $A(S)$ as the constant coefficient of $f(x,y)f(x^{-1},y^{-1})g(x,y)$, extracted by averaging over the two unit circles, and then work only with g.
3. Where you would hesitate, and the thought to reinforce: at the two variable inequality, where the negative monomials look unmanageable. On a box every negative monomial is a positive monomial times a factor of modulus at most one, so pair them off and split only on the sign the box does not fix.
4. The trap the question sets: the worked example with its sixteen terms, inviting local accounting; and the strict inequality, which the main argument does not give, so that stopping at $A(S) \geq 0$ loses marks after the hard part is done.
5. What makes you recognise it faster next time: any weight depending on a difference of lattice points is a Fourier problem, full stop; and any table symmetric in both coordinates was printed from a cosine polynomial.
6. The reusable decision rule: convolution structure implies pass to the symbol; positivity of the form is nonnegativity of the symbol; strictness comes from the size of the symbol's zero set.

Mirror drills

1. Let $v(0) = 2$, $v(\pm 1) = -1$ and $v = 0$ elsewhere on $\mathbb{Z}$. Show $\sum_{s,s' \in S} v(s - s') > 0$ for every finite nonempty $S \subseteq \mathbb{Z}$, in two ways. *Answer:* the symbol is $2 - 2\cos s = 4\sin^2(s/2) \geq 0$, vanishing only at $s = 0$, so the argument above applies verbatim; combinatorially the sum is $2|S| - 2e$ with e the number of pairs of consecutive integers in S, and $e \leq |S| - 1$ since those pairs form a union of paths, giving at least 2.
2. Prove that $\mathcal{M}\left[e^{i(ns+mt)}\right] = 1$ if $n = m = 0$ and 0 otherwise, and deduce that $A(S)$ is the constant coefficient of $f(x,y)f(x^{-1},y^{-1})g(x,y)$. *Answer:* integrate in each variable separately using $\int_0^{2\pi} e^{ins} ds = 0$ for $n \neq 0$; the deduction is Step 1 read backwards.
3. Compute $A(S)$ for S the $n \times n$ box and say what the answer demands of any correct proof. *Answer:* the number of ordered pairs of difference (a,b) is $(n - |a|)(n - |b|)$, so $A(S) = \sum_{a,b} w(a,b)(n - |a|)(n - |b|) = 32n - 32$ for $n \geq 2$, using $\sum w = 0$, $\sum w(a,b)(|a| + |b|) = -32$ and $\sum w(a,b)|a||b| = -32$. Since $A(S)$ grows like the perimeter while $|S|$ grows like the area, any proof must be global, which rules out every local charging scheme.

13.7 B1. Telescoping a parity-keyed sign recursion

For positive integers n, let the numbers $c(n)$ be determined by the rules $c(1) = 1$, $c(2n) = c(n)$, and $c(2n+1) = (-1)^n c(n)$. Find the value of

$$\sum_{n=1}^{2013} c(n)\, c(n+2).$$

Read it out loud

Say what c is before you touch the sum. It is defined on positive integers by how the integer is built from a smaller one by doubling, so it is a recursion keyed on parity, not on subtraction by one. Two rules, one for each parity class of the argument: $c(2n) = c(n)$ carries no sign, while $c(2n+1) = (-1)^n c(n)$ injects a sign that depends on the smaller index n, not on the number $2n+1$ itself. From $c(1) = 1$ and two multiplications by ± 1 at every step you get $c(n) \in \{-1, 1\}$ for every n: this is a sign sequence, and the question asks for the sum of 2013 products of signs taken two apart.

The cue that should fire first is the shift. You are not asked for $\sum c(n)c(n+1)$, you are asked for $\sum c(n)c(n+2)$, and the recursion that defines c is itself about halving the argument. So ask what a shift of 2 in n does to the halved argument $\lfloor n/2 \rfloor$: it always adds exactly 1, whichever parity n has, because $\lfloor (n+2)/2 \rfloor = \lfloor n/2 \rfloor + 1$ for every integer n. A shift of 1 would not have this property, since it changes the halved index for one parity class and leaves it alone for the other. The problem has chosen the one shift value that lines the two parity classes up against each other. That is the guiding light: split the sum by the parity of the summation index n, not by unwinding each $c(n)$ down to $c(1)$ one integer at a time.

Within thirty seconds you should have written the two rules again, side by side, and asked what $c(2k)c(2k+2)$ and $c(2k+1)c(2k+3)$ become separately. Both reduce to a product $c(k)c(k+1)$, up to sign, and comparing those two signs is the entire problem.

Approaches, ranked worst to best

1. **Direct unwinding.** *Cue:* a finite, explicit recursion and a finite sum. *Circuit:* compute $c(n)$ for every n from 1 to 2015 by repeated halving, then add the 2013 products. (worst. It is correct and it terminates, but it treats 2013 as an instruction to do 2013 separate pieces of work rather than as a number whose parity structure you should exploit once. No step explains itself to the next step, so a single sign slip anywhere is invisible until the final total is already wrong. This is grinding, not reading.)

2. **Binary digit count.** *Cue:* $c(n)$ has a closed form from the binary expansion of n. *Circuit:* write n in binary as $b_k \cdots b_0$, use $c(n) = (-1)^{b_0 b_1 + b_1 b_2 + \cdots + b_{k-1} b_k}$, the parity of the count of adjacent 11 pairs, and analyse how adding 2 to n changes that count. (middle. The closed form is true and worth knowing, but adding 2 to n in binary can trigger a carry of unbounded length whenever the bit above the units digit already sits inside a run of ones, so comparing the 11-counts of n and $n+2$ needs a case split on how long that run is. It gets there, but it costs more ink than the recursion already hands you for free.)

3. **Pair by the recursion's own parity.** *Cue:* the recursion is stated separately for even and odd arguments. *Circuit:* split $\sum_n c(n)c(n+2)$ into its even-n and odd-n parts, reduce each part to $c(k)c(k+1)$ using the defining rules directly, and compare the two resulting signs. (best. No case split on binary digits, no carries: the two defining rules already do the case split for you, and each reduction is one line.)

The ideal solution

Every value of c is ± 1: $c(1) = 1$, and each defining rule multiplies a previously constructed value by ± 1, so by strong induction $c(n) \in \{-1, 1\}$ for all $n \geq 1$.

Separate the one term the pairing below cannot reach from the rest:

$$\sum_{n=1}^{2013} c(n)c(n+2) = c(1)c(3) + \sum_{n=2}^{2013} c(n)c(n+2).$$

For the remaining sum, group the index n into consecutive pairs $(2k, 2k+1)$ for $k = 1, \ldots, 1006$. These pairs run through $n = 2, 3, 4, \ldots, 2013$ exactly once each: $2 \cdot 1 = 2$ is the first even value in range, $2 \cdot 1006 + 1 = 2013$ is the last odd value in range, and the 1006 pairs cover the 2012 integers from 2 to 2013.

Fix $k \geq 1$ and reduce both halves of the pair using the two defining rules.

Even half: $c(2k) = c(k)$ and $c(2k+2) = c(2(k+1)) = c(k+1)$, so

$$c(2k)\, c(2k+2) = c(k)\, c(k+1).$$

Odd half: $c(2k+1) = (-1)^k c(k)$, and applying the odd rule again with $n = k+1$ gives $c(2k+3) = c(2(k+1)+1) = (-1)^{k+1} c(k+1)$, so

$$c(2k+1)\, c(2k+3) = (-1)^k (-1)^{k+1} c(k)c(k+1) = (-1)^{2k+1} c(k)c(k+1) = -c(k)c(k+1),$$

since $2k+1$ is odd. Adding the two halves,

$$c(2k)c(2k+2) + c(2k+1)c(2k+3) = c(k)c(k+1) - c(k)c(k+1) = 0$$

for every $k \geq 1$. Summing this identity over $k = 1, \ldots, 1006$ gives

$$\sum_{n=2}^{2013} c(n)c(n+2) = \sum_{k=1}^{1006} \Big(c(2k)c(2k+2) + c(2k+1)c(2k+3) \Big) = 0.$$

It remains to compute the boundary term. From the odd rule with $n = 1$, $c(3) = (-1)^1 c(1) = -1$, so $c(1)c(3) = 1 \cdot (-1) = -1$. Therefore

$$\sum_{n=1}^{2013} c(n)c(n+2) = -1 + 0 = \boxed{-1}.$$

Layer 1: WHAT

Block 1: recognise that c is built by a doubling recursion, so the natural way to organise any sum over c is by the same doubling structure, not by evaluating each term separately.

Block 2: notice the shift is 2, and that $\lfloor (n+2)/2 \rfloor = \lfloor n/2 \rfloor + 1$ for every n, so pairing the summation index by parity makes both halves of a pair reduce to the same smaller pair $(k, k+1)$.

Block 3: reduce the even half, $c(2k)c(2k+2)$, to $c(k)c(k+1)$ with no sign, directly from $c(2n) = c(n)$.

Block 4: reduce the odd half, $c(2k+1)c(2k+3)$, to $c(k)c(k+1)$ with a sign of $(-1)^{2k+1} = -1$, from $c(2n+1) = (-1)^n c(n)$ applied twice.

Block 5: compare the two reductions, same magnitude and opposite sign, so the pair sums to zero for every $k \geq 1$.

Block 6: sum the zero identity over all 1006 pairs, covering $n = 2$ to $n = 2013$, and separately evaluate the one term the pairing cannot reach, $n = 1$.

The nominal route computes $c(n)$ for $n = 1, \ldots, 2015$ one integer at a time, unwinding each down to $c(1)$ by repeated halving, then adds 2013 signed products. The bifurcation point is Block 1: the ideal route regroups the summation index by parity before evaluating a single $c(n)$, because the recursion defining c is itself parity-keyed, so any structure in a sum over c has to come from matching that same key. The zombie route evaluates first and looks for structure second, by which point every value is a bare number with no visible relationship to its neighbours.

Layer 2: HOW

Block 1. **Cue.** Two separate defining rules, one for even arguments and one for odd arguments. **Why natural.** A function defined by cases on parity has no reason to behave uniformly across an arbitrary sum. The only sums of it you can control are ones that respect the same parity split, so you regroup the index before computing anything. **Link to the next block.** Once you commit to a parity split of n, you need to know exactly which shift in n gives a clean, uniform shift in the halved index $\lfloor n/2 \rfloor$.

Block 2. **Cue.** The problem's shift is $c(n)c(n+2)$, exactly 2. **Why natural.** $\lfloor (n+2)/2 \rfloor = \lfloor n/2 \rfloor + 1$ holds for every n, of either parity, whereas a shift of 1 does not have this property. The shift 2 is the smallest value for which halving turns it into a uniform shift of 1, which is exactly what makes pairing $n = 2k$ with $n = 2k+1$ reduce both to the same smaller pair $(k, k+1)$. **Link to the next block.** Evaluate the even half of the pair first, since it uses the rule with no sign.

Block 3. **Cue.** $c(2k)$ and $c(2k+2)$ both have even argument. **Why natural.** $c(2n) = c(n)$ applies directly to both, with no sign to track, giving $c(2k)c(2k+2) = c(k)c(k+1)$ in one line. **Link to the next block.** The odd half uses the other rule, the one that carries a sign, so that sign is where the content of the problem is hiding.

Block 4. **Cue.** $c(2k+1)$ and $c(2k+3)$ both have odd argument, and the odd rule is $c(2n+1) = (-1)^n c(n)$. **Why natural.** Applying the odd rule once at $n = k$ and once at $n = k+1$ multiplies in $(-1)^k$ and $(-1)^{k+1}$, opposite signs for consecutive integers, so their product is always -1 regardless of k. The sign rule was written as $(-1)^n$, not as a fixed -1, precisely so that it flips between consecutive values of the reduced index. **Link to the next block.** Compare this signed reduction with the unsigned one from Block 3; they share the same magnitude $c(k)c(k+1)$.

Block 5. **Cue.** Even half equals $c(k)c(k+1)$, odd half equals $-c(k)c(k+1)$. **Why natural.** Two quantities that are negatives of each other sum to zero. This holds for every $k \geq 1$ with no exceptions, so it is safe to sum over all of them at once. **Link to the next block.** Sum this zero identity over the full range of k and account for exactly which values of n that range covers.

Block 6. **Cue.** The pairs $(2k, 2k+1)$ for $k = 1, \ldots, 1006$ cover $n = 2$ through $n = 2013$, leaving $n = 1$ untouched. **Why natural.** $n = 1$ has no partner, because the pairing needs both $2k$ and $2k+1$ inside the range, and $2k = 1$ has no integer solution. $n = 1$ sits outside the block structure, not inside it as a special case. **Link to the next block.** Evaluate $c(1)c(3)$ directly from the definition and add it to the remainder, now known to be zero.

Layer 3: WHY

The truth underneath the cancellation is that the recursion for c is first order in the halved index: everything about $c(n)$ is determined by $c(\lfloor n/2 \rfloor)$ and the parity of n. Consecutive integers $2k$ and $2k+1$ share the same halved index k, so any product of two values of c taken at arguments shifted by two collapses to a product at the halved indices, and the only thing that can differ between the even case and the odd case is a sign contributed by the odd rule. The shift of exactly 2 is what makes the halved indices of the two paired terms match (Layer 2, Block 2); this is not a coincidence of the problem, it is the reason the problem is solvable in closed form at all.

The discernment mechanism to install: whenever a sequence is defined by a recursion keyed on a modulus m (here $m = 2$, halving), and you must sum an expression built from that sequence at arguments shifted by a fixed d, check first whether d is a multiple of m. If it is, the shift descends to a uniform shift on the reduced index regardless of residue class, and pairing residues is likely to

telescope. If it is not, the reduced shift depends on the residue class itself, and you should expect casework rather than a clean pairing. Here $d = 2$ and $m = 2$, so the test passes immediately, which is exactly why Approach 3 costs so much less ink than Approach 2, an attempt to run the same idea in the wrong coordinate (binary digits of n directly, rather than the halved index).

What the examiners nudged toward: writing the recursion as two rules, one keyed on $2n$ and one on $2n + 1$, is itself an instruction to think in halved indices; asking for a shift of 2, rather than 1 or 3, is an instruction that this particular shift behaves uniformly. Every number the problem gives you is load-bearing.

More generally, for any integer $e \geq 1$ and $k \geq 1$, the same two reductions give $c(2k)c(2k + 2e) = c(k)c(k + e)$ and $c(2k + 1)c(2k + 2e + 1) = (-1)^e c(k)c(k + e)$, so the paired sum $c(2k)c(2k + 2e) + c(2k + 1)c(2k + 2e + 1)$ equals $c(k)c(k + e)\big(1 + (-1)^e\big)$: it is 0 whenever e is odd, exactly the cancellation above, and it is $2c(k)c(k + e)$ whenever e is even, which does not cancel but instead reduces a shift-$2e$ sum to twice a shift-e sum of the same type, a smaller instance of the same problem. The shift $d = 2$ actually asked for is the case $e = 1$, the smallest odd e, which is exactly why the problem telescopes to a single boundary term rather than to a smaller sum of the same shape.

Revolving concepts

Sequences defined by a doubling recursion. A sequence $a(n)$ with $a(2n) = g(n, a(n))$ and $a(2n + 1) = h(n, a(n))$ is determined entirely by the binary expansion of n read one digit at a time; such sequences are called 2-automatic, produced by a finite automaton reading the base-2 digits of n. A question about $a(n)$ for a specific large n, or a sum of a over a range, should be attacked by descending along this digit structure rather than by treating n as an opaque integer. See Book 1, field: Discrete structures and graphs, topic: automatic sequences.

The Rudin and Shapiro sequence. The sequence here, with $c(1) = 1$, $c(2n) = c(n)$, $c(2n + 1) = (-1)^n c(n)$, is exactly the Rudin and Shapiro sequence, with closed form $c(n) = (-1)^{b_0 b_1 + b_1 b_2 + \cdots + b_{k-1} b_k}$ for binary expansion $b_k \cdots b_0$: the exponent counts adjacent pairs of 1's. The sequence is known for partial sums $\left|\sum_{n \leq N} c(n)\right|$ that grow only like $\sqrt{N}$, far slower than a typical ± 1 sequence, and for producing ± 1 coefficient polynomials with the smallest possible maximum modulus on the unit circle. See Book 1, field: Number theory, topic: digit sum sequences.

Telescoping by index-shift pairing. Grouping a sum's index into blocks whose contribution collapses is the method of differences applied to a pair rather than a single term. The generalisation above, where an even e doubles rather than cancels, shows the technique is really a reduction, of which cancellation is the special case e odd. See Book 1, field: Sequences and recurrences, topic: telescoping sums.

Circuit Bank

- **WHEN** a sequence is defined by separate rules for even and odd arguments **DO** regroup any sum over that sequence by the parity of the summation index before evaluating a single term **BECAUSE** the sequence's own structure is keyed on parity, so only a parity-respecting regrouping can expose it
- **WHEN** you must sum a shifted product $a(n)a(n + d)$ of a base-m-keyed recursion **DO** check whether m divides d before choosing a method **BECAUSE** when it does, the shift descends to a uniform shift on the reduced index for every residue class, which is what makes pairing and telescoping possible
- **WHEN** a pairing argument covers a range of the summation index but not all of it **DO** isolate and separately evaluate every boundary term the pairing cannot reach, and state explicitly why it cannot reach them **BECAUSE** silently absorbing a boundary term into a cancellation

you only proved for the interior is the most common way to get the right method and the wrong final number

- **WHEN** a recursive sign rule is written as $(-1)^n$ rather than a fixed constant **DO** treat the dependence on n as load-bearing and check what happens to it at consecutive values of n **BECAUSE** a sign that flips with n is what produces cancellation across consecutive terms, a constant sign would not

Backtesting

1. First useful cue: the recursion is stated as two separate rules keyed on the parity of the argument, so any sum over c should be regrouped by parity before evaluation.
2. Method the expression suggested: pair the summation index as $(2k, 2k+1)$, because the shift of 2 descends to a uniform shift of 1 on the halved index for both parities.
3. Where you would hesitate, and the thought to reinforce: at the range bookkeeping, whether the pairing covers $n = 1$. Reinforce by checking explicitly which n would require $2k = 1$ or $2k + 1 = 1$ for an integer $k \geq 1$, and noticing neither has a solution, so $n = 1$ sits outside the paired block by construction.
4. The trap the question sets: assuming the whole sum telescopes to zero and forgetting the one boundary term, worth -1, which is the entire final answer.
5. What makes you recognise it faster next time: seeing a recursion keyed on doubling together with a summation shift that is itself even. Test immediately whether the shift is a multiple of the recursion's modulus.
6. The reusable decision rule: when a sum's shift is a multiple of a recursion's base, pair residue classes of the index; the two rules of the recursion applied to consecutive reduced indices differ by at most a controllable sign.

Mirror drills

1. Show that $\sum_{n=1}^{N} c(n)c(n+2) = -1$ for every odd $N \geq 3$, not only $N = 2013$. *Answer:* the same pairing covers $n = 2, \ldots, N$ in blocks of two whenever N is odd, so the interior always cancels and only $c(1)c(3) = -1$ survives, independent of N.
2. Using the generalised identity for shift $2e$, reduce $\sum_{n=1}^{2013} c(n)c(n+4)$ to a sum of shift-2 type. *Hint:* here $e = 2$ is even, so each interior pair contributes $2c(k)c(k+2)$ rather than 0; separate the boundary terms $n = 1, 2, 3$ by hand and rewrite the rest as twice a shift-2 sum, which you already know how to telescope.
3. Define $d(1) = 1$, $d(2n) = d(n)$, $d(2n+1) = -d(n)$, a constant sign rather than $(-1)^n$, and compute $\sum_{n=1}^{7} d(n)d(n+2)$. *Answer:* -3. Here the odd rule applied twice gives $(-d(k))(-d(k+1)) = +d(k)d(k+1)$, the same sign as the even half, so interior pairs now double instead of cancel. This is the precise reason the original problem needed a sign rule depending on n, not a fixed -1.

13.8 B2. Maximising a cosine polynomial at zero

Let $C = \bigcup_{N=1}^{\infty} C_N$, where C_N denotes the set of those cosine polynomials of the form

$$f(x) = 1 + \sum_{n=1}^{N} a_n \cos(2\pi n x)$$

for which:

(i) $f(x) \geq 0$ *for all real* x*, and*

(ii) $a_n = 0$ *whenever* n *is a multiple of* 3*.*

Determine the maximum value of $f(0)$ *as* f *ranges through* C*, and prove that this maximum is attained.*

Read it out loud

Notice first that the quantity you are asked to maximise is not hidden: $f(0) = 1 + \sum_{n=1}^{N} a_n \cos(0) = 1 + \sum_{n=1}^{N} a_n$, so the whole problem is really how large the coefficients of a nonnegative cosine polynomial can sum to, given that every third coefficient is forced to be zero. Two hypotheses are in tension. Hypothesis (i) is a global statement, true at every real x at once, and on its own it is hard to use directly, since you cannot check infinitely many points one by one. Hypothesis (ii) is a local, arithmetic statement about the index n, tied to the number 3.

The cue that should fire is exactly that number 3. A cosine polynomial is a finite sum of functions $\cos(2\pi n x)$, each periodic in x with period $1/n$, and evaluating the whole sum at a rational point $x = j/m$ makes every term's value depend only on n mod m, because $\cos(2\pi n \cdot j/m)$ is unchanged when n is shifted by a multiple of m. Hypothesis (ii) hands you the modulus $m = 3$ for free. So the global hypothesis (i), unusable as stated, becomes usable the instant you specialise it to $x = 1/3$: it turns into a single numeric inequality involving only $\sum a_n$, which is exactly the quantity $f(0)$ needs.

Within thirty seconds you should have written $f(1/3) \geq 0$ and started computing $\cos(2\pi n/3)$ for the values of n that are still allowed to be nonzero.

Approaches, ranked worst to best

1. **Continuous optimisation over all coefficients.** *Cue:* maximise a linear function subject to $f \geq 0$ everywhere. *Circuit:* treat $f \geq 0$ for all x as an infinite family of linear constraints on $(a_1, \ldots, a_N)$ and reach for Lagrange multipliers or duality. (worst. This is the technically general method and it is not wrong, but the constraint set is infinite dimensional, one inequality per real x, and N itself is free. Nothing in the raw optimisation tells you to look at $x = 1/3$ specifically, so you would have to rediscover the binding constraint before the machinery does any work, which means the machinery is not actually doing the work.)

2. **Trial and error on small N.** *Cue:* the extremal example, once seen, is small. *Circuit:* try $N = 1$, find $f(0) \leq 2$ is forced, push to $N = 2$ and search numerically for coefficients that do better. (middle. This can stumble onto the right construction by luck, but it produces no proof that 3 is an upper bound for every N, only a candidate value. A full solution still needs the argument below to close the gap between having found something that gives 3 and knowing that nothing gives more.)

3. **Evaluate at the point the hypothesis names.** *Cue:* the vanishing condition is stated modulo 3. *Circuit:* compute $f(1/3)$ directly, using that $\cos(2\pi n/3)$ takes only one value among the surviving coefficients. (best. One evaluation converts an infinite dimensional hypothesis into a single linear inequality in $\sum a_n$, which is exactly $f(0) - 1$.)

The ideal solution

Upper bound. Fix $f \in C_N \subset C$. For any n with $3 \nmid n$, the residue of n modulo 3 is 1 or 2, and

$$\cos\left(\tfrac{2\pi n}{3}\right) = \cos\left(\tfrac{2\pi}{3}\right) = \cos\left(\tfrac{4\pi}{3}\right) = -\tfrac{1}{2},$$

since $\cos(4\pi/3) = \cos(2\pi - 2\pi/3) = \cos(2\pi/3)$. So every n with $3 \nmid n$ contributes $a_n \cos(2\pi n/3) = -\frac{1}{2}a_n$, while every n with $3 \mid n$ has $a_n = 0$ by hypothesis (ii) and so contributes 0 regardless of its cosine value. Hence

$$f\left(\tfrac{1}{3}\right) = 1 + \sum_{n=1}^{N} a_n \cos\left(\tfrac{2\pi n}{3}\right) = 1 - \tfrac{1}{2}\sum_{n=1}^{N} a_n,$$

where the sum on the right is the full sum $\sum_{n=1}^{N} a_n$, since the terms with $3 \mid n$ vanish in it too. By hypothesis (i), $f(1/3) \geq 0$, so $\sum_{n=1}^{N} a_n \leq 2$. Therefore

$$f(0) = 1 + \sum_{n=1}^{N} a_n \leq 3.$$

This holds for every $f \in C$, so 3 is an upper bound for $f(0)$ on all of C.

A tight example. Equality above forces $f(1/3) = 0$. Since $f \geq 0$ on all of $\mathbb{R}$ and f is smooth, a zero at the interior point $x = 1/3$ is a global minimum, so it is not a simple sign-changing zero: nonnegativity forbids that. The natural object to try is a perfect square vanishing exactly where $\cos(2\pi x) = -\frac{1}{2}$, namely a multiple of $\big(2\cos(2\pi x) + 1\big)^2$. Set

$$f(x) := \tfrac{1}{3}\big(2\cos(2\pi x) + 1\big)^2,$$

manifestly nonnegative for every x, since it is $\frac{1}{3}$ times a real square. Expand it with the double angle identity $\cos(4\pi x) = 2\cos^2(2\pi x) - 1$:

$$\big(2\cos(2\pi x) + 1\big)^2 = 4\cos^2(2\pi x) + 4\cos(2\pi x) + 1 = 2\big(2\cos^2(2\pi x) - 1\big) + 4\cos(2\pi x) + 3 = 2\cos(4\pi x) + 4\cos(2$$

so

$$f(x) = 1 + \tfrac{4}{3}\cos(2\pi x) + \tfrac{2}{3}\cos(4\pi x).$$

This is a cosine polynomial with $N = 2$, $a_1 = \frac{4}{3}$, $a_2 = \frac{2}{3}$. Neither index 1 nor 2 is a multiple of 3, so hypothesis (ii) holds vacuously, and hypothesis (i) holds because f is a nonnegative multiple of a square. Hence $f \in C_2 \subset C$, and

$$f(0) = 1 + \tfrac{4}{3} + \tfrac{2}{3} = 3.$$

The upper bound is attained, so the maximum value of $f(0)$ on C is $\boxed{3}$.

Layer 1: WHAT

Block 1: read $f(0) = 1 + \sum a_n$; the target of the problem is literally the sum of the coefficients.

Block 2: read hypothesis (ii) as an instruction of where to evaluate, namely $x = 1/3$, since it names the modulus 3.

Block 3: compute $\cos(2\pi n/3) = -\frac{1}{2}$ for every surviving n, so $f(1/3)$ collapses to a single linear expression in $\sum a_n$.

Block 4: use $f(1/3) \geq 0$ to get $\sum a_n \leq 2$ and hence $f(0) \leq 3$.

Block 5: read the equality condition, $f(1/3) = 0$, as forcing a global minimum of a nonnegative function, which motivates a perfect square ansatz vanishing there.

Block 6: build $\frac{1}{3}(2\cos 2\pi x + 1)^2$, expand via the double angle identity, read off a_1, a_2, check both hypotheses explicitly, and confirm $f(0) = 3$.

The nominal route sets up a Lagrangian or a blind coefficient search over an unspecified N, treating the divisibility condition as bookkeeping to carry through the optimisation rather than as an instruction. The bifurcation point is Block 2: the ideal route reads the number 3 in the hypothesis as telling you where to plug in, the zombie route treats it as just an algebraic side condition on the index set.

Layer 2: HOW

Block 1. **Cue.** $f(0)$ is asked for, and $\cos(0) = 1$. **Why natural.** Every $\cos(2\pi n \cdot 0)$ term equals 1, so the target collapses to 1 plus the coefficient sum with no cosine values to compute at all. Knowing exactly what you are chasing before you touch the constraint tells you what form the constraint needs to be squeezed into. **Link to the next block.** You need a way to bound $\sum a_n$ using hypothesis (i), which as stated says nothing about that sum directly.

Block 2. **Cue.** The vanishing condition is stated as a divisibility by 3. **Why natural.** A coefficient constraint tied to a modulus m is an invitation to evaluate the cosine polynomial at $x = j/m$, since that is exactly the substitution that makes every surviving term's phase depend only on n mod m, collapsing a sum over many different cosines into a sum over few. **Link to the next block.** Compute what that substitution actually does to the terms that are still allowed to be nonzero.

Block 3. **Cue.** The surviving residues modulo 3 are 1 and 2, and $\cos(2\pi/3) = \cos(4\pi/3) = -\frac{1}{2}$. **Why natural.** Cosine is even and 2π-periodic, so residues r and $m - r$ modulo m always give equal values at $x = 1/m$; with $m = 3$ the only two nonzero residues, 1 and 2, are exactly this pair, so every surviving coefficient is multiplied by the same number. **Link to the next block.** A single evaluation now gives a genuine linear inequality in $\sum a_n$, which you can combine with nonnegativity.

Block 4. **Cue.** $f(1/3) \geq 0$ by hypothesis (i). **Why natural.** This is the only place hypothesis (i) is used in the bound: one point suffices, because the earlier step arranged for that one point to see every surviving coefficient at once. **Link to the next block.** The bound $f(0) \leq 3$ is now proved; existence of an example achieving it is a separate task.

Block 5. **Cue.** Equality in $f(0) \leq 3$ forces $f(1/3) = 0$ exactly, together with $f \geq 0$ everywhere. **Why natural.** A nonnegative smooth function that touches zero at an interior point has that point as a global minimum, hence a critical point, and cannot cross through zero there; the natural way to build such a function is as a square, or a positive multiple of one, vanishing at the required point. **Link to the next block.** Choose the simplest expression, linear in $\cos(2\pi x)$, that vanishes at $\cos(2\pi x) = -\frac{1}{2}$, and square it.

Block 6. **Cue.** $2\cos(2\pi x) + 1$ vanishes exactly when $\cos(2\pi x) = -\frac{1}{2}$. **Why natural.** Squaring it and rescaling by $\frac{1}{3}$ so the constant term is 1 turns the candidate into an actual member of C; expanding with the double angle identity is the only way to see its coefficients a_1, a_2 explicitly and check both hypotheses against them. **Link to the next block.** Nothing remains: every hypothesis has been checked and the target value computed directly.

Layer 3: WHY

The mechanism beneath the bound is a roots-of-unity style collapse: evaluating a cosine polynomial at a rational point $x = j/m$ replaces $2\pi n x$ by an angle depending only on n mod m. In general this splits the surviving coefficients into as many distinct cosine values as there are residue classes paired by $r \leftrightarrow m - r$ that are not otherwise excluded. What makes $m = 3$ special is that it is the

smallest modulus with exactly one such pair covering every nonzero residue: 1 and $2 = 3 - 1$. A modulus like 4 does not have this property, since its nonzero residues split into the pair $\{1, 3\}$, giving $\cos(\pi/2) = 0$, and the self-paired residue $\{2\}$, giving $\cos(\pi) = -1$, two different values rather than one, so a single evaluation would not collapse everything there. The problem's choice of divisibility by 3 is exactly what makes one evaluation enough.

The construction step rests on a deeper fact worth naming rather than treating as luck: the Fejér and Riesz theorem states that every trigonometric polynomial nonnegative on the whole real line is $|P(e^{2\pi ix})|^2$ for some polynomial P, so restricting a search for an extremal nonnegative cosine polynomial to perfect squares is not a guess, it is a complete parametrisation. Once you also know the extremiser must vanish at $x = 1/3$, the square is forced up to scale, since the only degree-one factor of $\cos(2\pi x)$ vanishing there is a multiple of $2\cos(2\pi x) + 1$.

The discernment mechanism: whenever a family of Fourier or cosine coefficients is constrained to vanish on an arithmetic progression modulo m, and you are asked to bound a value of the function at a specific point, test evaluation at rational points with denominator m before attempting a general optimisation. Separately, whenever a linear bound derived from one inequality is tight, look for the extremal object as a square (or sum of squares) forced to vanish exactly where the bound was evaluated, since Fejér and Riesz guarantees this search is exhaustive for nonnegative trigonometric polynomials.

What the examiners nudged toward: writing the coefficient condition as divisibility by 3, rather than simply "$a_1 = a_2 = 0$" or some other finite list, is what points at a modulus to substitute rather than a fixed set of indices to avoid; asking for $f(0)$, the value at the one point where every cosine is 1, sets up the exact mirror of the evaluation at $x = 1/3$, where every surviving cosine is a single other value.

Revolving concepts

The Fejér and Riesz theorem. Every trigonometric polynomial $g(\theta) = \sum_{k=-N}^{N} c_k e^{ik\theta}$ that is nonnegative for all real θ can be written as $|P(e^{i\theta})|^2$ for a polynomial P of degree N. Consequently every nonnegative cosine polynomial is a positive multiple of a perfect square of a lower cosine polynomial, which is why the construction in this problem is a systematic search, not a guess. See Book 1, field: Real analysis, topic: nonnegative trigonometric polynomials.

Collapsing a sum by evaluating at a rational point. For a cosine polynomial, evaluating at $x = j/m$ makes every term depend only on n mod m, and $\cos(2\pi r/m) = \cos(2\pi(m - r)/m)$ for every residue r, so residues r and $m - r$ always coincide in value. This pairing covers every nonzero residue with a single value only for small m, notably $m = 3$; for larger m several distinct values survive and a single point evaluation is not enough. See Book 1, field: Number theory, topic: roots of unity filters.

Chebyshev polynomials. $\cos(n\theta) = T_n(\cos\theta)$ for the Chebyshev polynomial T_n of the first kind, with $T_2(t) = 2t^2 - 1$. This is the identity used to expand $(2\cos(2\pi x) + 1)^2$ back into a genuine cosine polynomial in x, and it generalises: T_n satisfies $T_{n+1}(t) = 2tT_n(t) - T_{n-1}(t)$ with $T_0 = 1$, $T_1 = t$, the same recursion that $\cos(n\theta)$ obeys as a function of n for fixed θ. See Book 1, field: Polynomials, topic: Chebyshev polynomials.

The Fejér kernel and unbounded coefficient sums. $F_N(y) = 1 + \sum_{j=1}^{N} 2\left(1 - \frac{j}{N+1}\right)\cos(2\pi jy)$ is nonnegative for every y and has $F_N(0) = N + 1$, unbounded as $N \to \infty$. Substituting $y = 3x$ turns F_N into a nonnegative cosine polynomial supported only on multiples of 3, showing that the reversed divisibility condition, requiring $a_n = 0$ *unless* $3 \mid n$, has no finite maximum at all. This is why excluding multiples of 3, rather than restricting to them, is essential to the finite answer 3. See Book 1, field: Real analysis, topic: summability kernels.

Circuit Bank

- **WHEN** a Fourier or cosine coefficient constraint vanishes on an arithmetic progression modulo m **DO** evaluate the function at $x = j/m$ for a small j **BECAUSE** the surviving cosines collapse to values depending only on n mod m, turning a global nonnegativity constraint into a single numeric inequality
- **WHEN** a linear bound obtained from one evaluation is tight **DO** search for the extremal object as a perfect square, or a positive multiple of one, vanishing exactly at the point the bound used **BECAUSE** the Fejér and Riesz theorem guarantees every nonnegative trigonometric polynomial has such a squared form, so the search is complete, not a guess
- **WHEN** you need to convert between $\cos(n\theta)$ and powers of $\cos\theta$ **DO** use the double angle or Chebyshev identity $T_n(\cos\theta) = \cos(n\theta)$ directly **BECAUSE** it is faster than expanding through complex exponentials and it keeps every quantity manifestly real

Backtesting

1. First useful cue: hypothesis (ii) names a modulus, 3, which is an instruction to evaluate the cosine polynomial at $x = 1/3$.
2. Method the expression suggested: a single evaluation collapses every surviving coefficient's cosine to $-\frac{1}{2}$, turning the global constraint $f \geq 0$ into the single inequality $\sum a_n \leq 2$.
3. Where you would hesitate, and the thought to reinforce: whether the constructed extremal example genuinely satisfies hypothesis (ii). Reinforce by checking the indices actually used, here only 1 and 2, against the divisibility condition explicitly, rather than assuming a square automatically qualifies.
4. The trap the question sets: attempting a full Lagrangian optimisation over an unspecified N with infinitely many pointwise constraints, which is technically sound but never terminates without first finding the binding point.
5. What makes you recognise it faster next time: a coefficient hypothesis phrased as divisibility by a fixed modulus, paired with a nonnegativity hypothesis; test rational evaluation points with that modulus as denominator before anything else.
6. The reusable decision rule: once a linear bound is proved tight at a specific point, build the extremal example as a square vanishing there rather than searching coefficient space unguided.

Mirror drills

1. Cosine polynomials with $a_n = 0$ whenever n is even, otherwise unconstrained, with $f \geq 0$; find the maximum of $f(0)$. *Answer:* evaluate at $x = 1/2$, where $\cos(n\pi) = -1$ for every surviving odd n, giving $f(0) \leq 2$; attained by $f(x) = 1 + \cos(2\pi x)$, already nonnegative since $\cos \geq -1$.
2. Same setup as the original problem but with $a_n = 0$ required whenever $4 \mid n$ instead of $3 \mid n$. Why does evaluating at $x = 1/4$ fail to reproduce the same clean bound? *Hint:* the surviving residues modulo 4 are $1, 2, 3$, and $\cos(2\pi n/4)$ equals 0 for $n \equiv 1, 3$ but -1 for $n \equiv 2$, two distinct values rather than one, so a single evaluation only bounds the coefficients with $n \equiv 2 \pmod 4$, not the full sum.
3. Suppose instead $a_n = 0$ is required *unless* $3 \mid n$ (the reversed condition). Show $f(0)$ has no finite maximum on the resulting family. *Hint:* substitute $x \mapsto 3x$ into the Fejér kernel F_N;

the result is nonnegative, supported only on multiples of 3, and has value $N+1$ at $x=0$, unbounded as $N \to \infty$.

13.9 B3. Additivity of a modular set function

Let $\mathcal{P}$ be a nonempty collection of subsets of $\{1, \ldots, n\}$ such that:

(i) if $S, S' \in \mathcal{P}$, then $S \cup S' \in \mathcal{P}$ and $S \cap S' \in \mathcal{P}$, and

(ii) if $S \in \mathcal{P}$ and $S \neq \emptyset$, then there is a subset $T \subset S$ such that $T \in \mathcal{P}$ and T contains exactly one fewer element than S.

Suppose that $f : \mathcal{P} \to \mathbb{R}$ is a function such that $f(\emptyset) = 0$ and

$$f(S \cup S') = f(S) + f(S') - f(S \cap S') \text{ for all } S, S' \in \mathcal{P}.$$

Must there exist real numbers $f_1, \ldots, f_n$ such that

$$f(S) = \sum_{i \in S} f_i$$

for every $S \in \mathcal{P}$?

Read it out loud

Name the structure before you name a strategy. A collection of subsets closed under union and intersection is closed under both lattice operations of the Boolean lattice at once, so $(\mathcal{P}, \subseteq)$ is a lattice in its own right, sitting inside $2^{\{1,\ldots,n\}}$. The identity $f(S \cup S') = f(S) + f(S') - f(S \cap S')$ is not an arbitrary equation, it is inclusion and exclusion for two sets, imposed as an axiom on an abstract real valued f rather than derived from f being a size or a measure. A function on a lattice satisfying exactly this identity has a name, a valuation, and the question is asking whether every valuation on this kind of lattice is automatically the simplest possible kind: a sum of weights attached to single elements.

Hypothesis (ii) is the second cue, and it is doing different work from (i). It says that below every nonempty set of the family sits another set of the family exactly one element smaller. That is a graded, covering condition: it lets you strip one element at a time and never leave $\mathcal{P}$, all the way down. Whenever a hypothesis hands you a covering structure like this, the shape of the proof is almost forced: define something using one covering step, check it does not depend on which step you used, then induct along the covering structure.

Within thirty seconds you should have written: for an element i that appears in some set of $\mathcal{P}$, look at a pair $S = T \sqcup \{i\}$ with both $S, T \in \mathcal{P}$, call $f(S) - f(T)$ the weight of i, and worry immediately about whether two different such pairs could disagree.

Approaches, ranked worst to best

1. **Assume singletons are available.** *Cue:* the target formula $f(S) = \sum_{i \in S} f_i$ looks like it wants $f_i = f(\{i\})$. *Circuit:* set $f_i := f(\{i\})$ whenever $\{i\} \in \mathcal{P}$ and try to build S up from singletons using the modularity identity. (worst, and not merely inelegant: it is not even well posed in general. Hypothesis (ii) guarantees a subset one element smaller than any nonempty S, not that every element has its own singleton in $\mathcal{P}$; a family can satisfy (i) and (ii) while never containing a single one-element set. Defining f_i this way can leave some elements with no definition at all.)

2. **Explore special cases.** *Cue:* small, symmetric families are easy to compute by hand. *Circuit:* check the claim when $\mathcal{P}$ is the full power set, or when $\mathcal{P}$ is a chain totally ordered by inclusion. (middle. This is genuinely useful for building intuition and for discovering the right definition of f_i, and it is where you should start scratch work. But a chain or a power set both happen to contain every singleton, so success there proves nothing about a general $\mathcal{P}$; stopping here leaves the real difficulty, families without singletons, completely untouched.)

3. **Define an invariant intrinsically and induct along the covering structure.** *Cue:* the two hypotheses are exactly a lattice identity and a graded covering condition. *Circuit:* define the weight of i as a difference across any covering step containing it, prove that difference is independent of the step using the modularity identity itself, then induct on $|S|$ using hypothesis (ii) for both the base case and the inductive step. (best. Every hypothesis is used exactly where it is needed, nothing about singletons is assumed, and the argument is the same length regardless of how far from a chain or a power set $\mathcal{P}$ happens to be.)

The ideal solution

Lemma 13.9.1. *If some $S \in \mathcal{P}$ contains i, then there exist $S, T \in \mathcal{P}$ with $S = T \sqcup \{i\}$, that is S is T together with i, disjointly.*

Proof. Among all sets in $\mathcal{P}$ containing i, choose S of minimum cardinality; such S exists since the family of sets in $\mathcal{P}$ containing i is nonempty and finite. Since $S \neq \emptyset$, hypothesis (ii) gives $T \subset S$ with $T \in \mathcal{P}$ and $|T| = |S| - 1$, so $T = S \setminus \{x\}$ for the unique element $x \in S \setminus T$. If $x \neq i$ then $i \in T$, and $T \in \mathcal{P}$ has smaller cardinality than S while still containing i, contradicting the choice of S. So $x = i$, that is $T = S \setminus \{i\}$, as claimed. □

Lemma 13.9.2. *Suppose $S_1 = T_1 \sqcup \{i\}$ and $S_2 = T_2 \sqcup \{i\}$ with $S_1, S_2, T_1, T_2 \in \mathcal{P}$. Then*

$$f(S_1) - f(T_1) = f(S_2) - f(T_2).$$

Proof. Since $i \notin T_2$, distributing intersection over union gives $S_1 \cap T_2 = (T_1 \cup \{i\}) \cap T_2 = T_1 \cap T_2$, and $S_1 \cup T_2 = T_1 \cup T_2 \cup \{i\}$. Apply the hypothesis to the pair $(S_1, T_2) \in \mathcal{P} \times \mathcal{P}$:

$$f(T_1 \cup T_2 \cup \{i\}) = f(S_1 \cup T_2) = f(S_1) + f(T_2) - f(S_1 \cap T_2) = f(S_1) + f(T_2) - f(T_1 \cap T_2).$$

Symmetrically, since $i \notin T_1$, $T_1 \cap S_2 = T_1 \cap T_2$ and $T_1 \cup S_2 = T_1 \cup T_2 \cup \{i\}$, the same set as before, and applying the hypothesis to the pair (T_1, S_2):

$$f(T_1 \cup T_2 \cup \{i\}) = f(T_1 \cup S_2) = f(T_1) + f(S_2) - f(T_1 \cap S_2) = f(T_1) + f(S_2) - f(T_1 \cap T_2).$$

The left sides agree, so $f(S_1) + f(T_2) = f(T_1) + f(S_2)$, which rearranges to the claim. □

Define $f_1, \ldots, f_n$ as follows. If no $S \in \mathcal{P}$ contains i, set $f_i = 0$. Otherwise, by Lemma 1 choose any $S, T \in \mathcal{P}$ with $S = T \sqcup \{i\}$, and set $f_i := f(S) - f(T)$; by Lemma 2 this value does not depend on which such pair was chosen.

Claim 13.9.3. *$f(S) = \sum_{i \in S} f_i$ for every $S \in \mathcal{P}$.*

Proof. First, $\emptyset \in \mathcal{P}$: since $\mathcal{P}$ is nonempty, take any $S_0 \in \mathcal{P}$ and, if it is nonempty, apply hypothesis (ii) repeatedly to descend through sets of $\mathcal{P}$ of strictly decreasing size, necessarily reaching $\emptyset \in \mathcal{P}$ after finitely many steps. The hypothesis $f(\emptyset) = 0$ is therefore meaningful, and it is the base case of an induction on $|S|$ for $S \in \mathcal{P}$: the empty sum on the right agrees with $f(\emptyset) = 0$.

For the inductive step, let $S \in \mathcal{P}$ be nonempty and suppose the claim holds for every set of $\mathcal{P}$ with fewer elements than S. By hypothesis (ii), there is $T \in \mathcal{P}$, $T \subset S$, with $|T| = |S| - 1$; write $S = T \sqcup \{j\}$ for the unique $j \in S \setminus T$. This is exactly a covering pair isolating j, so by the definition of f_j, applied to this particular pair,

$$f(S) - f(T) = f_j.$$

By the induction hypothesis, $f(T) = \sum_{i \in T} f_i$. Adding,

$$f(S) = f(T) + f_j = \sum_{i \in T} f_i + f_j = \sum_{i \in T \cup \{j\}} f_i = \sum_{i \in S} f_i,$$

since T and $\{j\}$ are disjoint with union S. This completes the induction. □

So yes: such real numbers $f_1, \ldots, f_n$ always exist.

Layer 1: WHAT

Block 1: name the two hypotheses' separate jobs. Closure under union and intersection makes the modularity identity a genuine, checkable algebraic fact about $\mathcal{P}$; the one-smaller subset condition is a covering condition letting you strip elements one at a time and stay inside $\mathcal{P}$.

Block 2: since the target is additivity over single elements, define, for each element i that occurs somewhere in $\mathcal{P}$, its own marginal contribution as the jump in f across a pair that adds exactly i. Hypothesis (ii) is exactly what produces such a pair.

Block 3: worry immediately that different covering pairs for the same i might give different jumps, and resolve this by feeding two candidate pairs into the modularity identity at once, using closure under union and intersection to force the two resulting expressions to agree.

Block 4: with every f_i pinned down, or set to zero, prove $f(S) = \sum_{i \in S} f_i$ by strong induction on $|S|$, with hypothesis (ii) supplying both the base case, that $\emptyset \in \mathcal{P}$, and the inductive step, a size-one-smaller predecessor of S inside $\mathcal{P}$.

Block 5: conclude that such $f_1, \ldots, f_n$ always exist.

The nominal route tries to define f_i as $f(\{i\})$ and build every set up from singletons using the modularity identity, or attempts an induction over an arbitrary enumeration of $\mathcal{P}$ not respecting inclusion. The bifurcation point is Block 2: the moment you ask what quantity, defined intrinsically from f and not assuming any singleton lies in $\mathcal{P}$, deserves to be called f_i. Recognising that a difference across a covering step, not a value at a literal singleton, is the right invariant is the fork between an argument that stalls the moment $\mathcal{P}$ has no singletons and one that never needed them.

Layer 2: HOW

Block 1. **Cue.** A family of subsets closed under both union and intersection, together with a graded covering condition. **Why natural.** Closure under the two lattice operations is precisely what makes $(\mathcal{P}, \subseteq)$ a lattice, and a graded covering condition is precisely what a rank-based induction needs; naming the structure up front tells you which two tools to reach for before you have written a single line of proof. **Link to the next block.** The target claim, additivity over elements, asks for a per-element quantity, so the next question is how to define one without assuming more than the hypotheses give you.

Block 2. **Cue.** The target formula sums over $i \in S$, so it wants a value f_i attached to each element. **Why natural.** The only elements the hypotheses let you isolate are ones for which hypothesis (ii) supplies a covering pair; that pair is a legitimate way to isolate i's contribution even when $\{i\}$ itself is nowhere in $\mathcal{P}$. **Link to the next block.** A quantity defined by an arbitrary choice is not yet well defined; the choice of covering pair must be shown not to matter.

Block 3. **Cue.** Two different covering pairs, $S_1 = T_1 \sqcup \{i\}$ and $S_2 = T_2 \sqcup \{i\}$, both isolating the same element i. **Why natural.** Apply the governing identity to (S_1, T_2) and separately to (T_1, S_2): because i sits outside both T_1 and T_2, both applications compute f of the very same set, $T_1 \cup T_2 \cup \{i\}$, on the union side, forcing the two right-hand expressions to be equal. This is not a special property of the particular pairs chosen, it works for any two covering pairs at once. **Link to the next block.** With f_i now well defined for every occurring element, the additivity claim becomes a statement you can try to prove by induction on the size of S.

Block 4. **Cue.** The target is a statement for every $S \in \mathcal{P}$, and hypothesis (ii) supplies a smaller set inside $\mathcal{P}$ for every nonempty one. **Why natural.** Strong induction on $|S|$ is the natural vehicle whenever a hypothesis is phrased in terms of cardinality directly, as (ii) is; the covering pair used to descend from S to a smaller set is exactly a covering pair isolating one element, so it plugs directly

into the definition of f_j from Block 3. **Link to the next block.** The only remaining gap is the base case, since $f(\emptyset) = 0$ is only useful if $\emptyset \in \mathcal{P}$ in the first place.

Block 5. Cue. $\mathcal{P}$ is nonempty, but nothing yet says $\emptyset$ is one of its members. **Why natural.** Hypothesis (ii), applied repeatedly starting from any element of $\mathcal{P}$, strictly decreases cardinality at each step and must terminate, and the only place it can terminate is at $\emptyset$; this is the same covering hypothesis doing a second job, securing the floor of the induction rather than a step of it. **Link to the next block.** The induction is now complete in both its base case and its step, so the claim holds for every $S \in \mathcal{P}$.

Layer 3: WHY

The truth underneath the proof is that $\mathcal{P}$, closed under union and intersection, is a finite distributive lattice, and by Birkhoff's representation theorem every finite distributive lattice arises exactly this way, as a ring of subsets of some ground set. The hypothesis on f is the definition of a valuation on that lattice. Hypothesis (ii) additionally makes the lattice graded by cardinality with every element covering another, and a valuation on a graded lattice of this kind is reconstructible from its jumps across covering pairs in exactly the way a function with path-independent increments along the edges of a graph is reconstructible from a single value plus those increments: you need the increments to be well defined regardless of path, which is Lemma 2, and you need every point to be reachable from the base point by a path of covering steps, which is hypothesis (ii). The word valuation is not decoration: it tells you the exact theorem this problem is a disguised instance of, and it tells you where to look if a harder version of this problem ever drops hypothesis (ii) and asks what survives.

The discernment mechanism: whenever a hypothesis gives you closure under two lattice-like operations together with an inclusion-exclusion identity, and a second hypothesis gives you a graded, one-step-at-a-time covering property, look for a per-element invariant defined as a jump across one covering step, prove it path-independent using the SAME identity applied to two candidate steps simultaneously, then induct along the covering relation for the base case and the general claim together. The reason equality, not merely an inequality, is essential here is worth isolating: Lemma 2 needs the identity in both directions at once to force $f(S_1) - f(T_1) = f(S_2) - f(T_2)$ exactly; a submodular inequality, $f(S \cup S') + f(S \cap S') \leq f(S) + f(S')$, of the kind matroid rank functions satisfy, only gives one-directional information and does not pin down a well defined per-element jump. The two parallel-element matroid on $\{1, 2\}$, with $\text{rank}(\{1, 2\}) = 1$ but $\text{rank}(\{1\}) = \text{rank}(\{2\}) = 1$, is exactly such a submodular function that is not additive over elements, and it satisfies hypotheses (i) and (ii) trivially on the full power set of $\{1, 2\}$, confirming the equality hypothesis is where the additivity genuinely comes from, not the lattice structure alone.

What the examiners nudged toward: phrasing hypothesis (ii) as "exactly one fewer element", rather than merely "a proper subset", is the unmistakable signature of a graded poset with a rank function, and it is the direct instruction to induct on cardinality; writing the identity on f with a union and an intersection rather than, say, only unions of disjoint sets, is the instruction that the natural setting is a lattice closed under both operations, not merely a union-closed family.

Revolving concepts

Distributive lattices as rings of sets. A family of subsets of a finite set closed under union and intersection forms a distributive lattice under inclusion, and by Birkhoff's representation theorem every finite distributive lattice arises this way up to relabelling, so $\mathcal{P}$ here is a completely general finite distributive lattice, not a special case of one. See Book 1, field: Discrete structures and graphs, topic: lattice theory.

Valuations on a lattice. A function f on a lattice with $f(a \vee b) + f(a \wedge b) = f(a) + f(b)$ for all a, b is a valuation, or modular function; the hypothesis in this problem is exactly this identity specialised to a ring of sets, with $\vee, \wedge$ read as union and intersection. See Book 1, field: Discrete structures and graphs, topic: lattice valuations.

Graded posets and induction along covering relations. Hypothesis (ii) says $(\mathcal{P}, \subseteq)$ is graded by cardinality, with every nonempty element covering another element of $\mathcal{P}$ exactly one size smaller; such a poset supports strong induction on rank, with the base case obtained by iterating the covering property down to the minimum element. The same pattern, reconstruct a valuation from its edge jumps by inducting along covering relations, applies to any graded lattice with a modular rank function, not only rings of sets: for instance the flats of a matroid under a modular rank function, or the subgroup lattice of a finite group restricted to a modular chain. See Book 1, field: Combinatorics, topic: graded posets.

Matroid rank as a submodular, non additive contrast. A matroid rank function satisfies $\text{rank}(A \cup B) + \text{rank}(A \cap B) \leq \text{rank}(A) + \text{rank}(B)$, submodularity, with strict inequality possible: two parallel elements $1, 2$ have $\text{rank}(\{1,2\}) = 1 \neq \text{rank}(\{1\}) + \text{rank}(\{2\}) = 2$. This shows the equality in this problem's hypothesis, not merely an inequality, is what forces additivity over elements. See Book 1, field: Combinatorics, topic: matroid rank functions.

Two-set inclusion and exclusion. For a counting or measure function μ, $\mu(A \cup B) = \mu(A) + \mu(B) - \mu(A \cap B)$ is inclusion and exclusion for two sets; this problem imposes exactly that identity as an axiom on an abstract real valued f, which is what makes the lattice reading of the problem natural rather than invented. See Book 1, field: Combinatorics, topic: inclusion and exclusion.

Circuit Bank

- **WHEN** a hypothesis gives closure under two lattice-like operations together with an inclusion-exclusion style identity **DO** recognise the structure as a valuation on a lattice **BECAUSE** this tells you immediately which theorems, such as Birkhoff's representation theorem and the theory of modular functions, are relevant, and reframes "prove additivity" as "prove the valuation is determined by its covering-edge jumps"
- **WHEN** a covering-type hypothesis says there is always a legal object exactly one smaller or bigger, still in the family **DO** set up strong induction on size or rank **BECAUSE** it supplies both the base case, by iterating down to the bottom of the family, and the inductive step, one legal predecessor, for free
- **WHEN** you want a per-element quantity from a set function, but individual elements' singleton sets might not lie in your family **DO** define it as a difference across any legal covering step containing that element, then immediately prove independence of the step using the same functional identity applied to two candidate steps at once **BECAUSE** assuming singletons exist without proof is exactly the trap this kind of problem is built to catch

Backtesting

1. First useful cue: closure under union and intersection together with an inclusion-exclusion style identity names f as a valuation on a lattice, which tells you the target is really "is every valuation on this lattice additive over ground set elements".
2. Method the expression suggested: define a per-element weight as a jump across a covering pair supplied by hypothesis (ii), prove it well defined by feeding two candidate pairs into the modularity identity at once, then induct on cardinality.
3. Where you would hesitate, and the thought to reinforce: whether $\emptyset \in \mathcal{P}$ can be assumed. Reinforce by deriving it explicitly from hypothesis (ii), iterating the one-smaller condition down from any starting set, rather than treating $f(\emptyset) = 0$ as proof that $\emptyset$ is a member.

4. The trap the question sets: defining $f_i := f(\{i\})$, which silently assumes every element has its own singleton set inside $\mathcal{P}$, a fact hypothesis (ii) never actually guarantees.
5. What makes you recognise it faster next time: seeing closure under both union and intersection together with a "one fewer element" covering condition; that pairing is the signature of a graded lattice valuation problem, not a generic functional equation.
6. The reusable decision rule: when a functional identity is imposed as an axiom on a lattice-closed family together with a graded covering hypothesis, reconstruct the function from jumps across covering steps rather than trying to build every element up from singletons.

Mirror drills

1. Suppose additionally that $\mathcal{P}$ is exactly the full power set of $\{1, \ldots, n\}$. Show directly that $f_i = f(\{i\})$, matching the general construction. *Answer:* the pair $(\{i\}, \emptyset)$ is a legal covering pair for every i, since $\emptyset \in \mathcal{P}$ here trivially, so by the well-definedness lemma the general construction's f_i equals $f(\{i\}) - f(\emptyset) = f(\{i\})$.
2. Show that $\mathcal{P} = \{\{1\}, \{1,2\}\}$, for $n \geq 2$, is closed under union and intersection but does not contain $\emptyset$, and identify exactly which part of hypothesis (ii) this violates. *Answer:* $\{1\} \cup \{1,2\} = \{1,2\}$ and $\{1\} \cap \{1,2\} = \{1\}$, both in $\mathcal{P}$, so (i) holds; but (ii) applied to $S = \{1\}$ demands a subset of size 0 inside $\mathcal{P}$, forcing $\emptyset \in \mathcal{P}$, which this family does not contain, so (ii) fails and this is precisely the kind of family (ii) is written to exclude.
3. Replace the hypothesis by the inequality $f(S \cup S') + f(S \cap S') \leq f(S) + f(S')$ (submodularity) under the same (i) and (ii). Show the conclusion can fail. *Hint:* take $\mathcal{P}$ the full power set of $\{1,2\}$ and f = rank of the matroid where $1, 2$ are parallel: $\text{rank}(\emptyset) = 0$, $\text{rank}(\{1\}) = \text{rank}(\{2\}) = \text{rank}(\{1,2\}) = 1$; this satisfies the inequality but $\text{rank}(\{1,2\}) \neq \text{rank}(\{1\}) + \text{rank}(\{2\})$, so no such f_1, f_2 exist.

13.10 B4. Variance of a product of continuous functions

For any continuous real-valued function f defined on the interval $[0,1]$, let

$$\mu(f) = \int_0^1 f(x)\,dx, \quad \mathrm{Var}(f) = \int_0^1 (f(x) - \mu(f))^2\,dx,$$
$$M(f) = \max_{0\le x\le 1} |f(x)|.$$

Show that if f and g are continuous real-valued functions defined on the interval $[0,1]$, then

$$\mathrm{Var}(fg) \le 2\,\mathrm{Var}(f)M(g)^2 + 2\,\mathrm{Var}(g)M(f)^2.$$

Read it out loud

Say the structure before you touch a pen. The interval $[0,1]$ with dx is a probability space, because its total measure is 1. So μ is expectation, Var is variance, and M is the supremum norm. The claim is a statement about two random variables: the variance of a product is controlled by the variance of each factor weighted by the size of the other factor. Nothing about $[0,1]$ matters except the total mass 1, and nothing about continuity matters except that it makes $M(f)$ an attained maximum (extreme value theorem) and every integral finite. This is L^2 geometry on a probability space, plus one elementary inequality. There is no integral to evaluate, no special function, no differentiation. What is being tested is whether you know what variance *is*, as opposed to what its formula looks like.

The second cue is the constant 2 sitting in front of both terms on the right. A clean factor of 2 in an inequality almost always comes from one place: $(A+B)^2 \le 2A^2 + 2B^2$. Read the right side backwards and it is telling you what to do. It wants the quantity inside $\mathrm{Var}(fg)$ split into exactly two pieces, one piece carrying $\mathrm{Var}(f)$ and $M(g)$, the other carrying $\mathrm{Var}(g)$ and $M(f)$. Two terms, two bounds, one factor of 2 each. The examiners have told you the shape of the proof in the statement.

The third cue decides the problem. Var is invariant under adding a constant, but M is not. So the reflex "without loss of generality $\mu(f) = 0$" is illegal here: centring f leaves the left side and the Var factors alone but destroys your control of $M(f)$. That one observation is the entire difficulty. You may not normalise the means away, so you must carry $\mu(f)$ and $\mu(g)$ through the argument and kill them only at the last line with $|\mu(f)| \le M(f)$. Every candidate who lost time on this problem lost it by trying to centre and then not knowing what to do with the M terms.

Within thirty seconds you should have written three lines: $f_0 = f - \mu(f)$ and $g_0 = g - \mu(g)$; the algebraic identity $fg - \mu(f)\mu(g) = f_0 g + \mu(f) g_0$; and the fact that $\mathrm{Var}(h) \le \int_0^1 (h(x) - c)^2\,dx$ for *every* constant c, not just $c = \mu(h)$. Those three lines are the solution.

Approaches, ranked worst to best

1. **Bound everything by sup norms.** *Cue:* $M(f)$ and $M(g)$ appear on the right. *Circuit:* crude domination: replace each factor by its maximum. (worst, and it fails outright. You write $\mathrm{Var}(fg) \le \int_0^1 f^2 g^2 \le M(f)^2 M(g)^2$ and then discover the right side of the problem does not dominate that. Test it: take g constant. Then $\mathrm{Var}(fg) = g^2\mathrm{Var}(f) = \mathrm{Var}(f)M(g)^2$, while your bound gives $M(f)^2 M(g)^2$, which is far too big. The right side of the problem vanishes whenever f and g are both constant; any proof built from quantities that do not vanish there is dead on arrival. Kill this route in ten seconds by testing constants.)

2. **Full expansion.** *Cue:* everything in sight is an explicit integral. *Circuit:* expand $\mathrm{Var}(fg) = \int f^2 g^2 - (\int fg)^2$, substitute $f = f_0 + \mu(f)$ and $g = g_0 + \mu(g)$, and grind. (this is the route the official solution essentially takes, in an organised form. It works. It costs seven or eight terms,

several of which cancel only because $\int f_0 = \int g_0 = 0$, and it needs an auxiliary inequality at the end to absorb the surviving cross term $2\mu(f)\mu(g)\int f_0 g_0$. Two thirds of a page of correct algebra with no structural guidance, and every line is a chance for a skipped-calculation error. Zombie maths: correct, expensive, and it teaches you nothing about why the 2 is there.)

3. **Variance of a sum.** *Cue:* the right side is a sum of two terms with a 2 each. *Circuit:* write fg as a sum of two functions and use $\mathrm{Var}(A+B) \le 2\mathrm{Var}(A) + 2\mathrm{Var}(B)$. (good, and morally the ideal route. $fg = f_0 g + \mu(f)g$, so $\mathrm{Var}(fg) \le 2\mathrm{Var}(f_0 g) + 2\mu(f)^2\mathrm{Var}(g)$, then $\mathrm{Var}(f_0 g) \le \int f_0^2 g^2 \le M(g)^2\mathrm{Var}(f)$. It ranks just below the next one only because it makes you quote the sub-additivity of variance as a separate fact rather than exhibiting it.)

4. **Distance to the constants.** *Cue:* Var is a squared distance, and the problem forbids centring. *Circuit:* $\mathrm{Var}(h) = \min_c \int_0^1 (h-c)^2$, so choose the constant yourself. (best. You never compute $\mu(fg)$ at all: you bound the minimum by one well-chosen competitor, $c = \mu(f)\mu(g)$, which factors the difference as $f_0 g + \mu(f)g_0$ in one line. Then $(A+B)^2 \le 2A^2 + 2B^2$ pointwise and two sup-norm extractions finish it. Four lines, no cancellation, and it hands you the strictly stronger inequality in the remark below for free.)

The ideal solution

Write $\mu_f = \mu(f)$, $\mu_g = \mu(g)$, $f_0 = f - \mu_f$ and $g_0 = g - \mu_g$, so that

$$\int_0^1 f_0 = \int_0^1 g_0 = 0, \qquad \int_0^1 f_0^2 = \mathrm{Var}(f), \qquad \int_0^1 g_0^2 = \mathrm{Var}(g).$$

All of these integrals exist because f and g are continuous on a compact interval, and for the same reason $M(f)$ and $M(g)$ are attained and finite.

Lemma 13.10.1. *For any continuous h on $[0,1]$ and any real constant c,*

$$\mathrm{Var}(h) \le \int_0^1 (h(x) - c)^2 \, dx,$$

with equality exactly when $c = \mu(h)$.

Proof. Put $h_0 = h - \mu(h)$. Then $h - c = h_0 + (\mu(h) - c)$, and since $\int_0^1 h_0 = 0$ the cross term integrates to zero:

$$\int_0^1 (h-c)^2 = \int_0^1 h_0^2 + 2(\mu(h)-c)\int_0^1 h_0 + (\mu(h)-c)^2 = \mathrm{Var}(h) + (\mu(h)-c)^2.$$

The last term is nonnegative and vanishes only for $c = \mu(h)$. □

Apply the lemma to $h = fg$ with the constant $c = \mu_f \mu_g$. The point of this choice is the identity

$$f(x)g(x) - \mu_f\mu_g = \big(f(x) - \mu_f\big)g(x) + \mu_f\big(g(x) - \mu_g\big) = f_0(x)g(x) + \mu_f g_0(x),$$

which is checked by expanding the middle expression: the two copies of $\mu_f g(x)$ cancel. Hence

$$\mathrm{Var}(fg) \le \int_0^1 \big(f_0(x)g(x) + \mu_f g_0(x)\big)^2 dx.$$

Now use $(A+B)^2 \le 2A^2 + 2B^2$, valid for all reals because it rearranges to $(A-B)^2 \ge 0$, at each point x:

$$\mathrm{Var}(fg) \le 2\int_0^1 f_0(x)^2 g(x)^2 \, dx + 2\mu_f^2 \int_0^1 g_0(x)^2 \, dx.$$

For the first integral, $g(x)^2 \le M(g)^2$ for every x and $f_0(x)^2 \ge 0$, so

$$\int_0^1 f_0^2 g^2 \le M(g)^2 \int_0^1 f_0^2 = \operatorname{Var}(f) M(g)^2.$$

The second integral is $\operatorname{Var}(g)$. Finally

$$|\mu_f| = \left| \int_0^1 f(x)\,dx \right| \le \int_0^1 |f(x)|\,dx \le M(f),$$

so $\mu_f^2 \le M(f)^2$. Putting the three estimates together,

$$\operatorname{Var}(fg) \le 2\operatorname{Var}(f) M(g)^2 + 2\operatorname{Var}(g) M(f)^2,$$

which is the required inequality.

Remark 13.10.2. The same three lines give something stronger at no extra cost. Writing $\|u\|_2 = (\int_0^1 u^2)^{1/2}$, the triangle inequality in L^2 (Minkowski) applied to $f_0 g + \mu_f g_0$ gives

$$\sqrt{\operatorname{Var}(fg)} \le \|f_0 g\|_2 + |\mu_f|\,\|g_0\|_2 \le M(g)\sqrt{\operatorname{Var}(f)} + M(f)\sqrt{\operatorname{Var}(g)},$$

and squaring recovers the stated inequality through $(u+v)^2 \le 2u^2 + 2v^2$. So the constant 2 is exactly the slack in one application of the quadratic mean against the arithmetic mean. The 2 is not optimal: taking $g \equiv 1$ gives $\operatorname{Var}(fg) = \operatorname{Var}(f)$ and $\operatorname{Var}(g) = 0$, $M(g) = 1$, so no constant below 1 can work. The true optimal constant lies somewhere in $[1, 2]$ and the problem sensibly does not ask for it.

Layer 1: WHAT

Block 1. Read $[0, 1]$ as a probability space and Var as a squared L^2 distance from h to the constant functions.

Block 2. Notice that you cannot normalise $\mu(f)$ to 0, because $M(f)$ is not translation invariant. Conclusion: do not centre the inputs; centre the *output* instead.

Block 3. Bound $\operatorname{Var}(fg)$ by $\int (fg - c)^2$ for a constant c of your choosing, and choose $c = \mu(f)\mu(g)$ because it makes $fg - c$ factor as $f_0 g + \mu(f) g_0$.

Block 4. Split with $(A + B)^2 \le 2A^2 + 2B^2$. This is where the 2 in the problem is spent.

Block 5. Extract sup norms: $g^2 \le M(g)^2$ inside the first integral, and $\mu(f)^2 \le M(f)^2$ by the triangle inequality for integrals.

The nominal route bifurcates from the ideal at Block 3. The zombie writes $\operatorname{Var}(fg) = \int f^2 g^2 - \left(\int fg\right)^2$, because that is the definition unpacked, and then substitutes $f = f_0 + \mu_f$, $g = g_0 + \mu_g$ into both terms and expands. That produces the correct answer after eight terms and one extra auxiliary inequality. The ideal route refuses to compute $\mu(fg)$ at all, on the grounds that a minimum only ever needs to be bounded above by one competitor. **The bifurcation point is the line where you decide whether to expand** $\operatorname{Var}(fg)$ **or to over-estimate it by a distance to a constant you get to name.** Every saving in this problem comes from that one decision.

Layer 2: HOW

Block 1. Cue. The three definitions given in the question are exactly expectation, variance and supremum norm on a measure space of total mass 1. The question defines them rather than naming them, which is the examiner telling you that the probabilistic reading is available but not assumed. **Why natural.** A definition-level reading always beats a formula-level reading. $\operatorname{Var}(h) = \int (h - \mu(h))^2$ is a formula; "the squared L^2 distance from h to the constant function nearest it" is what the object is. The second reading immediately supplies a family of upper bounds, one for each constant, and upper bounds are what you need. **Link to the next block.** Once variance is a distance to the constants, the next question asks itself: which constant should I compare fg to?

Block 2. **Cue.** $\mathrm{Var}(f+c) = \mathrm{Var}(f)$ but $M(f+c) \neq M(f)$. **Why natural.** The standard reflex on any variance problem is to assume the mean is zero. Here the right side of the inequality contains M, which is not translation invariant, so that reflex would be changing the problem. Spotting a forbidden normalisation early is worth more than any amount of algebra later; it tells you that $\mu(f)$ and $\mu(g)$ are genuine actors in the proof and must survive to the last line. **Link to the next block.** If the means cannot be removed at the start, they must be removed at the end, and the only tool for that is $|\mu(f)| \leq M(f)$. Now you know the last line of the proof before you know the middle.

Block 3. **Cue.** You need a constant c near fg. The only constants in the problem are $\mu(f)$, $\mu(g)$ and their combinations. **Why natural.** Take $c = \mu_f \mu_g$ because it is the unique choice that makes $fg - c$ split into two products, each with one centred factor: $fg - \mu_f\mu_g = f_0 g + \mu_f g_0$. This is the same telescoping move as $ab - a'b' = (a-a')b + a'(b-b')$, which you already use for products of sequences and for the product rule. The right side of the problem has two terms, so you need exactly two pieces, so you need exactly one telescoping step. **Link to the next block.** The expression is now a sum of two functions, and the target is a bound on the square of that sum.

Block 4. **Cue.** A squared sum, and a target with a 2 in front of each term. **Why natural.** $(A+B)^2 \leq 2A^2 + 2B^2$ is the cheapest possible way to break a squared sum, and the presence of the 2s in the statement is confirmation that the intended proof breaks the sum exactly once and crudely. If the intended constant had been 1 you would have had to be delicate about the cross term; the 2 is the examiners paying you to be lazy. **Link to the next block.** Two integrals remain, each with one centred factor and one uncentred factor.

Block 5. **Cue.** $\int f_0^2 g^2$ has a factor bounded by a constant and a factor whose integral is a named quantity. **Why natural.** This is Hoelder with the exponent pair $(1, \infty)$, which in plain language is: pull the maximum out of the integral. It costs one line and it is the only estimate available that keeps $\mathrm{Var}(f)$ intact. The second integral is $\mathrm{Var}(g)$ on the nose, and the coefficient μ_f^2 is converted by the triangle inequality for integrals, which is where the promise made in Block 2 is honoured. **Link to the next block.** Nothing remains. Assemble.

Layer 3: WHY

The mathematical truth underneath is that $\sqrt{\mathrm{Var}}$ is a seminorm. Consider the space of continuous functions on $[0,1]$ modulo the constants: $\mathrm{Var}(h)$ is the squared L^2 norm of the class of h in that quotient. Two consequences follow immediately and both are used. First, a seminorm satisfies the triangle inequality, so $\sqrt{\mathrm{Var}(A+B)} \leq \sqrt{\mathrm{Var}(A)} + \sqrt{\mathrm{Var}(B)}$, which is exactly the sub-additivity that makes the two-term split legal. Second, a squared distance to a subspace is a minimum over that subspace, so it is bounded above by the value at any single point of it. Almost all of the ink saved in this solution is saved by the second consequence: you never compute the foot of the perpendicular, you just name a nearby point.

The discernment mechanism is a general one and you should install it as a habit. *Inspect the degenerate cases of the inequality before choosing a method, and build the proof only from quantities that degenerate the same way.* Here the right side vanishes when f and g are both constant, and more sharply, the right side is unchanged when a constant is added to f while the left side is not. That asymmetry says the proof must treat $\mu(f)$ as a coefficient, never as something to be removed. A candidate who tests g constant in the first minute learns three things: crude sup-norm bounds are dead, the inequality is nearly tight in that case, and the factor 2 is slack. Three facts for ten seconds of work.

What the examiners nudged. They wrote the definitions out instead of saying "variance", which invites the probabilistic reading without requiring it. They put a 2 in front of both terms, which is a

public announcement that a single crude split is intended. They used $M(f) = \max |f|$ rather than $\max f - \min f$, which forces the appearance of $|\mu(f)| \leq M(f)$ and thereby forces you to confront the translation issue. Every one of those choices is a guiding light, and none of them is decoration.

To train the discernment: for the next month, whenever you meet $\int (h - \text{something})^2$, write the sentence "this is the squared distance from h to the set of somethings" and then ask what the nearest something is and whether you can afford to guess it. That reflex converts a large family of analysis inequalities (variance bounds, best approximation, least squares, Bessel and Parseval, the Poincare inequality) into one move.

Revolving concepts

Variance as a squared distance. For $h \in L^2$ of a probability space, $\mathrm{Var}(h) = \min_{c \in \mathbb{R}} \int (h-c)^2 = \int h^2 - \left(\int h\right)^2$, the minimum being attained at $c = \mu(h)$. Orbiting facts: $\mathrm{Var}(ah+b) = a^2\mathrm{Var}(h)$; $\mathrm{Var}(h) = 0$ if and only if h is constant (for continuous h); $\mathrm{Cov}(u,v) = \int u_0 v_0$ and $\mathrm{Cov}(u,v)^2 \leq \mathrm{Var}(u)\mathrm{Var}(v)$, which is Cauchy and Schwarz applied to the centred functions. See Book 1, field: Real analysis, topic: L^2 geometry.

Minkowski and Hoelder. $\|u+v\|_p \leq \|u\|_p + \|v\|_p$ for $p \geq 1$, and $\int |uv| \leq \|u\|_p \|v\|_q$ for $1/p + 1/q = 1$. The two special cases used here are $p = q = 2$ (Cauchy and Schwarz) and the pair $(1, \infty)$, that is $\int |uv| \leq \|v\|_\infty \int |u|$, which is the formal name of "pull the maximum out of the integral". See Book 1, field: Inequalities, topic: L^p norms.

The two-term power bound and its generalisation. $(A+B)^2 \leq 2(A^2+B^2)$ generalises to $(A_1 + \cdots + A_m)^2 \leq m(A_1^2 + \cdots + A_m^2)$, which is Cauchy and Schwarz against the all-ones vector, and further to $(\sum A_i)^p \leq m^{p-1} \sum A_i^p$ for $p \geq 1$ by convexity of $t \mapsto t^p$. If a problem hands you a constant m in front of an m-term right side, that is the intended tool. There is no recursion in this problem, but the m-term version is proved by induction on m from the two-term version, and the general convexity statement is Jensen. See Book 1, field: Inequalities, topic: power mean.

Popoviciu and the range bound. A companion to the lemma: choosing c to be the midpoint of the range gives $\mathrm{Var}(h) \leq \frac{1}{4}(\max h - \min h)^2$. This is a second, sharper way to convert a sup bound into a variance bound and it is often the missing ingredient in Putnam variance problems. See Book 1, field: Inequalities, topic: variance bounds.

Extreme value theorem. A continuous real function on a closed bounded interval attains its maximum. This is what makes $M(f)$ well defined as a maximum rather than a supremum, and it is the only place continuity is used beyond integrability. See Book 1, field: Real analysis, topic: compactness.

Circuit Bank

- **WHEN** you see $\int (h - \mu(h))^2$ or the word variance **DO** write $\mathrm{Var}(h) \leq \int (h-c)^2$ for a constant c you will choose **BECAUSE** variance is the squared distance from h to the constants, so any constant gives an upper bound and you never have to compute the true mean
- **WHEN** an inequality has a factor m in front of an m term right side **DO** split the left side into m pieces and apply $(\sum A_i)^2 \leq m \sum A_i^2$ **BECAUSE** that constant is the examiner telling you the intended proof splits once and crudely
- **WHEN** a supremum norm multiplies an integral **DO** bound the squared factor pointwise by its maximum and pull it outside **BECAUSE** this is Hoelder with the pair $(1, \infty)$, the cheapest estimate that leaves the other factor intact
- **WHEN** you want to normalise a mean to zero **DO** first check every quantity in the target for translation invariance **BECAUSE** Var is translation invariant and M is not, so centring silently changes the problem

- **WHEN** you must compare a product fg with a product ab of constants **DO** telescope as $fg - ab = (f - a)g + a(g - b)$ **BECAUSE** one telescoping step turns a product difference into a sum of two terms, each with exactly one centred factor

Backtesting

1. First useful cue: the definitions given are expectation, variance and supremum norm on a probability space, so $\mathrm{Var}(h)$ is a squared distance from h to the constant functions.
2. Method the expression suggested: bound that distance by the distance to one named constant, $\mu(f)\mu(g)$, then split the resulting square into two pieces because the right side has two terms with a 2 each.
3. Where you would hesitate, and the thought to reinforce: at the temptation to set $\mu(f) = 0$. Reinforce by checking translation invariance of every symbol in the target before normalising anything. M moves, Var does not, so the means stay.
4. The trap the question sets: expanding $\mathrm{Var}(fg) = \int f^2 g^2 - (\int fg)^2$ and grinding. It is correct and it costs eight terms plus one extra inequality to absorb the surviving cross term $2\mu(f)\mu(g)\int f_0 g_0$.
5. What makes you recognise it faster next time: the pattern "squared deviation from a mean" plus a constant multiplier on the right. Test the degenerate case (g constant) in the first ten seconds, which simultaneously kills the crude bounds and shows the 2 is slack.
6. The reusable decision rule: a minimum is bounded above by any single competitor, so never compute the optimal one when you only need an upper bound.

Mirror drills

1. Show that $\mathrm{Var}(f+g) \le 2\mathrm{Var}(f) + 2\mathrm{Var}(g)$ for continuous f, g on $[0,1]$, and state when equality holds. *Answer:* $\mathrm{Var}(f+g) = \int (f_0+g_0)^2 \le 2\int f_0^2 + 2\int g_0^2$; equality requires $f_0 = g_0$ almost everywhere, that is f and g differ by a constant.
2. Prove that $\mathrm{Var}(f) \le \frac{1}{4}(\max f - \min f)^2$ for continuous f on $[0,1]$. *Answer:* take c to be the midpoint of $[\min f, \max f]$ in the lemma; then $|f - c| \le \frac{1}{2}(\max f - \min f)$ pointwise, so $\mathrm{Var}(f) \le \int (f-c)^2 \le \frac{1}{4}(\max f - \min f)^2$.
3. Prove the sharper bound $\sqrt{\mathrm{Var}(fg)} \le M(g)\sqrt{\mathrm{Var}(f)} + M(f)\sqrt{\mathrm{Var}(g)}$, deduce the problem's inequality from it, and show that the constant 2 in the problem cannot be replaced by any constant smaller than 1. *Answer:* Minkowski in L^2 on $f_0 g + \mu(f) g_0$, then $(u+v)^2 \le 2u^2 + 2v^2$; for the lower bound on the constant take $g \equiv 1$, so the left side is $\mathrm{Var}(f)$ and the right side is $C\,\mathrm{Var}(f)$.

13.11 B5. Counting maps that funnel into a set

Let $X = \{1, 2, \ldots, n\}$, and let $k \in X$. Show that there are exactly $k \cdot n^{n-1}$ functions $f : X \to X$ such that for every $x \in X$ there is a $j \geq 0$ such that $f^{(j)}(x) \leq k$. (Here $f^{(j)}$ denotes the jth iterate of f, so that $f^{(0)}(x) = x$ and $f^{(j+1)}(x) = f(f^{(j)}(x))$.)

Read it out loud

This is a labelled counting problem about a discrete dynamical system. A function $f : X \to X$ on a finite set is nothing but a directed graph in which every vertex has out-degree exactly 1, the functional graph. Following $x, f(x), f^{(2)}(x), \ldots$ you must eventually repeat a value, so every orbit runs down a tail and then loops forever around a cycle. The condition imposed is that every orbit passes through the target block $K = \{1, \ldots, k\}$. Read that once more in graph language and it says: every vertex can reach K, that is, K absorbs the whole system. The fields wired in are enumerative combinatorics of labelled structures (trees, forests, Cayley's formula) and induction with a binomial recursion.

Two features of the answer are shouting at you. First, $k \cdot n^{n-1}$ is linear in k. A count that is linear in a parameter almost never comes out of a case analysis; it comes out of a factorisation or a telescoping, so look for a place where k enters exactly once. Second, n^{n-1} and n^{n-2} are the Cayley numbers: n^{n-2} labelled trees on n vertices, n^{n-1} labelled rooted trees on n vertices, $q\, n^{n-q-1}$ labelled rooted forests on n vertices with a prescribed set of q roots. An answer of that shape is the examiners saying "this object is a forest in disguise". Third, and most useful of all, divide by the total: $kn^{n-1} = \frac{k}{n} \cdot n^n$. So the claim is equivalent to saying that a uniformly random function $X \to X$ funnels into K with probability exactly k/n. A clean probability like that is never a coincidence, and it is worth keeping in view because it tells you the final identity will be exact and simple, with no floor functions or case splits.

Now the cue that starts the work, and you should have it within twenty seconds. For $x \leq k$ the condition is satisfied by $j = 0$: nothing is being asked about the points of K at all. So the values $f(1), \ldots, f(k)$ ought to be completely unconstrained, giving a free factor n^k. That is a guess until you prove it, because $f(1)$ could in principle be needed on somebody else's orbit. It is not, and the reason is the only genuinely delicate observation in the problem: once an orbit reaches K it has already succeeded, so the part of the orbit that matters never consults a value of f at a point of K. Write that down, pull out n^k, and you are left with counting maps from $Y = \{k+1, \ldots, n\}$ into X that are absorbed by K.

Approaches, ranked worst to best

1. **Inclusion and exclusion over the bad set.** *Cue:* count objects avoiding a global condition. *Circuit:* complement plus sieve. (worst. The complementary condition is "some cycle of f avoids K", and sieving over which subsets carry those cycles produces sums over cycle types with factorial weights. Nothing closes, and there is no sign of kn^{n-1} at the end of it.)

2. **Induction on n with k fixed.** *Cue:* a formula in two integer parameters. *Circuit:* peel off the point n and relate to the same problem one size down. (stalls. Deleting a point of Y changes the ambient set that everything maps into, and deleting a point of K changes the target. The recursion you get relates the count for (n, k) to counts with a different, structurally new target set, so with k held fixed it never closes. The failure is informative: it is telling you which parameter must be freed.)

3. **Exponential generating functions for functional graphs.** *Cue:* labelled objects, so use the species machinery. *Circuit:* $T = xe^T$ for rooted trees, functional graphs are sets of cycles of trees. (viable and heavy. You must install Lagrange inversion to extract coefficients, and the

marked block K of fixed size k breaks the plain symmetry of the species, so you end up with a two variable generating function anyway. In the arena this costs three times what the ideal route costs.)

4. **Quote the rooted forest formula.** *Cue:* n^{n-1} is Cayley shaped. *Circuit:* a map absorbed by K is a forest of trees hanging off K, and forests on n vertices with q prescribed roots number qn^{n-q-1}. (fast and correct if the formula is installed. Two risks: you must justify the bijection between absorbed maps and forests carefully, and you are leaning on the matrix tree theorem or on Pruefer codes, which a grader may reasonably ask you to prove. Excellent as a sanity check on the answer, slightly exposed as a write-up.)

5. **Induction on $n-k$ through the new cycle.** *Cue:* the answer increases by exactly n^{n-1} when k increases by 1. *Circuit:* count the maps absorbed by $\{1,\dots,k+1\}$ but not by $\{1,\dots,k\}$, which are those with a unique cycle inside $\{k+1,\dots,n\}$, necessarily through $k+1$. (this is the official route and it works. The count for fixed cycle length ℓ is a product of falling factorials, and the resulting sum only collapses after you rewrite $k+\ell$ as $n-(n-k-\ell)$ to make two telescoping halves. Correct, but the collapse is the sort of step you will not find under time pressure unless you already know it.)

6. **Peel the first entry layer.** *Cue:* the condition is about first arrival at a set, so condition on the set of points that arrive in one step. *Circuit:* strengthen the statement to two free parameters, sink size and non-sink size, then induct. (best. The recursion is forced by the structure, the induction closes because the sink is a variable, and the binomial sum collapses in one line using $j\binom{p}{j} = p\binom{p-1}{j-1}$ and the binomial theorem. It also proves Cayley's formula and the forest formula as by-products, so you are never quoting anything you cannot derive.)

The ideal solution

Throughout, $K=\{1,\dots,k\}$ and $Y=\{k+1,\dots,n\}$, so $X=K\cup Y$ with $|K|=k\geq 1$ and $|Y|=n-k\geq 0$. Call $f:X\to X$ *good* if for every $x\in X$ there is $j\geq 0$ with $f^{(j)}(x)\in K$.

Lemma 13.11.1. *Whether f is good depends only on the restriction $f|_Y$. Consequently the number of good functions is n^k times the number of good restrictions.*

Proof. Let f and $\tilde{f}$ agree on Y, and suppose f is good. Fix $x\in X$. If $x\in K$ then $j=0$ works for $\tilde{f}$ as well. If $x\in Y$, let j be minimal with $f^{(j)}(x)\in K$; then $j\geq 1$ and $f^{(i)}(x)\in Y$ for $0\leq i<j$ by minimality. Since f and $\tilde{f}$ agree on Y, an induction on i gives $\tilde{f}^{(i)}(x)=f^{(i)}(x)$ for $0\leq i\leq j$, so $\tilde{f}^{(j)}(x)\in K$. Hence $\tilde{f}$ is good. The values $f(1),\dots,f(k)$ are therefore free, contributing the factor n^k. □

Now fix the general shape of what remains. Let Y and S be disjoint finite sets with $|Y|=p\geq 0$ and $|S|=q\geq 1$, and let $h:Y\to Y\cup S$. Define the orbit of $y\in Y$ by $y_0=y$ and $y_{i+1}=h(y_i)$, continued only while $y_i\in Y$. Call h *absorbing* (for the pair (Y,S)) if the orbit of every $y\in Y$ reaches S.

Lemma 13.11.2. *The number of absorbing $h:Y\to Y\cup S$ is $q\,(p+q)^{p-1}$.*

Proof. Induct on p. If $p=0$ there is exactly one map, the empty map, and it is vacuously absorbing; the formula gives $q\cdot q^{-1}=1$, as required.

Let $p\geq 1$ and let h be absorbing. Put $T=h^{-1}(S)\subseteq Y$. First, $T\neq\emptyset$: pick any $y\in Y$ and let i be minimal with $y_i\in S$; then $i\geq 1$ and $y_{i-1}\in Y$ satisfies $h(y_{i-1})\in S$, so $y_{i-1}\in T$.

Fix a subset $T\subseteq Y$ with $|T|=j\geq 1$. I claim that the absorbing maps h with $h^{-1}(S)=T$ are in bijection with the pairs consisting of an arbitrary map $T\to S$ and an absorbing map $Y\setminus T\to (Y\setminus T)\cup T$ for the pair $(Y\setminus T,T)$. Indeed, $h^{-1}(S)=T$ says exactly that h maps T into S and maps $Y\setminus T$ into $Y=(Y\setminus T)\cup T$, so h splits into those two pieces and any pair of pieces can

be recombined. It remains to see that h is absorbing for (Y, S) if and only if $h|_{Y\setminus T}$ is absorbing for $(Y \setminus T, T)$. If h is absorbing and $y \in Y \setminus T$, its orbit reaches S, and the point immediately before it does so lies in T; every earlier point of the orbit lies in $Y \setminus T$, since a point of T is sent straight into S. So the orbit reaches T while staying inside $Y \setminus T$ beforehand, which is precisely absorption for $(Y \setminus T, T)$. Conversely, if every $y \in Y \setminus T$ reaches T, then one further step sends it into S, and points of T enter S in one step, so h is absorbing.

Since $|Y \setminus T| = p - j < p$ and $|T| = j \geq 1$, the induction hypothesis counts the second piece as $j\,\big((p-j)+j\big)^{p-j-1} = j\,p^{p-j-1}$, while the first piece may be chosen in q^j ways. Summing over j and over the $\binom{p}{j}$ choices of T,

$$\#\{h \text{ absorbing}\} = \sum_{j=1}^{p} \binom{p}{j} q^j\, j\, p^{p-j-1}.$$

Use $j\binom{p}{j} = p\binom{p-1}{j-1}$, which is the identity "choose a committee of j from p and then its chair" counted the other way round. The factor p cancels one power of p:

$$\sum_{j=1}^{p} p\binom{p-1}{j-1} q^j p^{p-j-1} = \sum_{j=1}^{p} \binom{p-1}{j-1} q^j p^{p-j} = q \sum_{i=0}^{p-1} \binom{p-1}{i} q^i p^{(p-1)-i},$$

where $i = j - 1$. The last sum is the binomial expansion of $(p+q)^{p-1}$, so the total is $q(p+q)^{p-1}$. □

Apply the second lemma with $S = K$, so $q = k$ and $p = n - k$ and $p + q = n$: the number of good restrictions $f|_Y$ is $k\,n^{n-k-1}$. Note this is exactly the statement that $f|_Y$ is absorbing, which by the definition of good is what "good" says once the points of K are known to be free. By the first lemma the number of good functions is

$$n^k \cdot k\, n^{n-k-1} = \boxed{k\, n^{n-1}}.$$

For $k = n$ the set Y is empty, every function is good, and the formula correctly returns $n \cdot n^{n-1} = n^n$.

Remark 13.11.3. Two reformulations worth carrying away. Since every orbit is eventually periodic, f is good if and only if every cycle of f meets K: a cycle avoiding K traps its own points forever, and conversely every orbit runs into a cycle. And dividing by n^n, the theorem says that a uniformly random $f : X \to X$ is good with probability exactly k/n, the fraction of the ground set occupied by K.

Remark 13.11.4. The second lemma with $q = 1$ says: the number of maps h from a p element set Y into $Y \cup \{r\}$ all of whose orbits reach r is $(p+1)^{p-1}$. Drawing the edge $y \to h(y)$, such maps are exactly the trees on the $p + 1$ vertices $Y \cup \{r\}$, rooted at r with all edges directed towards the root. With $N = p + 1$ vertices that count is N^{N-2}, which is Cayley's formula. So the ideal route proves the tool it would otherwise have had to quote.

Layer 1: WHAT

Block 1. Read the condition on the functional graph: every vertex reaches K. Notice it is vacuous on K itself.

Block 2. Prove that goodness reads only $f|_Y$, by taking the *first* entry time into K, and pull out the free factor n^k.

Block 3. The residual count is an absorption count. Recognise that an induction will change the sink set, so promote the sink from the fixed set K to a free parameter: state the two parameter lemma.

Block 4. Peel the first entry layer $T = h^{-1}(S)$. Prove it is nonempty, and that the rest of h is an absorbing map with sink T.

Block 5. Assemble the binomial recursion, kill the stray factor j with $j\binom{p}{j} = p\binom{p-1}{j-1}$, and recognise the binomial theorem.

Block 6. Multiply the two factors and check $k = n$.

The nominal route sets k up as a fixed constant, tries to induct on n, and drowns. The bifurcation point is Block 3: **the line where you decide that the target set is a variable of the problem and not a constant.** Everything downstream is forced once the statement has two free parameters, because the peel then lands you back inside the same statement rather than outside it. This is the classic strengthen the induction hypothesis moment, and the tell is precisely that the naive recursion produced an object of the same kind but the wrong size.

Layer 2: HOW

Block 1. **Cue.** "For every x there is $j \geq 0$ with $f^{(j)}(x) \leq k$" is a reachability statement, and $j = 0$ is allowed. **Why natural.** Allowing $j = 0$ is not decoration; it is the examiner telling you that the points of K are exempt. When a condition is vacuous on part of the domain, the corresponding coordinates are candidates to be free, and free coordinates should always be factored out before any counting begins, because they shrink the problem without costing anything. **Link to the next block.** You now need to prove the values on K really are free, which means proving that nobody else's orbit depends on them.

Block 2. **Cue.** The word "there is j" hides a minimal j, and minimal first entry times are what make orbit arguments finite and clean. **Why natural.** Take the least j with $f^{(j)}(x) \in K$. Then the whole path $x, f(x), \ldots, f^{(j-1)}(x)$ lies in Y, so it only ever reads values of f at points of Y. That is the definition-level reason the factor n^k exists: success is decided before the orbit ever touches K. Never argue with an arbitrary j when a minimal one is available. **Link to the next block.** With n^k removed, the object left is a map $Y \to X$ absorbed by K, and K now behaves like a single exit door rather than a set of ordinary points.

Block 3. **Cue.** The naive induction wants to remove a point, and removing one changes the sink. **Why natural.** If a recursion produces the same kind of object with a different parameter, the statement you are inducting on must have that parameter free. Here the peel will replace the sink K by a subset of Y of some new size j, so a lemma phrased with sink size exactly k can never be applied to its own consequences. Freeing the parameter costs one line of notation and buys the entire induction. **Link to the next block.** Once the lemma reads "sink of size q, ground of size p", you may look for the natural way to cut Y.

Block 4. **Cue.** "Every orbit reaches S" is a first arrival condition, and the natural slice of a first arrival condition is the set of points that arrive in exactly one step. **Why natural.** Set $T = h^{-1}(S)$. It is nonempty (take any orbit and look one step before it lands), it is canonically determined by h (no choices, so no overcounting), and by construction the rest of h maps $Y \setminus T$ into Y and must funnel into T. So the peel is exactly the same problem with sink T: the structure regenerates itself. Compare this with the official route, which peels a cycle instead; a cycle needs to be chosen and ordered, which is why falling factorials appear there and binomials appear here. **Link to the next block.** Summing over the size and the choice of T produces a binomial recursion.

Block 5. **Cue.** A binomial sum with a stray linear factor j in it. **Why natural.** The identity $j\binom{p}{j} = p\binom{p-1}{j-1}$ exists precisely to remove such factors, and after removing it the summand is $\binom{p-1}{i} q^i p^{(p-1)-i}$, which is a term of $(p+q)^{p-1}$. The fact that everything collapses to the plain binomial theorem is the confirmation that the peel was the right cut: a wrong decomposition leaves

you with a sum that needs an Abel type identity instead. **Link to the next block.** The answer $q(p+q)^{p-1}$ with $p+q=n$ is the missing factor.

Block 6. **Cue.** Two independent factors, one free and one counted. **Why natural.** Multiply, then test the extreme case $k=n$ where Y is empty. Checking a boundary case at the end costs five seconds and catches an off by one in the exponent, which is the most likely error in a formula with n^{n-k-1} in it. **Link to the next block.** Done.

Layer 3: WHY

The structural truth is that an absorbing map is a rooted forest. Draw an edge from y to $h(y)$ for each $y \in Y$. Absorption says no cycle lies inside Y, so the digraph on $Y \cup S$ is a forest of trees whose roots are the elements of S, edges directed towards the roots. The second lemma is therefore the classical count of labelled rooted forests on $p+q$ vertices with a prescribed set of q roots, namely $q(p+q)^{p-1}$, and the case $q=1$ is Cayley's formula. That is why the answer had to look like kn^{n-1}: nothing else of that shape exists in the labelled world.

Why is the count linear in q? Because the true statement is a probability. Of all $(p+q)^p$ maps $Y \to Y \cup S$, exactly the fraction $q/(p+q)$ are acyclic on Y. In the original problem this is the statement that a random $f : X \to X$ funnels into K with probability $|K|/|X|$. That is the same phenomenon as the cycle lemma of Dvoretzky and Motzkin, which computes the probability that a random cyclic arrangement never dips below a level and returns an answer linear in the parameter for the same reason: there is a $(p+q)$ to 1 symmetry acting on all maps under which exactly q of every $p+q$ related objects are good. Knowing that a clean fraction is in play tells you before you start that the final identity will be an exact binomial collapse, not an estimate.

The discernment mechanism has three parts, and all three transfer. First, *separate free coordinates from constrained coordinates before counting anything*: any coordinate the condition never reads contributes a bare power, and removing it shrinks the problem for free. Second, *when a decomposition regenerates your problem with a parameter you were treating as constant, promote that parameter*. A statement is easier to prove when it is stronger, if the extra strength is exactly what the recursion consumes. Third, *cut along a canonical set, never along a chosen one*. The first entry layer $h^{-1}(S)$ is determined by h, so summing over it partitions the objects with no overcounting and no ordering factors; choosing a cycle, or a vertex, or an edge, introduces a symmetry you must divide out later.

To train it: take any counting problem whose answer contains n^{n-1}, n^{n-2} or $(n+1)^{n-1}$ and force yourself to name the forest. Then take any condition of the form "every point eventually reaches A" and write down $h^{-1}(A)$ before doing anything else.

Revolving concepts

Functional graphs. For finite X, a map $f : X \to X$ drawn as the digraph $x \to f(x)$ has every out-degree 1. Each connected component consists of a unique directed cycle with rooted trees hanging off its vertices (the rho shape). Consequences used here: every orbit is eventually periodic; f is good if and only if every cycle meets K; the maps with no cycle inside Y are exactly the forests rooted at Y^c. See Book 1, field: Discrete structures and graphs, topic: functional graphs.

Cayley's formula and rooted forests. The number of labelled trees on N vertices is N^{N-2}; the number rooted at a prescribed vertex is also N^{N-2}; the number of rooted forests on N vertices whose roots are a prescribed set of q vertices is qN^{N-q-1}. Proofs available: Pruefer sequences (bijective), the matrix tree theorem of Kirchhoff (linear algebraic), Joyal's doubly rooted trees (bijective), and the first entry peel used above (recursive). See Book 1, field: Discrete structures and graphs, topic: labelled trees.

The generalised recursion. The recursion extracted here is

$$F(p,q) = \sum_{j=1}^{p} \binom{p}{j} q^j F(p-j,j), \qquad F(0,q) = 1,$$

with solution $F(p,q) = q(p+q)^{p-1}$. Its general form is a binomial convolution $a_p = \sum_j \binom{p}{j} b_j a_{p-j}$, which in exponential generating function language is $A(x) = B(x)A(x)$ style multiplication, that is, the sequence of a labelled structure decomposed into a first layer and a remainder. Whenever a labelled counting problem is cut into a canonical layer plus a smaller copy of itself, you get a binomial convolution, and the two standard finishing moves are (a) recognise the binomial theorem after clearing a linear factor with $j\binom{p}{j} = p\binom{p-1}{j-1}$, or (b) pass to exponential generating functions and use Lagrange inversion when the convolution is genuinely nonlinear. The same peel counts surjections (layer = preimage of a chosen element), parking functions, and forests by number of trees. See Book 1, field: Combinatorics, topic: binomial convolutions.

Binomial identities. $j\binom{p}{j} = p\binom{p-1}{j-1}$ (committee and chair); $\binom{p}{j}\binom{j}{i} = \binom{p}{i}\binom{p-i}{j-i}$ (subset of a subset); and the binomial theorem $\sum_i \binom{m}{i} q^i p^{m-i} = (p+q)^m$, which is the target shape you steer every such sum towards. See Book 1, field: Combinatorics, topic: binomial coefficients.

Random mappings. A uniformly random $f : X \to X$ has about $\sqrt{\pi n/2}$ cyclic points and expected rho length of order $\sqrt{n}$; the statement proved here, that the probability of being absorbed by a k set is exactly k/n, is one of the few facts in this area that is exact rather than asymptotic. See Book 1, field: Probability, topic: random mappings.

Circuit Bank

- **WHEN** a counting condition never reads certain coordinates **DO** factor out the corresponding bare power immediately, after proving the independence with a minimal first entry time **BECAUSE** free coordinates shrink the problem at zero cost, and the proof of freeness is always the same: the successful path stops before it touches them
- **WHEN** a condition says every point eventually reaches the set S **DO** condition on the layer $h^{-1}(S)$, prove it is nonempty, and recurse with S replaced by that layer **BECAUSE** the layer is canonical, so summing over it partitions the objects with no overcounting, and the remainder is the same problem one size down
- **WHEN** your recursion regenerates the problem with a parameter you were holding fixed **DO** promote that parameter to a variable and prove the stronger two parameter statement **BECAUSE** an induction can only close if the hypothesis is broad enough to cover what the recursion produces
- **WHEN** the answer contains n^{n-1}, n^{n-2} or qn^{n-q-1} **DO** look for labelled trees and rooted forests **BECAUSE** those are the only standard labelled counts of that shape, and identifying the structure tells you what the proof must construct
- **WHEN** a binomial sum carries a stray linear factor j **DO** apply $j\binom{p}{j} = p\binom{p-1}{j-1}$ and re-index **BECAUSE** clearing the linear factor is what turns the sum into a plain binomial expansion, and if it does not, your decomposition was the wrong one

Backtesting

1. First useful cue: $j = 0$ is permitted, so the condition is vacuous on $\{1,\dots,k\}$ and those k values of f should be free.
2. Method the expression suggested: pull out n^k, then count absorbed maps $Y \to X$ by peeling the layer that enters K in one step, with the sink size promoted to a free parameter.

3. Where you would hesitate, and the thought to reinforce: at the claim that $f(1), \ldots, f(k)$ are free. Reinforce with the minimal first entry time: the winning path lies entirely in Y before it lands, so it never reads a value on K.
4. The trap the question sets: holding k fixed and inducting on n. The recursion changes the target set, so the hypothesis must carry a free sink size or the induction cannot be applied to its own output.
5. What makes you recognise it faster next time: the shape $kn^{n-1} = \frac{k}{n}n^n$. An exact rational probability plus a Cayley number means forests plus a canonical peel, every time.
6. The reusable decision rule: for reachability conditions, cut at the first entry layer, because it is canonical and it reproduces the problem exactly.

Mirror drills

1. Deduce Cayley's formula from the absorbing lemma. *Answer:* take $q = 1$ and $p = N - 1$; absorbing maps $Y \to Y \cup \{r\}$ are exactly the trees on $Y \cup \{r\}$ rooted at r with edges pointing to the root, so their number is $1 \cdot N^{N-2}$.
2. Count the functions $f : \{1, \ldots, n\} \to \{1, \ldots, n\}$ such that every x has some iterate equal to 1, and check your answer by hand for $n = 2$. *Answer:* n^{n-1}; for $n = 2$ the good maps are $f(2) = 1$ with $f(1)$ either value, so $2 = 2^1$.
3. Prove directly that $\sum_{j=1}^{p} \binom{p}{j} j\, p^{p-j-1} q^j = q(p+q)^{p-1}$. *Answer:* replace $j\binom{p}{j}$ by $p\binom{p-1}{j-1}$, cancel one power of p, substitute $i = j - 1$ and apply the binomial theorem to $(p+q)^{p-1}$.

13.12 B6. Stone game on a line of odd length

Let $n \geq 1$ be an odd integer. Alice and Bob play the following game, taking alternating turns, with Alice playing first. The playing area consists of n spaces, arranged in a line. Initially all spaces are empty. At each turn, a player either

- *places a stone in an empty space, or*
- *removes a stone from a nonempty space s, places a stone in the nearest empty space to the left of s (if such a space exists), and places a stone in the nearest empty space to the right of s (if such a space exists).*

Furthermore, a move is permitted only if the resulting position has not occurred previously in the game. A player loses if he or she is unable to move. Assuming that both players play optimally throughout the game, what moves may Alice make on her first turn?

Read it out loud

Impartial game, normal play, two players, a finite board, and one clause that changes everything: no position may be repeated. Read the pieces separately. The move set is symmetric under left and right reflection, the board has odd length, and the initial position is symmetric. So the only reflection invariant first move is the central space, and your first guess, made in ten seconds and before any analysis, is that the answer is exactly that. Guessing the answer early is not cheating; it tells you what you are trying to prove and therefore which invariant to hunt for.

Now the fields. Combinatorial game theory supplies the vocabulary (a position is an N position if the player to move wins, a P position if the previous player wins), but the Sprague and Grundy theorem is of no use here because this game is not a disjunctive sum of independent components: a type 2 move at one end can reach across the whole board. What is genuinely being tested is whether you can build a numerical invariant on positions such that from every non target value exactly one move restores the target. That is the Nim mechanism stripped of Nim.

The no-repetition clause is the real obstacle and it must be dealt with first, not last. A game whose legal moves depend on the whole history is not a game on positions at all; it is a game on histories, and none of the standard machinery applies to it. So the opening job is to prove that the clause is inert: find a quantity that never decreases, show that it forces every position to be new, and confine the damage to the small set of positions where the quantity is maximal.

Within thirty seconds you should have tabulated what a type 2 move does to the number of stones. Take the maximal block of consecutive stones containing s, and let i and j be the empty spaces flanking it. The move deletes the stone at s and fills i and j, so it changes the count by $+1$ if both flanks are on the board, by 0 if exactly one flank falls off the end, and by -1 if both do, which happens only when the board is full. That table is the whole skeleton of the solution: the number of stones never decreases until the board is nearly full.

Approaches, ranked worst to best

1. **Grundy values on positions with history.** *Cue:* impartial game, so compute Grundy values. *Circuit:* Sprague and Grundy. (worst. The state is a pair consisting of a position and the set of all positions used so far, so the state space has size around 2^{2^n}, and the game is not a sum of components, so the Grundy value of a state tells you nothing you could not read off from a win or lose label. The machinery is real and it is the wrong machinery.)

2. **Brute force small cases and guess.** *Cue:* the answer should be a simple description. *Circuit:* compute $n = 1, 3, 5$ and extrapolate. (this correctly produces the answer, the central space, in a few minutes of hand or machine work. As a solution it is worth nothing, and as reconnaissance

it is worth a great deal: it tells you the answer is unique, which means the invariant you are looking for separates one move from all $n-1$ others.)

3. **Induction on the board length.** *Cue:* a family of games indexed by n. *Circuit:* relate the game on n spaces to smaller boards. (stalls badly. A type 2 move at the end of a block can move stones across a gap, so the two halves of the board never become independent games and there is no smaller board hiding inside.)

4. **Mirror strategy.** *Cue:* odd board, symmetric rules, symmetric start. *Circuit:* take the centre, then reflect every reply. (good and genuinely half of the truth. Alice takes the centre and thereafter restores left and right symmetry; the symmetric positions with the centre occupied are exactly her safe positions. Two defects: proving that the reflected reply is always legal takes real care, especially against a type 2 move that straddles the centre, and the strategy says nothing about why the other $n-1$ first moves lose. A mirror argument proves one move wins; the question asks for all winning moves.)

5. **Level by level descending induction with two pile Nim.** *Cue:* the count of stones is nearly monotone. *Circuit:* analyse P_{n-2} as two pile Nim on the extremal blocks, then induct downwards on the number of stones. (this is the official route and it is correct. The extremal block moves really are Nim moves, and the induction does close. It costs a separate analysis of one level plus an induction, and it obscures the fact that the modular invariant alone already settles every level at once.)

6. **Weight modulo $n+1$ plus the end zone.** *Cue:* the board has n spaces and the type 2 move sometimes loses a stone off the end. *Circuit:* label the spaces 1 to n, add ghost spaces 0 and $n+1$ whose labels are both $\equiv 0$, and take the sum of the occupied labels modulo $n+1$. (best. The ghost convention makes one formula cover all four cases of the move, the increments then realise every nonzero residue exactly once, and the whole game collapses to a single congruence with no induction on levels at all. It also explains the mirror strategy: the symmetric positions with the centre occupied are precisely the ones of weight $(n+1)/2$.)

The ideal solution

The answer: Alice's only winning first move is to place a stone in the central space $\frac{n+1}{2}$.

Number the spaces 1 to n from left to right, and adopt two permanently empty *ghost* spaces labelled 0 and $n+1$ at the two ends. Identify a position with its set of occupied spaces, and let P_i denote the set of positions with i stones. For a stone at s, its *block* is the maximal set of consecutive occupied spaces containing s; write i and j for the empty spaces immediately to the left and right of the block, where $i = 0$ or $j = n+1$ if the block runs to an end of the board. A type 2 move at s deletes the stone at s and places a stone at i and at j, ignoring any ghost. Define the *weight*

$$w(x) \equiv \sum_{s \in x} s \pmod{n+1}, \qquad T = \frac{n+1}{2},$$

and call x *balanced* if $w(x) \equiv T$. Set $Z = P_{n-1} \cup P_n$, the *end zone*, so $\#Z = n+1$.

Assume $n \geq 3$; the case $n = 1$ is treated at the end.

Lemma 13.12.1. *The number of stones never decreases except from the full board, where it drops by one. Precisely: a type 1 move adds a stone; a type 2 move adds a stone if both flanks are on the board, keeps the count if exactly one flank is a ghost, and removes a stone if both flanks are ghosts, which happens only from the full board.*

Proof. Immediate from the description: one stone is removed and one stone is placed for each non-ghost flank. □

Lemma 13.12.2. *Let x have at most $n-2$ stones, and let a and b be the lengths of the maximal blocks of stones at the left and right ends of the board (possibly 0). The moves from x that do not increase the stone count are exactly the type 2 moves at a stone of one of those two extremal blocks. Such a move at $s \le a$ replaces a by $s-1$ and changes nothing else; symmetrically at the right. In particular $a+b$ strictly decreases, so no position can repeat while the stone count stays fixed.*

Proof. By the first lemma, a move keeps the count only if it is type 2 with exactly one ghost flank, that is, at a stone of an extremal block. Take $s \le a$, so the block is $\{1,\dots,a\}$, i is the ghost 0 and $j = a+1$. The new position is x with s emptied and $a+1$ filled, so it agrees with x outside $\{s, a+1\}$ and its left extremal block is $\{1,\dots,s-1\}$, of length $s-1 < a$. Since x has at least two empty spaces, some empty space $e \ge a+2$ survives the move, so the occupied spaces beyond e, and hence the right extremal block, are untouched. □

Lemma 13.12.3. *Every move from a position with at most $n-2$ stones is legal, so such a position always has exactly n legal moves, one for each space.*

Proof. By the first lemma the stone count is nondecreasing until the board is full, and the board is full only after passing through P_{n-1}; so while the count is at most $n-2$ it is nondecreasing. Let $x \in P_i$ with $i \le n-2$ be the current position. Every earlier position has at most i stones, and those with exactly i form a consecutive run ending at x along which $a+b$ strictly decreases, by the second lemma. A move to P_{i+1} produces a position with more stones than any that has occurred; a move inside P_i produces a position with smaller $a+b$ than any that has occurred at this level. Either way the resulting position is new. Finally there are exactly n moves available, one type 1 move per empty space and one type 2 move per occupied space. □

Lemma 13.12.4. *From any position of Z, the positions reachable in one move are exactly the other n positions of Z. Consequently, once the game enters Z it stays there and every move consumes a fresh element of Z, so the player who first moves into Z loses.*

Proof. Write F for the full board. From F there is no type 1 move, and a type 2 move at s has both flanks ghosts, so it produces $F \setminus \{s\}$; as s varies this gives all of P_{n-1}. From $F \setminus \{e\}$ the type 1 move at e gives F, and a type 2 move at $s \ne e$ acts on the block $\{1,\dots,e-1\}$ or $\{e+1,\dots,n\}$, which has exactly one ghost flank and the other flank e, so it produces $F \setminus \{s\}$; as s varies over the $n-1$ occupied spaces this gives every element of P_{n-1} except the current one. So the move graph on Z is complete. By the first lemma no position of Z can occur before the game first enters Z, so from that moment the players simply enumerate distinct elements of Z until none is left. Since $\#Z = n+1$ is even and the entering player supplies the first, third and so on, the entering player is the one facing an exhausted end zone, and loses. □

Lemma 13.12.5. *Fix any position x. For each $t \in \{1,\dots,n\}$ there is exactly one move from x whose weight increment is t modulo $n+1$. No move leaves the weight unchanged.*

Proof. A type 1 move at an empty space e changes the weight by e. A type 2 move at s, with flanks i and j, changes it by $i+j-s$ modulo $n+1$: this is exact when both flanks are on the board, and it remains correct when a flank is a ghost, because the ghost labels 0 and $n+1$ are both $\equiv 0$. This is the reason the modulus is $n+1$ and not something else. Now fix a block $B = \{i+1,\dots,j-1\}$. The map $s \mapsto i+j-s$ sends B bijectively onto itself, so the type 2 moves at the stones of B realise exactly the increments lying in B, each once. The empty spaces and the blocks partition $\{1,\dots,n\}$, and the type 1 moves realise exactly the increments lying in the set of empty spaces, each once. Hence the n moves realise the n nonzero residues bijectively. □

Lemma 13.12.6. *$w(F) \equiv T$, and no position of P_{n-1} is balanced.*

Proof. $w(F) = 1+2+\cdots+n = n\cdot\frac{n+1}{2} \equiv (-1)T \equiv (n+1) - T = T \pmod{n+1}$, using $n \equiv -1$ and $2T = n+1$. Hence $w(F \setminus \{e\}) \equiv T - e$, and $1 \le e \le n$ forces $T - e \not\equiv T$. □

Theorem 13.12.7. *A position outside Z is a loss for the player to move if and only if it is balanced.*

Proof. Let x lie outside Z, so x has at most $n-2$ stones and every move from it is legal, and every resulting position has at most $n-1$ stones and so is not F.

Suppose x is unbalanced. By the increment lemma there is a unique move with increment $T - w(x) \not\equiv 0$; it produces a position y with $w(y) \equiv T$. Then $y \notin P_{n-1}$, since no position of P_{n-1} is balanced, and $y \neq F$, so y lies outside Z and is balanced. So from any unbalanced position outside Z there is a move to a balanced position outside Z.

Suppose x is balanced. Every move changes the weight, so every move produces an unbalanced position, which is either outside Z or in P_{n-1}.

Now let a player face an unbalanced position outside Z and always play the unique restoring move above. That player never moves into Z. The game terminates, because no position ever repeats and there are finitely many positions; and by the third lemma a player at a position outside Z always has a move, so the game can only end inside Z. Hence the opponent is the player who first moves into Z, and by the fourth lemma the opponent loses. So an unbalanced position outside Z is a win for the player to move. A balanced position outside Z hands the opponent either a position in Z, which means the mover entered Z first and loses, or an unbalanced position outside Z, which the opponent then wins; so it is a loss for the player to move. □

The initial position is empty, with $0 \leq n-2$ stones and weight $0 \not\equiv T$, so it is unbalanced and outside Z: Alice wins, and her winning first moves are exactly the moves to a balanced position. From the empty board every move is a type 1 move at a space e, with increment e, so the unique balancing move is $e = T$. Any other first move leaves an unbalanced position with one stone, which lies outside Z because $1 \leq n-2$, and therefore hands Bob the win. Alice's unique winning first move is to place a stone in the central space $\boxed{\frac{n+1}{2}}$.

For $n = 1$ the only first move is to fill the single space, which is the central space, and Bob's only candidate move returns the empty board, which has already occurred; Bob cannot move and loses. (This case needs the reading that the initial empty position counts as having occurred once the game has begun; that reading affects no other n.)

Remark 13.12.8. The invariant is the mirror strategy in disguise. A position symmetric about the centre with the centre occupied has weight T, because the off centre stones pair as s and $n+1-s$ with $s + (n+1-s) \equiv 0$, leaving only the central label T. Alice's rule "restore the symmetry" is a special case of "restore the weight", and the weight version has the advantage that it is defined for every position, needs no case analysis for moves straddling the centre, and shows the other first moves lose.

Layer 1: WHAT

Block 1. Guess the answer from the symmetry of the rules and the parity of n: the centre.

Block 2. Tabulate the effect of each move type on the number of stones, using ghost spaces at 0 and $n+1$ so that all four cases read off one description.

Block 3. Deduce that the count is nondecreasing away from the full board, that level preserving moves only shrink the two extremal blocks, and hence that no position can repeat outside the end zone. The no-repetition clause is now quarantined.

Block 4. Identify the end zone $Z = P_{n-1} \cup P_n$, show its move graph is complete, count $\#Z = n+1$, and conclude that the first player to move into Z loses.

Block 5. Introduce the weight modulo $n+1$ and prove the increment lemma: the n available moves realise the n nonzero increments bijectively.

Block 6. Compute the weights inside the end zone: the full board is balanced, nothing in P_{n-1} is.

Block 7. Conclude: balanced positions outside Z are exactly the losing ones, and the empty board has a unique balancing move, at the centre.

The nominal route reads "impartial game" and starts computing Grundy values, or reads "what may Alice do" and starts playing out small cases hoping for a pattern to prove itself. **The bifurcation point is Block 2: the decision to classify a type 2 move by the two empty spaces flanking its block rather than by the stone it moves.** Everything follows from that reindexing. It makes the stone count table trivial, it produces the formula $i + j - s$ for the weight increment, and it exposes the involution $s \mapsto i + j - s$ that gives the bijection in Block 5. A player who keeps thinking about the stone at s sees an unruly move; a player who thinks about the flanks sees a reflection inside an interval.

Layer 2: HOW

Block 1. **Cue.** Odd n, an empty symmetric start, and rules invariant under reflecting the board. **Why natural.** In a symmetric game the symmetric option is always the first candidate, because after taking it the second player's every reply can be answered by its mirror image. Guessing early is cheap and it fixes your target: you are now looking for a quantity that distinguishes the centre from every other space. **Link to the next block.** A mirror argument alone will not show the other moves lose, so you need an invariant that is defined at every position, not just at symmetric ones.

Block 2. **Cue.** The move description has two parenthetical clauses, "if such a space exists", which is the question flagging its own boundary cases. **Why natural.** When a rule has exceptions only at the ends of the board, invent objects that make the exceptions disappear. Ghost spaces at 0 and $n + 1$ let you say "the move deletes the stone at s and fills the two flanks", with the convention that filling a ghost does nothing. Now there is one rule and the case analysis is bookkeeping. The same instinct adds a point at infinity in projective geometry and an empty product in algebra. **Link to the next block.** With one uniform description, the effect on the stone count is a two line table.

Block 3. **Cue.** The table shows the count can only fall from the full board. **Why natural.** A quantity that never decreases is a potential function, and a potential function is exactly what kills a no-repetition rule: positions at different levels are automatically distinct, so repetition can only happen inside a level. Then look at what a level preserving move does, discover that it only shortens one extremal block, and repetition dies there too. That is the whole reason the clause is harmless. **Link to the next block.** Only the levels where the count can fall remain dangerous, and those are P_{n-1} and P_n.

Block 4. **Cue.** The moves inside the top two levels are unusually rich: from the full board every stone can be removed, and from a board with one gap every stone can be moved to the gap. **Why natural.** Once you notice every position of Z can reach every other in one move, the game inside Z has no structure left: it is the trivial game "name an unused element", whose outcome is decided by the parity of $\#Z$. Here $\#Z = n + 1$ is even, so entering Z is fatal. Notice that this is where the oddness of n enters the argument, and the only place it does. **Link to the next block.** You may now forget the repetition rule entirely and play the equivalent game: no repetitions, and moving into Z loses.

Block 5. **Cue.** A game where you must control who is forced to make the last kind of move, and a board whose spaces are naturally labelled 1 to n. **Why natural.** Sum the labels. Two facts make this the right functional. First, the ghosts are labelled 0 and $n + 1$, which are congruent modulo $n + 1$, so working in $\mathbb{Z}/(n + 1)$ makes the boundary cases obey the interior formula $\Delta \equiv i + j - s$. Second, the symmetric positions Alice wants all have the same weight T, because s pairs with $n + 1 - s$. So the modulus and the target are both forced by the guess in Block 1, and neither is pulled out of the air. Then compute the set of achievable increments and find the bijection: the map $s \mapsto i + j - s$

reflects a block onto itself, so the type 2 moves in a block hit exactly the labels of that block, and the type 1 moves hit exactly the labels of the empty spaces. **Link to the next block.** An invariant with surjective increments always produces a single winning residue, provided the terminal positions behave.

Block 6. Cue. Before declaring the target residue, check what it does at the boundary of your analysis. **Why natural.** The strategy "always restore weight T" is only safe if the restoring move never walks into the end zone. It does not, and for a sharp reason: the only balanced position with many stones is the full board, which cannot be reached from a position with at most $n-2$ stones. That one computation, $w(F) \equiv T$ and $w(F \setminus \{e\}) \equiv T - e$, is what makes the whole strategy legal. **Link to the next block.** All the pieces are in place.

Block 7. Cue. The empty board has weight 0, and $T \neq 0$. **Why natural.** Since the empty board is unbalanced, Alice wins, and the increment lemma says exactly one of her n moves balances it. From an empty board the increments are just the labels, so the balancing move is the type 1 move at T, the centre. Uniqueness is not an extra argument; it is the same lemma read once. **Link to the next block.** Handle $n = 1$ separately and stop.

Layer 3: WHY

Three truths are doing the work.

The first is the standard characterisation of losing positions in an impartial normal play game: a set $\mathcal{L}$ of positions is the set of losses for the player to move, provided every move from a position of $\mathcal{L}$ leaves $\mathcal{L}$, and from every position outside $\mathcal{L}$ some move enters $\mathcal{L}$, and every terminal position lies in $\mathcal{L}$. You never need to compute anything recursively if you can guess $\mathcal{L}$ and verify those three closure conditions. Here $\mathcal{L}$ is a single congruence class, and the verification is the increment lemma plus the end zone parity. This is exactly the mechanism of Nim, where $\mathcal{L}$ is the set of positions of zero binary digit sum, and of every other game that turns out to be governed by a modular invariant.

The second is that a no-repetition rule is only dangerous where the position graph has cycles. Find a potential function that never decreases, and cycles can only live inside a level; kill those by finding a second quantity that strictly decreases inside a level. What is left is a subgraph where cycles are unavoidable, here the end zone, and in a strongly connected terminal set of size N with no repetition the game is pure parity. Any game with a Ko style rule should be attacked in that order: potential, then level structure, then the residual cycles.

The third is the reason the modulus is $n+1$. A type 2 move conserves the sum of labels up to the two flanks, and the flanks are labelled 0 and $n+1$ when they fall off the board. A conservation law that is exact in the interior and off by $n+1$ at the boundary is an exact conservation law modulo $n+1$. Whenever a local rearrangement rule conserves something except for a fixed boundary defect, quotient by that defect and the rule becomes clean. That is the single most transferable idea in this problem.

The discernment mechanism, stated as a protocol you can run on any unfamiliar game. (1) Test the symmetry of the rules and the start; guess the answer. (2) Find a monotone potential and use it to quarantine any history dependent rule. (3) Identify the terminal region and settle it by counting, not by strategy. (4) Label the cells and compute the set of increments of the label sum from a general position; if the increments realise every nonzero residue modulo some m exactly once, the losing positions form one residue class and you only have to find which one. (5) Check that the winning move never falls into the terminal region.

Honest knowledge gaps. Before this problem is even approachable you need: the language of impartial games under normal play and the three closure conditions above; the fact that Sprague and Grundy applies to disjunctive sums and that this game is not one, so Grundy values buy

nothing; two pile Nim, which is where the official solution routes its level P_{n-2} analysis and which is worth knowing even though the route above avoids it; and the notion of a loopy game, meaning a game whose move graph has cycles, together with the fact that the standard theory assumes a directed acyclic graph and that the no-repetition rule is what restores acyclicity here. None of that is in the A level or Further Maths syllabus and none of it is hard; it is simply a body of definitions that must be installed before the reflexes can fire.

Revolving concepts

Impartial games, normal play, N and P positions. Both players have the same options; the player unable to move loses. $\mathcal{P}$ is the set of positions losing for the player to move, characterised by: terminal positions lie in $\mathcal{P}$; every option of a $\mathcal{P}$ position lies outside $\mathcal{P}$; every position outside $\mathcal{P}$ has an option in $\mathcal{P}$. Exhibiting $\mathcal{P}$ and checking these three is always cheaper than a recursion. See Book 1, field: Games and invariants, topic: normal play.

Nim and Sprague and Grundy. Nim with piles $a_1, \dots, a_r$ is a loss for the mover exactly when $a_1 \oplus \cdots \oplus a_r = 0$; every impartial game position has a Grundy value, and the value of a disjunctive sum is the binary digit sum of the values. Two pile Nim, the case used in the official route, has $\mathcal{P}$ equal to the equal pile positions. The relevance here is negative and worth internalising: this game is not a sum of independent components, so Grundy theory does not apply, and recognising that saves a wasted half hour. See Book 1, field: Games and invariants, topic: Nim.

Modular invariants with surjective increments. Suppose φ maps positions to $\mathbb{Z}/m$ and from every non terminal position each nonzero increment is realised by exactly one move. Then no move fixes φ, and every value is reachable from every other in one move, so $\mathcal{P}$ is a single class $\varphi^{-1}(T)$ as soon as the terminal behaviour selects T. This is the abstract engine of the solution, and of subtraction games, Mock Turtles style games, and many coin and token games on a labelled strip. See Book 1, field: Games and invariants, topic: modular invariants.

Potentials, loopy games and the no-repetition rule. A game whose move graph has cycles is called loopy and has draws in general; adding a no-repetition rule makes the state space the set of histories and restores finiteness. The technique used here is the standard one: find a monotone potential (stone count), then a strictly decreasing secondary quantity within a level ($a + b$), which together force the history graph to be acyclic except on a small terminal set. The residual recursion is not a sequence recursion but a descending induction over the levels $P_{n-2}, P_{n-3}, \dots$; the general form of that recursion is "grade the state space by a monotone potential, solve the top grade directly, and induct downwards", and the invariant here is exactly what lets you solve all grades at once instead. See Book 1, field: Games and invariants, topic: loopy games.

Terminal cliques and parity. If a set Z of positions is closed under moves, mutually reachable in one move, and subject to no repetition, the game inside Z is "name an unused element of Z" and is decided by the parity of $\#Z$: with $\#Z$ even the player who enters Z loses, with $\#Z$ odd that player wins. This is where the hypothesis that n is odd is consumed, and it is also why the even case is a genuinely different and still unresolved problem. See Book 1, field: Combinatorics, topic: parity arguments.

Symmetry and mirror strategies. On a board with a reflection symmetry fixing a unique cell, the first player takes the fixed cell and thereafter mirrors, provided mirrored replies are always legal. The weight invariant here is the arithmetic shadow of that strategy, since central symmetry with the centre occupied is equivalent to weight T in the cases where both make sense. See Book 1, field: Games and invariants, topic: strategy stealing and symmetry.

Circuit Bank

- **WHEN** a game forbids repeating a position **DO** find a quantity that never decreases, then a second quantity that strictly decreases whenever the first is constant **BECAUSE** together

they make the history graph acyclic, so the clause is inert except where the first quantity is maximal, and that residue is small enough to count

- **WHEN** a set of positions is closed under moves and mutually reachable **DO** stop doing strategy and count the set **BECAUSE** with no repetition the play inside such a set is a bare enumeration, so only the parity of its size matters
- **WHEN** a move rule has exceptions at the ends of the board **DO** introduce ghost cells at 0 and $n+1$ and choose the modulus $n+1$ **BECAUSE** the ghost labels are then congruent to zero, so one formula covers interior and boundary and the conservation law becomes exact
- **WHEN** the rules and the starting position are symmetric and the board has a unique fixed cell **DO** guess that the fixed cell is the winning move and look for an invariant that is constant on symmetric positions **BECAUSE** a mirror strategy proves that move wins, and its arithmetic shadow proves the others lose
- **WHEN** from every position each nonzero increment of a labelling is realised by exactly one move **DO** declare the losing positions to be one residue class and verify the terminal condition **BECAUSE** that is the Nim mechanism, and the only remaining work is to identify the class and to check the restoring move never lands in the terminal region

Backtesting

1. First useful cue: the two clauses "if such a space exists" flag the boundary, so index a type 2 move by the empty spaces flanking its block, with ghosts at 0 and $n+1$.
2. Method the expression suggested: the stone count table, then a weight given by the sum of occupied labels modulo $n+1$, with target $(n+1)/2$.
3. Where you would hesitate, and the thought to reinforce: at the no-repetition clause. Reinforce with the protocol potential first, level structure second, residual cycles third, so that the clause is quarantined before any strategy is attempted.
4. The trap the question sets: treating this as a disjunctive sum and reaching for Grundy values, or proving the mirror strategy and thinking the question has been answered when it asked for all winning first moves.
5. What makes you recognise it faster next time: a local rearrangement rule that conserves a label sum except for a fixed defect at the boundary is a conservation law modulo that defect.
6. The reusable decision rule: if each nonzero increment of an invariant is realised exactly once from every position, the losing positions form a single residue class; find it by evaluating the invariant on the terminal region.

Mirror drills

1. Play the game with $n = 3$ by hand and confirm that space 2 is the unique winning first move. *Answer:* after Alice plays 2 every one of Bob's three moves reaches a two stone position, and $Z = P_2 \cup P_3$ with $\#Z = 4$, so Bob has entered the end zone first and loses; after Alice plays 1 or 3, Bob replies at the centre by the same reasoning.
2. Show that any position symmetric about the centre with the central space occupied has weight $(n+1)/2$, and that any symmetric position with the centre empty does not. *Answer:* pair s with $n+1-s$, each pair contributing $n+1 \equiv 0$; the centre contributes $(n+1)/2$ if occupied and 0 if not.

3. Identify exactly where the argument fails when n is even, and say what is known. *Answer:* $\#Z = n + 1$ becomes odd, so the first player into the end zone now wins and every position of P_{n-2} is a win; the weight argument collapses and must be replaced by a different invariant. Savitt conjectured, on the evidence of $n = 2$ and $n = 4$, that Alice still wins with either central space, and only a partial analysis is known.

Chapter 14

Putnam 2012

14.1 A1. an acute triple forced by Fibonacci growth

Let $d_1, d_2, \ldots, d_{12}$ be real numbers in the open interval $(1, 12)$. Show that there exist distinct indices i, j, k such that d_i, d_j, d_k are the side lengths of an acute triangle.

Read it out loud

Twelve real numbers, each confined to $(1, 12)$, and a claim that some three of them, in some order, form an acute triangle. The command term is "there exist": an existence claim, not a "for all", which means proof by contradiction is on the table from the first read, since contradicting a universal negation is usually cheaper than constructing a witness by hand. The fields wired into this problem are elementary geometry (what makes a triangle acute, given only its side lengths) and sequences (a forced growth argument). What is really being tested is whether you notice that twelve objects and a range factor of twelve, next to each other, are not a coincidence.

Within thirty seconds you should have written down two things. First: acuteness only depends on the relative sizes of the three chosen numbers, so sorting the twelve values costs nothing and turns an unordered search into an ordered one. Second: twelve numbers means $\binom{12}{3} = 220$ possible triples, and no fluent solution checks 220 cases, so whatever route you take must collapse that count drastically, most likely by restricting attention to a much smaller, structured sub-family and letting an induction do the rest.

The number 12 doing double duty, once as the count of terms and once as the upper bound of the interval, is the loudest cue on the page. Anyone who has drilled sequences knows that $F_{12} = 144 = 12^2$ for the Fibonacci numbers $F_1 = F_2 = 1$, $F_{n+2} = F_n + F_{n+1}$; seeing a count of exactly twelve objects bounded by a range whose square is a suspiciously round number should fire the reaction circuit for a growth-outpaces-the-range contradiction before you have written a single inequality.

Approaches, ranked worst to best

1. **brute enumeration.** *Cue:* "there exist distinct indices i, j, k". *Circuit:* casework over all triples. (checking all 220 triples individually against the cosine rule offers no structural insight, costs enormous ink for a ten point problem, and is exactly the kind of grinding this problem is designed to punish).
2. **sort, then search without a growth bound.** *Cue:* sorting makes "largest side" well defined for every triple. *Circuit:* ordered casework. (sorting is a real improvement, since it tells you instantly which of the three sorted values plays the role of the longest side in any candidate triple, but without noticing the Fibonacci substructure you are still hunting through an unstructured set of comparisons with no closed reason to stop early; better than raw enumeration, still far more ink than necessary).
3. **sort, negate on consecutive triples only, induct.** *Cue:* the sorted list turns "no acute triple" into a two-term recursive inequality. *Circuit:* Fibonacci domination. (the ideal route: assume for contradiction that even the ten cheapest candidate triples, the consecutive ones in sorted order, all fail to be acute; this assumption is a Fibonacci-shaped recursion in disguise, and a two-line induction turns it into a single numerical contradiction against the given bounds).

The ideal solution

Relabel the twelve given numbers so that $d_1 \leq d_2 \leq \cdots \leq d_{12}$. This is legitimate because the conclusion only asks for the existence of three distinct indices among the original twelve whose values form an acute triangle; a permutation of labels changes nothing about which triples of values are available, so it suffices to find three consecutive positions in the sorted list.

First fix exactly what "acute triangle" costs you to verify. Suppose $a \le b \le c$ are positive reals with $c^2 < a^2 + b^2$. Since $(a+b)^2 = a^2 + 2ab + b^2 \ge a^2 + b^2 > c^2$ and $a + b > 0$, this already gives $a + b > c$, so the triangle inequality holds automatically; the other two instances of it, $a + c > b$ and $b + c > a$, are immediate since $a, b, c > 0$ and c is the largest. So a, b, c genuinely are the side lengths of a triangle. In that triangle, c is the longest side, hence opposite the largest angle γ; by the cosine rule, $\cos\gamma = \dfrac{a^2 + b^2 - c^2}{2ab} > 0$, so γ is acute. Since the three angles of a triangle sum to π, at most one of them can be at least $\pi/2$, and that one, if it existed, would have to be the largest; since the largest angle γ is already acute, all three are. Conversely if $c^2 \ge a^2 + b^2$ the triangle is right angled or obtuse at γ. So for positive reals $a \le b \le c$: they form an acute triangle exactly when $c^2 < a^2 + b^2$, one inequality, nothing more to check.

Suppose, for contradiction, that no three of $d_1, \ldots, d_{12}$ are the side lengths of an acute triangle. In particular no three consecutive terms of the sorted list are, so for every $i = 1, \ldots, 10$,

$$d_{i+2}^2 \ge d_i^2 + d_{i+1}^2.$$

Let $F_1 = F_2 = 1$ and $F_{n+2} = F_n + F_{n+1}$ be the Fibonacci numbers. Claim: $d_i^2 \ge F_i\, d_1^2$ for every $i = 1, \ldots, 12$. For $i = 1$ this reads $d_1^2 \ge d_1^2$. For $i = 2$, $d_2 \ge d_1 > 0$ gives $d_2^2 \ge d_1^2 = F_2 d_1^2$. For the inductive step, if $d_i^2 \ge F_i d_1^2$ and $d_{i+1}^2 \ge F_{i+1} d_1^2$ then

$$d_{i+2}^2 \ge d_i^2 + d_{i+1}^2 \ge (F_i + F_{i+1}) d_1^2 = F_{i+2} d_1^2,$$

so the claim holds for all $i \le 12$ by induction on i. Taking $i = 12$, and using $F_{12} = 144$,

$$d_{12}^2 \ge 144\, d_1^2.$$

Since $d_1 \in (1, 12)$, $d_1 > 1$ strictly, so $d_1^2 > 1$ and $d_{12}^2 > 144$, giving $d_{12} > 12$. But $d_{12} \in (1, 12)$ forces $d_{12} < 12$. This is a contradiction.

Hence the assumption fails: some three consecutive terms of the sorted list, and therefore some three of the original $d_1, \ldots, d_{12}$ at three distinct original indices i, j, k, are the side lengths of an acute triangle. ■

Layer 1: WHAT

1. Sort and relabel the twelve values into increasing order.
2. Reduce "acute triangle" to a single inequality: largest side squared less than the sum of the squares of the other two, with the triangle inequality automatic.
3. Assume, for contradiction, only the weakest necessary sub-claim: that no three *consecutive* sorted values are acute.
4. Recognise that assumption as a Fibonacci-shaped recursive inequality and induct to $d_{12}^2 \ge 144\, d_1^2$.
5. Plug in the two given numeric bounds, $d_1 > 1$ and $d_{12} < 12$, to close the contradiction.

The nominal route enumerates some or all of the $\binom{12}{3} = 220$ triples directly, checking the cosine-rule inequality case by case with no structural reduction. The ideal route restricts the negation to the ten consecutive triples in sorted order and lets a single two-line induction absorb all ten checks at once. The bifurcation point sits immediately after sorting: it is the decision to assume the negation only on consecutive triples, a strict sub-family of all triples, rather than on every triple. That one choice is what turns two hundred and twenty cases into one Fibonacci induction of length ten, since a contradiction obtained from the smaller sub-family already proves the larger claim false as well.

Layer 2: HOW

Block 1. **Cue.** Twelve unordered real numbers, and a target property (acuteness) that depends only on which of three chosen values is largest, not on their original positions. **Why natural.** Sorting costs nothing precisely because the property you are hunting for is invariant under relabelling; once sorted, any candidate triple instantly tells you which value plays the role of the longest side, without further casework. **Link to the next block.** With a sorted list in hand, the cheapest candidate triples to examine are neighbours, since they require no extra bookkeeping about which positions to compare.

Block 2. **Cue.** The problem hands you only side lengths and the word "acute", nothing about angles directly. **Why natural.** The cosine rule converts an angle condition into a polynomial inequality in the squared side lengths, and because the three angles of a triangle sum to π, only the largest angle can possibly fail to be acute; testing all three angles collapses to testing one inequality on the longest side. **Link to the next block.** With a single inequality test available, "no acute triple exists" translates directly into a chain of numerical inequalities that can be chased by induction.

Block 3. **Cue.** You need a contradiction from "no acute triple exists" among all 220 triples, but the sorted list hands you ten much cheaper candidates for free: the consecutive ones. **Why natural.** Assuming the negation on the smallest sufficient sub-family, rather than on every triple, is the ink-saving move: if a contradiction already follows from the weaker assumption (failure on consecutive triples only), the stronger claim (failure on all triples) is impossible too, for free, since consecutive triples are a subset of all triples. **Link to the next block.** Written out, the negation on ten consecutive triples is exactly the inequality $d_{i+2}^2 \geq d_i^2 + d_{i+1}^2$ for $i = 1, \ldots, 10$: a recursion in disguise.

Block 4. **Cue.** An inequality of the shape "term $i+2$ is at least the sum of the two before it", repeated ten times. **Why natural.** Whenever an inequality has this shape, the sequence of terms is forced to grow at least as fast as the Fibonacci numbers, by an immediate two-line induction; recognising the shape tells you the growth rate, and hence the bound you are heading toward, without inventing anything from scratch. **Link to the next block.** Once $d_{12}^2 \geq 144\, d_1^2$ is established, the only work left is to substitute the two numeric bounds the problem actually gave you on d_1 and d_{12}.

Block 5. **Cue.** The problem's interval is $(1, 12)$, and $144 = 12^2$ is exactly F_{12}. **Why natural.** This is not a coincidence: the numbers were chosen so the Fibonacci bound at $i = 12$ lands exactly on the boundary 12^2, leaving no room to spare, which is also why twelve numbers are needed and not eleven (the same argument with eleven numbers only forces $d_{11} > \sqrt{89} \approx 9.43$, no contradiction against an interval of width twelve). **Link to the next block.** This closes the proof: the assumption that no acute triple exists is false, so three of the original twelve numbers, at three distinct indices, form one.

Layer 3: WHY

The truth underneath the route is that any two-term recursive inequality $x_{n+2} \geq x_n + x_{n+1}$ among positive terms grows at least geometrically, at the golden ratio rate $\phi = (1 + \sqrt{5})/2$, because the Fibonacci numbers themselves grow like $\phi^n/\sqrt{5}$. This problem is one instance of a wide family: a local avoidance condition, assumed everywhere, forces a monotone quantity to grow at a fixed exponential rate; make the given range too short to sustain that growth for as many steps as you have terms, and avoidance becomes impossible.

The discernment mechanism is this: whenever a problem gives you n bounded quantities together with a numeric bound whose ratio (upper over lower, or upper alone against a natural

scale) is suspiciously close to n itself, suspect that n has been tuned to a named growth sequence, Fibonacci, powers of two, factorials, evaluated near n. The setter needs the forced growth to exactly outrun the given range at the given count, no earlier and no later, and that exactness is the strongest possible hint that a growth-versus-range contradiction is the intended engine, not a red herring. Train this by asking, whenever a problem says "distinct indices" and "show there exist" about n bounded reals: what happens if I sort, then assume the negation locally, on neighbours only, rather than on every subset; does that generate a recursion I recognise?

Revolving concepts

Acute triangle from side lengths: for positive reals $a \le b \le c$, they form an acute triangle exactly when $c^2 < a^2 + b^2$, via the cosine rule $c^2 = a^2 + b^2 - 2ab\cos\gamma$ and the fact that the largest angle is opposite the largest side; since at most one angle in a triangle can be at least $\pi/2$, one inequality on the longest side decides all three angles at once, and the triangle inequality is then automatic. See Book 1, field Geometry, topic triangle classification by side lengths.

Fibonacci recursion and its generalisation: $F_1 = F_2 = 1$, $F_{n+2} = F_n + F_{n+1}$, with closed form (Binet) $F_n = (\phi^n - \psi^n)/\sqrt{5}$ where $\phi, \psi = (1 \pm \sqrt{5})/2$ solve $t^2 = t + 1$, giving geometric growth at rate $\phi \approx 1.618$. The recursion generalises directly: for any inequality $x_{n+2} \ge \alpha x_n + \beta x_{n+1}$ with $\alpha, \beta > 0$ and positive initial terms, the same two-line induction shows x_n grows at least like the dominant positive root of $t^2 = \beta t + \alpha$; Fibonacci is the case $\alpha = \beta = 1$. Any linear recursion of higher order $x_{n+k} = c_1 x_{n+k-1} + \cdots + c_k x_n$ is handled the same way, via the characteristic polynomial $t^k = c_1 t^{k-1} + \cdots + c_k$ and its root of largest absolute value. See field Sequences and recurrences, topic linear recurrence lower bounds by induction.

Extremal ordering: sorting a finite unordered collection so an order-dependent or symmetric claim becomes tractable, a standing technique across combinatorics whenever a statement does not depend on the original labelling. See field Combinatorics, topic the extremal principle.

Sufficient sub-family reroute: to prove existence of a k-subset with a property among n objects, it suffices to show the property holds somewhere in a smaller, structured sub-family, here the consecutive windows of a sorted list, since that sub-family is contained in the full collection of k-subsets. See field Combinatorics, topic search-space reduction for existence proofs.

Circuit Bank

- **WHEN** a problem gives n bounded reals in an interval and asks you to find k of them satisfying an order-dependent inequality, such as the acute triangle condition **DO** sort them first and rename in increasing order **BECAUSE** the target property depends only on relative size, so sorting is free and turns "which k-subset" into "which window of the sorted list"
- **WHEN** you want to contradict "no such k-tuple exists" **DO** apply the assumption only to consecutive windows of the sorted list, not to every k-subset **BECAUSE** a contradiction from the smaller, structured sub-family already proves the full statement, and consecutive windows are exactly what turn into a one-parameter recursion
- **WHEN** a recursive inequality of the shape $x_{i+2} \ge x_i + x_{i+1}$ appears among positive terms, or any order-two linear recursion **DO** identify it immediately as at least Fibonacci growth and induct $x_i \ge F_i x_1$, or the analogous bound for general coefficients **BECAUSE** Fibonacci-type recursions grow geometrically at the golden ratio rate, and this rate is almost always the engine behind whatever numeric bound the problem handed you
- **WHEN** you must decide whether a triangle with given side lengths is acute **DO** compute only the longest side squared against the sum of the squares of the other two **BECAUSE** the largest angle is opposite the longest side, at most one angle in a triangle can be non-acute, and the triangle inequality follows automatically once that one inequality holds

Backtesting

1. First useful cue: twelve numbers, each confined to $(1, 12)$, a range factor of twelve sitting next to a count of twelve.
2. Method the expression suggested: an order-statistic argument, sort then bound growth, since the target property is entirely about relative size.
3. Where you would hesitate, and the thought to reinforce: the moment you decide to assume the negation only on consecutive triples rather than on all 220; reinforce that a contradiction from a sub-family is still a contradiction for the whole family.
4. The trap the question sets: spending a line verifying the triangle inequality separately from the acuteness inequality, when it is automatic once the longest side squared is less than the sum of the other two squared.
5. What makes you recognise it faster next time: a count of objects matching an interval's ratio bound exactly, twelve numbers against a ratio of twelve, is a fingerprint of a hidden Fibonacci or geometric-growth argument.
6. The reusable decision rule: when a bounded existence claim about k-tuples from n reals appears, sort, restrict the negation to consecutive windows, and compare the induced recursion's growth rate against the given numeric bound.

Mirror drills

1. Show that among any six positive reals in the open interval $(1, \sqrt{8})$, three form an acute triangle. *Answer:* identical argument with $n = 6$: sort, assume no three consecutive are acute, induct to $d_6^2 \geq F_6 d_1^2 = 8d_1^2 > 8$, contradicting $d_6 < \sqrt{8}$.
2. Explain in one line why the same conclusion fails to follow from only eleven numbers in $(1, 12)$. *Answer:* the induction only reaches $d_{11}^2 \geq F_{11} d_1^2 = 89 d_1^2 > 89$, giving $d_{11} > \sqrt{89} \approx 9.43$, which does not contradict $d_{11} < 12$.
3. Twelve reals lie in $(1, 12)$, all equal to 6. Does the argument produce a contradiction, and what does this tell you about the sharpness of the bound? *Answer:* no contradiction is needed; every triple is equilateral, hence acute, since equal side lengths trivially satisfy $c^2 < a^2 + b^2$; this shows the bound is not violated by a "flat" example, only genuinely spread-out, near-Fibonacci-ratio examples come close to avoiding an acute triple.

14.2 A2. forcing cancellation without identity or inverses

Let $*$ be a commutative and associative binary operation on a set S. Assume that for every x and y in S, there exists z in S such that $x * z = y$. (This z may depend on x and y.) Show that if a, b, c are in S and $a * c = b * c$, then $a = b$.

Read it out loud

No ambient structure is given beyond three axioms on an otherwise bare set S. "Commutative and associative" is a command term telling you that you may rebracket and reorder any expression built from $*$ freely, forever, without further comment, exactly as with ordinary multiplication. The solvability clause, for every x, y there exists z with $x * z = y$, is a disguised surjectivity statement: fixing x, the map $z \mapsto x * z$ hits every element of S. The field wired into this problem is abstract algebra, specifically the theory of cancellative and invertible structures sitting just below group theory.

What is really being tested is whether you can recognise that surjectivity of every one of these translation maps, together with associativity and commutativity, is already enough to force cancellation on one specific pair of elements, without first reconstructing the whole group structure the remark afterward promises exists. The goal equation, $a * c = b * c \Rightarrow a = b$, is literally asking you to cancel c. Since S has no named identity or inverses to cancel with directly, your only tool is the solvability axiom, so within thirty seconds you should have written down, symbolically, that solvability lets you solve $x * z = y$ for a fresh z whenever you choose x and y, and started hunting for the two applications of it that will bridge a and b.

One phrase deserves a second look: "this z may depend on x and y." That is a warning, not decoration. It tells you not to expect a single uniform witness reusable across every equation you write; each application of the axiom earns you one disposable helper element, valid only through the one equation it satisfies, and the proof must be built so that it never needs more from that helper than exactly that equation.

Approaches, ranked worst to best

1. **concrete guessing.** *Cue:* "binary operation on a set S". *Circuit:* testing familiar operations. (trying the claim on $\mathbb{Z}$ under addition or the positive reals under multiplication to guess the mechanism never becomes a proof for an abstract S and abstract $*$; every minute here is unrecoverable in the arena).

2. **build the full group structure first.** *Cue:* commutative, associative, always solvable reads like the group axioms minus a named identity. *Circuit:* the full group theorem. (prove an identity element exists and is unique, then that every element has an inverse, then cancel using ordinary group cancellation; this is valid, the remark confirms S is in fact an abelian group, but it proves a strictly stronger global theorem than the problem asks for, costing far more ink for a result that only needs the pair a, b reconciled).

3. **local bootstrap via two witnesses.** *Cue:* $a * c = b * c$ names a single shared value. *Circuit:* surjectivity of translations, applied exactly twice. (the ideal route: name the shared value $d = a * c = b * c$, solve $d * e = a$, build $f = c * e$, which is simultaneously a right identity for a and for b, then solve $g * a = b$ to close the loop; no global structure is ever proved, matching exactly what the problem asks and nothing more).

The ideal solution

Write d for the common value $a * c = b * c \in S$.

By hypothesis, applied to the pair $(x, y) = (d, a)$, there exists $e \in S$ with

$$d * e = a.$$

Set $f = c * e \in S$. Using associativity and then $a * c = d$,

$$a * f = a * (c * e) = (a * c) * e = d * e = a.$$

Using associativity again, and $b * c = d$, the same d as above,

$$b * f = b * (c * e) = (b * c) * e = d * e = a.$$

So f satisfies both $a * f = a$ and $b * f = a$.

By hypothesis, applied to the pair $(x, y) = (a, b)$, there exists $g \in S$ with

$$g * a = b.$$

Using $a = a * f$ from above, then associativity, then $g * a = b$,

$$b = g * a = g * (a * f) = (g * a) * f = b * f.$$

But $b * f = a$ was already shown. Hence $b = a$, as required. ■

It is worth repeating that this argument never constructs a global identity for S, only the single element f, built exclusively from c and the witness e, that happens to fix both a and b. A caveat worth clarifying: with more work one can show that the same f fixes every element of S, giving S a genuine two-sided identity, and that every element then has an inverse under $*$, so $(S, *)$ is in fact an abelian group; the problem only asks for the cheapest consequence of that structure, extracted without paying for the rest of it.

Layer 1: WHAT

1. Name the shared value $d = a * c = b * c$.
2. Solve $d * e = a$ using solvability: the first witness.
3. Build $f = c * e$; associativity gives $a * f = a$.
4. Run the identical computation with b in place of a, using $b * c = d$ as well, giving $b * f = a$.
5. Solve $g * a = b$ using solvability: the second witness.
6. Chain $b = g * a = g * (a * f) = (g * a) * f = b * f = a$.

The nominal route reconstructs the full group structure of S, a global identity followed by inverses for every element, then invokes ordinary group cancellation. The ideal route builds one local bridging element f tailored only to a, b, and c, using exactly two applications of the solvability axiom. The bifurcation point sits right after writing $d = a * c = b * c$: the choice either to chase a global identity valid for all of S, or to chase a local identity that only needs to work for the pair a, b. The ideal route is the realisation that the problem only ever needs one pair of elements reconciled, not the whole set.

Layer 2: HOW

Block 1. **Cue.** $a * c = b * c$: two different left-hand sides producing the identical element of S. **Why natural.** Naming that common output as a single symbol d is natural because everything you know about a and about b, for the rest of the proof, only enters through how each relates to d; collapsing two equations into one named quantity is what lets you treat a and b symmetrically in every later step. **Link to the next block.** Having a single target d, the next question is whether you can undo d back to a using the only tool the problem gives you, which is exactly the solvability axiom applied with $x = d, y = a$.

Block 2. **Cue.** The solvability axiom licenses a witness for any equation $x * z = y$ you choose to write down, for any $x, y \in S$; you have just produced a specific target, $d * z = a$. **Why natural.** Choosing $(x, y) = (d, a)$ is natural because d is exactly the quantity you want to strip away to recover a, and the axiom is licence to name a witness for that without knowing anything else about S. **Link to the next block.** The witness e only becomes useful once combined with the leftover factor c, since c is what is still attached to a and to b inside d.

Block 3. **Cue.** You have e with $d * e = a$, and c is the common factor inside $d = a * c = b * c$. **Why natural.** Forming $f = c * e$ and expanding $a * f = a * (c * e) = (a * c) * e = d * e = a$ uses only associativity, licensed freely by hypothesis; the reason to build f from exactly c and e, rather than any other combination, is that it is the unique combination that will let the identical computation run again with b in place of a. **Link to the next block.** Since f was built without ever referring to a specifically, only to c and e, the identical computation should run again verbatim with b.

Block 4. **Cue.** $b * c = d$ also, by the given hypothesis $a * c = b * c$. **Why natural.** Running the identical three-line computation with b in place of a, $b * f = b * (c * e) = (b * c) * e = d * e = a$, is natural precisely because f was deliberately built from c and e alone, so it treats a and b identically; this is the moment the shared hypothesis $a * c = b * c$ earns its keep a second time. **Link to the next block.** Two facts now sit side by side, $a * f = a$ and $b * f = a$; the goal $a = b$ will fall out the instant $b * f$ can be related back to b itself, not only to a.

Block 5. **Cue.** You want to turn "$b * f = a$" into "$b = a$", and your only tool remains the solvability axiom. **Why natural.** Applying it with $(x, y) = (a, b)$ produces g with $g * a = b$: a second, independent bridge, this time from a to b rather than from d to a; this pair is natural because b is the element you are trying to reach, and a is the element over which you already have full control, through f. **Link to the next block.** Substituting $a = a * f$ inside $g * a$ is the only way to bring f, and hence the fact $b * f = a$, into contact with $g * a = b$.

Block 6. **Cue.** $b = g * a$ on one hand, $a = a * f$ on the other. **Why natural.** Substituting the second into the first and re-associating, $b = g * a = g * (a * f) = (g * a) * f$, replaces the inner $g * a$ with b, by definition of g, purely through associativity, landing on $b * f$, a quantity already evaluated in Block 4 to equal a; the whole construction was aimed so that this final substitution has nowhere else to go but $a = b$. **Link to the next block.** None; this closes the proof.

Layer 3: WHY

The solvability hypothesis says every translation map $L_x : S \to S$, $L_x(z) = x * z$, is surjective. Associativity and commutativity make $*$-expressions manipulable exactly like ordinary multiplication, regrouping and reordering always licensed once stated. The proof shows that surjectivity of translations, together with associativity and commutativity, forces injectivity of translations too, which is exactly what cancellation means: L_c injective, even though injectivity was never assumed.

The discernment mechanism: whenever a hypothesis gives existence of a solution to an equation, without uniqueness, inside an abstract algebraic structure, and the goal is a cancellation or uniqueness statement, the standard reroute is to apply the existence hypothesis exactly twice, choosing the two input pairs so the resulting witnesses compose back into the two sides of the equation you are trying to equate. You are not solving for the witnesses explicitly, since in general you cannot; you are only ever using the one defining equation each witness satisfies. Train this by noticing the pattern in the problem: the goal equation ($a = b$) and the hypothesis equation ($a * c = b * c$) differ by exactly one factor of c, and you then look for a way to attach and detach that c using the existence axiom, which is precisely what e and f do. The phrase "this z may depend on x and y"

in the problem statement is a signpost that you must not expect uniform witnesses, only ad hoc ones for the specific pairs you choose, and that is exactly why the proof never names e or g except through the one equation each satisfies.

Revolving concepts

Translation maps and surjectivity in a magma: for $(S, *)$, $L_x(z) = x * z$; the hypothesis states L_x is surjective for every x. See field Abstract algebra, topic translations in a groupoid.

Generalised associativity and commutativity as bookkeeping licence: once associativity holds for three terms, any bracketing of a fixed sequence of elements under $*$ agrees, provable by induction on the number of terms; commutativity additionally frees the order. Used four times in this proof without further comment. See field Abstract algebra, topic semigroup bracketing.

Existential witnesses used opaquely: when a hypothesis only guarantees existence, the standard technique is to name the object and use only its defining equation afterward, never attempting to solve for it explicitly; this is how e and g are used throughout, neither ever computed. See field Logic and set theory, topic existential elimination in proofs.

Commutative, associative, everywhere solvable implies abelian group: construct an identity as any solution u of $u * a = a$ for a fixed a, show by an argument in the same spirit as this problem that u fixes every element of S, then produce inverses similarly. Cancellation, the content of this problem, is the cheapest consequence of that structure, extracted without paying for the rest of it. See field Abstract algebra, topic quasigroups, Latin squares, and when they are groups.

Circuit Bank

- **WHEN** a hypothesis guarantees a solution to $x * z = y$ exists for every x, y, but not uniquely **DO** name the witness with a fresh letter and use only the one equation it satisfies in every later step **BECAUSE** the witness cannot be solved for explicitly in an abstract structure, so the proof must stay entirely inside the algebra generated by the defining equations
- **WHEN** you must prove a cancellation law $a * c = b * c \Rightarrow a = b$ in a structure without a named identity or inverses **DO** look for an existence axiom and apply it exactly twice, choosing the two input pairs so the witnesses compose back into a and b **BECAUSE** cancellation is equivalent to injectivity of the translation map by c, and two applications of a solvability axiom typically suffice to convert surjectivity into injectivity for one specific element
- **WHEN** a problem's hypotheses read like group axioms minus a named identity **DO** resist proving the full group structure unless the problem actually asks for it **BECAUSE** proving only the minimal local fact the problem wants costs far less ink than reconstructing identity and inverses for the whole set, even when the stronger theorem is also true
- **WHEN** the same algebraic expression must be evaluated for two different elements sharing a piece of data, here c inside $d = a * c = b * c$ **DO** build one auxiliary object from only the shared data, then run the identical computation for each element **BECAUSE** an auxiliary object that never refers to either element individually is guaranteed to apply verbatim to both, which is exactly what lets $a * f = a$ and $b * f = a$ both fall out of a single construction

Backtesting

1. First useful cue: the goal $a * c = b * c \Rightarrow a = b$ is literally "cancel c", with no identity or inverse anywhere in sight.
2. Method the expression suggested: repeated, controlled use of the solvability axiom as an existence tool, combined with free rebracketing from associativity and commutativity.

3. Where you would hesitate, and the thought to reinforce: right after naming e with $d * e = a$, unsure what to do with it; reinforce that the next move is always to attach the leftover factor, here c, to the witness, building something usable on both a and b.
4. The trap the question sets: the temptation to prove S is a full abelian group before cancelling, which is true but far more expensive than the problem requires.
5. What makes you recognise it faster next time: reading "there exists z such that $x * z = y$, for every x, y" and translating it instantly into "every translation map is surjective", a single phrase naming exactly which tool you may invoke, and roughly how many times, here twice, for a two-element cancellation.
6. The reusable decision rule: when an abstract commutative, associative structure gives solvability but not identity or inverses, and asks for cancellation, apply solvability exactly twice, choosing input pairs that let the two witnesses recombine into the two sides of the target equation.

Mirror drills

1. Under the same hypotheses on $(S, *)$, show that for any $a \in S$ there is a unique $u_a \in S$ with $u_a * a = a$. *Answer:* existence is solvability with $(x, y) = (a, a)$; uniqueness follows from the cancellation law just proved, since $u * a = a = u' * a$ gives $u = u'$.
2. Show the element u_a from the previous drill does not depend on a, so S has a genuine two-sided identity. *Answer:* use solvability to find z with $a * z = b$; then $u_a * b = u_a * (a * z) = (u_a * a) * z = a * z = b$, so u_a also fixes b, and uniqueness forces $u_a = u_b$.
3. If $(S, *)$ satisfies the original hypotheses and S is finite, explain in one line why S is in fact a group. *Answer:* on a finite set, cancellativity makes each translation L_x injective, hence bijective since domain and codomain coincide, so every equation $x * z = y$ now has a unique solution, giving inverses as well as identity.

14.3 A3. pinning a functional equation at its fixed point

Let $f : [-1,1] \to \mathbb{R}$ be a continuous function such that

(i) $f(x) = \dfrac{2-x^2}{2} f\left(\dfrac{x^2}{2-x^2}\right)$ *for every x in $[-1,1]$,*

(ii) $f(0) = 1$, *and*

(iii) $\lim\limits_{x\to 1^-} \dfrac{f(x)}{\sqrt{1-x}}$ *exists and is finite.*

Prove that f is unique, and express $f(x)$ in closed form.

Read it out loud

This is a functional equation of the self-referential kind: f at x is expressed in terms of f at a different point, $\phi(x) = \dfrac{x^2}{2-x^2}$, together with an explicit algebraic prefactor $\dfrac{2-x^2}{2}$. The fields wired into this problem are functional equations, real analysis (continuity, limits, sequential arguments) and a touch of dynamics: ϕ is a self-map of $[-1,1]$, and the whole problem is really about where its iterates go. The command "prove that f is unique, and express $f(x)$ in closed form" is two separate tasks in disguise: an at-most-one-solution argument, and a genuine existence check, both required for a complete answer.

The first useful cue is $f(0) = 1$ sitting next to the prefactor $\frac{2-x^2}{2}$, which equals 1 exactly at $x = 0$. Substituting $x = \sin\theta$ mentally, or simply noticing that $\sqrt{1-x^2}$ is the one elementary function that is 1 at $x = 0$ and behaves well under this kind of rescaling, should be in your head within the first thirty seconds: the shape of the prefactor is screaming for a normalisation by $\sqrt{1-x^2}$, so that whatever multiplies f after you divide it out becomes an unadorned invariance.

The second cue, easy to miss on a first read, is that $\phi(0) = 0$: the argument transformation fixes the very point where hypothesis (ii) hands you a value. Whenever a functional equation's argument transformation has a fixed point, and you are independently given the function's value there, the fixed point is where the whole problem collapses; everything else, including the limit condition (iii) near the other end of the interval, should be treated with some suspicion until you have tried building the solution around that fixed point first.

Approaches, ranked worst to best

1. **guess and verify only.** *Cue:* $f(0) = 1$ suggests a natural closed form. *Circuit:* pattern matching. (guessing $f(x) = \sqrt{1-x^2}$ from the shape of the equation and checking it satisfies (i) to (iii) confirms existence, but the problem explicitly demands uniqueness as well; stopping here leaves open the possibility of other solutions and loses most of the marks despite having the right formula).

2. **boundary driven, via hypothesis (iii).** *Cue:* a limit condition is stated at $x \to 1^-$, so use it. *Circuit:* control f near the singular end and propagate inward. (a genuine route, and the one that uses every hypothesis on the page, which often feels reassuring; but it requires delicate estimates to relate values across the domain from a boundary point, and Elkies' own remark on this problem confirms condition (iii) is not even necessary, so this route pays for machinery the problem does not require).

3. **normalise, then iterate to the interior fixed point.** *Cue:* $\phi(0) = 0$ sits exactly where $f(0) = 1$ is given. *Circuit:* invariance under an attracting map, closed by continuity. (the ideal route: divide by $\sqrt{1-x^2}$ to strip the prefactor, reduce (i) to the bare invariance $g(x) = g(\phi(x))$, iterate ϕ from any starting point to its attracting fixed point at 0, and read off $g \equiv 1$ from continuity and $f(0) = 1$; only (ii) and the standing continuity of f are used).

The ideal solution

Uniqueness. Suppose f satisfies (i), (ii), (iii). Define $g : (-1,1) \to \mathbb{R}$ by

$$g(x) = \frac{f(x)}{\sqrt{1-x^2}},$$

well defined and continuous on $(-1,1)$ since f is continuous there and $\sqrt{1-x^2} > 0$ there.

Substitute $f(x) = g(x)\sqrt{1-x^2}$ into (i). Write $\phi(x) = \dfrac{x^2}{2-x^2}$. Since $2 - x^2 > 0$ on $[-1,1]$,

$$1 - \phi(x)^2 = \frac{(2-x^2)^2 - x^4}{(2-x^2)^2} = \frac{(2-2x^2)(2)}{(2-x^2)^2} = \frac{4(1-x^2)}{(2-x^2)^2},$$

using the difference of squares $(2-x^2)^2 - x^4 = \big((2-x^2)-x^2\big)\big((2-x^2)+x^2\big)$. For $x \in (-1,1)$, $1 - x^2 > 0$, so

$$\sqrt{1-\phi(x)^2} = \frac{2\sqrt{1-x^2}}{2-x^2}.$$

Hence (i) becomes

$$g(x)\sqrt{1-x^2} = \frac{2-x^2}{2} \cdot g(\phi(x)) \cdot \frac{2\sqrt{1-x^2}}{2-x^2} = g(\phi(x))\sqrt{1-x^2},$$

and dividing by $\sqrt{1-x^2} > 0$,

$$g(x) = g(\phi(x)) \qquad \text{for every } x \in (-1,1).$$

Fix $x \in (-1,1)$ and define a sequence by $a_1 = x$, $a_{n+1} = \phi(a_n) = \dfrac{a_n^2}{2-a_n^2}$. Since $|a_1| < 1$, an easy induction shows $a_n \in [0,1)$ for all $n \geq 2$: if $|a_n| < 1$ then $2 - a_n^2 > 1$, so $\phi(a_n) = \dfrac{a_n^2}{2-a_n^2} < a_n^2 < 1$, and $\phi(a_n) \geq 0$ always. In particular $|a_{n+1}| < a_n^2 \leq |a_n|$ for $a_n \neq 0$, so the sequence $\{|a_n|\}$ is decreasing, and in fact $|a_n| \leq |x|^n$ for all n: this holds for $n = 1$, and if $|a_n| \leq |x|^n$ then $|a_{n+1}| < a_n^2 \leq |x|^{2n} \leq |x|^{n+1}$ since $|x| < 1$. As $|x| < 1$, $|x|^n \to 0$, so $a_n \to 0$.

By the invariance just derived, $g(a_1) = g(a_2) = \cdots = g(x)$: the sequence $g(a_n)$ is constant, equal to $g(x)$, for every n. Since g is continuous at 0 and $a_n \to 0$, $g(a_n) \to g(0)$; a constant sequence converges only to its constant value, so

$$g(x) = g(0) = \frac{f(0)}{\sqrt{1-0}} = f(0) = 1.$$

This holds for every $x \in (-1,1)$, so $f(x) = \sqrt{1-x^2}$ throughout the open interval.

It remains to pin down $x = \pm 1$, and hypothesis (i) does this by itself, with no limiting argument at all. Hypothesis (i) is asserted for every $x \in [-1,1]$, including the endpoints, and $\phi(1) = \dfrac{1}{2-1} = 1$: the point $x = 1$ is itself a fixed point of ϕ. Substituting $x = 1$ into (i) directly,

$$f(1) = \frac{2-1}{2} f(\phi(1)) = \frac{1}{2} f(1),$$

a single algebraic equation in the one unknown $f(1)$, forcing $f(1) = 0$. Substituting $x = -1$, and using $\phi(-1) = \dfrac{1}{2-1} = 1$,

$$f(-1) = \frac{2-1}{2} f(\phi(-1)) = \frac{1}{2} f(1) = 0.$$

So $f(\pm 1) = 0 = \sqrt{1-(\pm 1)^2}$ as well, and $f(x) = \sqrt{1-x^2}$ on the whole of $[-1,1]$. This shows any f satisfying (i) to (iii) must equal this formula: at most one solution exists.

Existence. Direct substitution confirms $F(x) = \sqrt{1-x^2}$ satisfies all three hypotheses. For (i): with $\phi(x) = x^2/(2-x^2)$, the identity $1-\phi(x)^2 = 4(1-x^2)/(2-x^2)^2$ derived above gives

$$\frac{2-x^2}{2} F(\phi(x)) = \frac{2-x^2}{2} \cdot \frac{2\sqrt{1-x^2}}{2-x^2} = \sqrt{1-x^2} = F(x).$$

For (ii): $F(0) = \sqrt{1-0} = 1$. For (iii):

$$\lim_{x\to 1^-} \frac{F(x)}{\sqrt{1-x}} = \lim_{x\to 1^-} \frac{\sqrt{1-x^2}}{\sqrt{1-x}} = \lim_{x\to 1^-} \sqrt{1+x} = \sqrt{2},$$

which exists and is finite. So F is continuous on $[-1,1]$ and satisfies all of (i) to (iii): a solution exists.

Combining both halves, f is unique, and

$$\boxed{f(x) = \sqrt{1-x^2}}. \qquad \blacksquare$$

Layer 1: WHAT

1. Normalise by the natural candidate $\sqrt{1-x^2}$: set $g = f/\sqrt{1-x^2}$ on $(-1,1)$.
2. Simplify (i) after substitution, using a difference-of-squares identity, until the prefactor cancels and only the bare invariance $g(x) = g(\phi(x))$ survives.
3. Iterate $\phi(t) = t^2/(2-t^2)$ from any starting point: the orbit is squeezed toward its fixed point at 0.
4. Use continuity of g at 0 to pass from "g constant along the orbit" to "$g(x) = g(0) = f(0) = 1$" on the open interval.
5. Pin the two endpoints directly, by substituting $x = \pm 1$ into (i) itself, since 1 is also a fixed point of ϕ: no limiting argument is needed there at all.
6. Verify the resulting formula independently against all three hypotheses, to confirm a solution genuinely exists and not only that at most one could.

The nominal route reaches for hypothesis (iii) immediately, since it is the hypothesis that looks hardest to justify, and tries to control f near the boundary $x = 1$ and propagate values inward from there. The ideal route instead notices that the argument transformation ϕ already fixes the interior point $x = 0$, exactly where hypothesis (ii) hands over a known value, and drives every orbit there instead. The bifurcation point is the choice of which point in the domain to build the whole proof around: the boundary, where a hypothesis is visibly aimed at you, or the interior fixed point, which requires noticing a piece of hidden structure inside hypothesis (i) itself. The ideal route needs no limiting argument at the boundary either, since $x = 1$ turns out to be a second fixed point of ϕ, resolved by one substitution.

Layer 2: HOW

Block 1. **Cue.** The prefactor $\frac{2-x^2}{2}$ equals exactly 1 at $x = 0$, the same point where hypothesis (ii) gives $f(0) = 1$. **Why natural.** Dividing out a natural candidate function turns a multiplicative, inhomogeneous-looking functional equation into a plain invariance, the shape you know how to attack by iteration; guessing the normalising factor from the boundary data and the coefficient structure of (i) is a standard reroute whenever a functional equation mixes an unknown function with an explicit algebraic prefactor, and $\sqrt{1-x^2}$ is the simplest function matching both the value at 0 and the visible $(2-x^2)$ structure. **Link to the next block.** Once g is defined, every part of hypothesis (i) involving $\sqrt{1-x^2}$ should cancel if the guess was correct, so the next step is to perform that algebra and watch it collapse.

Block 2. **Cue.** After substitution, the surviving expression $1-\phi(x)^2$ is exactly "1 minus a squared fraction". **Why natural.** Factoring as a difference of two squares is the reflex whenever that shape appears, since it is cheaper than expanding directly, and here it produces a factor of $(2-x^2)$ in the numerator that exactly cancels the prefactor sitting outside f; watching that cancellation happen is the confirmation that $\sqrt{1-x^2}$ was the right choice of normalisation, not an assumption taken on faith. **Link to the next block.** With every $\sqrt{1-x^2}$ factor gone, what remains is an equation purely in g, of the form "value at x equals value at another specific point", an open invitation to iterate.

Block 3. **Cue.** The relation $g(x)=g(\phi(x))$ holds for every x in the domain, including $\phi(x)$ itself, and $\phi(\phi(x))$, and so on. **Why natural.** Whenever a functional equation asserts invariance under a self-map of the domain, the natural move is to iterate that map and ask where the orbit goes: if it converges to a point where the function's value is separately known, invariance forces the function to equal that value everywhere the orbit reaches. Here $\phi(t)=t^2/(2-t^2)$ visibly fixes 0, and the bound $\phi(t)<t^2$ for $|t|<1$ shows every orbit is squeezed toward 0, never toward the boundary. **Link to the next block.** Convergence of the orbit to 0 only becomes useful once that information can be transferred there through continuity, the next block.

Block 4. **Cue.** $g(a_n)=g(x)$ for every n, a constant sequence in disguise, and $a_n\to 0$. **Why natural.** Continuity is precisely the tool that turns "the same value along a convergent sequence" into "the same value at the limit point", and g is continuous at 0 because it is a quotient of the given continuous f by $\sqrt{1-x^2}$, itself continuous and strictly positive there. This is the single quantum leap of the problem: hypothesis (ii), $f(0)=1$, sits exactly at the attracting fixed point of the recursion hidden inside (i), so it, not the limit condition (iii), is what pins the function down on the open interval. **Link to the next block.** Having fixed $g\equiv 1$ on $(-1,1)$, only the two endpoints remain, and the domain of the closed interval $[-1,1]$ on which f is defined has not yet been fully covered.

Block 5. **Cue.** The interval is closed, $[-1,1]$, but the g-equation only ever made sense where $\sqrt{1-x^2}\neq 0$. **Why natural.** Hypothesis (i) itself, not merely its consequence for g, is asserted at every point of the closed interval, including $x=\pm 1$, and $\phi(1)=1$: the boundary point is itself a fixed point of ϕ, only a repelling one rather than an attracting one. Substituting $x=1$ into (i) directly therefore produces a closed algebraic equation in the single unknown $f(1)$, solving it outright with no limiting argument, cheaper even than invoking continuity of f at the boundary. **Link to the next block.** With $f(1)=0$ in hand, $x=-1$ resolves the same way in one further substitution, completing the domain without ever touching hypothesis (iii).

Block 6. **Cue.** The problem asks for both uniqueness and a closed form, which in a functional equation problem always means two separate half-proofs. **Why natural.** Skipping direct verification and treating the derived formula as automatically valid would leave open the possibility that no function satisfies (i) to (iii) at all, making the whole derivation vacuous; substituting $\sqrt{1-x^2}$ back into all three hypotheses is the cheapest possible way to rule that out. **Link to the next block.** None; both halves together give the complete answer the problem wants.

Layer 3: WHY

The truth underneath the route is a general one about functional equations built from an iterated self-map: whenever $f\circ(\text{normalisation})$ satisfies $g(x)=g(\phi(x))$ for a self-map ϕ with an attracting fixed point, and the value of g is independently known at that fixed point, continuity forces g to be constant on the whole basin of attraction. This is a recurring analytic technique, not specific to this problem: invariance under an attracting map, plus continuity, forces constancy.

The discernment mechanism is to examine every functional equation of the form $f(x) = c(x)f(\phi(x))$ for the fixed points of ϕ inside the domain, before reaching for any other given hypothesis. Compute ϕ at a couple of natural points, check whether a fixed point is attracting by a quick bound or a derivative, and check whether the function's value is already known there. If so, that fixed point is almost always the cheapest route, and every other hypothesis, however prominently placed, should be treated as possibly redundant until proven otherwise. Here, hypothesis (ii) is planted exactly at the point the hidden recursion collapses to, while hypothesis (iii), the limit near $x = 1$, is a genuine red herring for this route: Elkies observed precisely this, that (iii) is unnecessary, and the reason is now visible, $x = 1$ is a second fixed point of ϕ, but a repelling one, so it never receives an orbit from the interior; it only ever needs to be checked once, directly, by substitution, which needs no limit at all. Train the discernment by, on every functional equation with a visible argument transformation, computing where that transformation sends 0 and where it sends the endpoints of the domain, before touching any other hypothesis on the page.

Revolving concepts

Functional equations invariant under an iterated self-map: normalise by an explicit factor to remove any algebraic prefactor, reducing $f(x) = c(x)f(\phi(x))$ to the bare invariance $g(x) = g(\phi(x))$, then iterate ϕ toward a fixed point where the value is separately known. See field Functional equations, topic invariance under iteration and fixed points.

Attracting versus repelling fixed points of a real map: if $\phi(t_0) = t_0$ and ϕ is differentiable at t_0, the fixed point is attracting when $|\phi'(t_0)| < 1$, so nearby orbits converge to it, and repelling when $|\phi'(t_0)| > 1$, so nearby orbits move away. Here $\phi(t) = t^2/(2 - t^2)$ has $\phi'(t) = 4t/(2 - t^2)^2$, giving $\phi'(0) = 0$, an attracting, in fact superattracting, fixed point, and $\phi'(1) = 4$, a repelling one; this is exactly why iterating from any interior point drives the orbit to 0 and never toward 1. See field Sequences and recurrences, topic fixed points of iterated maps.

Self-referential boundary points resolve algebraically: if a functional equation $f(x) = c(x)f(\phi(x))$ is asserted at a fixed point t_0 of ϕ lying in the domain, substituting $x = t_0$ gives the single algebraic equation $f(t_0) = c(t_0)f(t_0)$, pinning $f(t_0)$ directly, to 0 whenever $c(t_0) \neq 1$, without any limiting or continuity argument; every fixed point of ϕ deserves this check, not only the attracting one used for the main argument. See field Functional equations, topic fixed-point substitution.

Difference of squares as a standing reflex: $1 - u^2 = (1 - u)(1 + u)$, used here to simplify $1 - \phi(x)^2$ into a form sharing a common factor with the prefactor $(2 - x^2)/2$. See field Polynomials, topic factoring in functional equation simplification.

Sequential continuity transfers a constant-along-a-sequence property to the limit: if h is continuous at L and $x_n \to L$, then $h(x_n) \to h(L)$; combined with $h(x_n)$ constant, this forces $h(L)$ to equal that constant. See field Real analysis, topic sequential continuity.

Recursion generalisation: the sequence $a_{n+1} = \phi(a_n)$ with $\phi(t) = t^2/(2 - t^2)$ is a first-order nonlinear recursion with no closed form for a_n; the general method for such "invariance under iteration" functional equations is to locate every fixed point of ϕ in the domain, classify each as attracting or repelling by $|\phi'|$ there, and note that any continuous function invariant under ϕ must be constant on the full basin of attraction of an attracting fixed point wherever a side condition pins its value there. This skeleton solves many Putnam functional equations of the shape $f(x) = c(x)f(\phi(x))$: first remove $c(x)$ by an integrating-factor-style substitution, as $\sqrt{1 - x^2}$ did here, then analyse ϕ alone. See field Sequences and recurrences, topic nonlinear first-order recursions and their fixed points.

Circuit Bank

- **WHEN** a functional equation has the shape $f(x) = c(x)f(\phi(x))$ for an explicit prefactor $c(x)$ and an explicit self-map ϕ **DO** guess a normalising function $h(x)$, often suggested by a boundary value or the shape of $c(x)$, so that $g = f/h$ satisfies the bare invariance $g(x) = g(\phi(x))$ **BECAUSE** stripping the explicit prefactor turns an inhomogeneous equation into a pure invariance statement solvable by iteration, and the correct h is the one for which the prefactor exactly cancels against $h(x)/h(\phi(x))$
- **WHEN** an iterated self-map ϕ appears inside a functional equation **DO** find its fixed points and classify each by $|\phi'|$ there against 1 **BECAUSE** an attracting fixed point is where every nearby orbit converges, and if the function's value is independently known there, continuity forces the function to equal that value on the whole basin
- **WHEN** you see 1 minus something squared inside a root or a simplification **DO** factor immediately as a difference of two squares **BECAUSE** it is always cheaper than expanding, and it very often exposes a common factor against another part of the expression
- **WHEN** a problem gives three hypotheses but your cleanest route only visibly needs two of them **DO** finish the proof with the two you needed, then state explicitly which hypothesis was not used and why the route did not require it **BECAUSE** full marks proofs must be honest about which hypotheses are load bearing, and naming the unused one shows the redundancy was noticed rather than missed

Backtesting

1. First useful cue: the coefficient $\frac{2-x^2}{2}$ multiplying f at a rescaled argument, sitting next to $f(0) = 1$, suggests dividing by a function equal to 1 at $x = 0$ that interacts cleanly with that coefficient.
2. Method the expression suggested: normalise by $\sqrt{1-x^2}$, reduce to a bare invariance $g(x) = g(\phi(x))$, then iterate ϕ toward its fixed point.
3. Where you would hesitate, and the thought to reinforce: uncertainty about whether hypothesis (iii) needs to appear somewhere; reinforce that a hypothesis not yet used is not automatically a hypothesis you are missing, check first whether the route is already complete and rigorous without it, and if so, say so explicitly.
4. The trap the question sets: the limit condition (iii) at a visually singular-looking boundary tempts you to build the whole proof around $x \to 1^-$; the actual pivot is the interior fixed point at 0, and even the boundary itself resolves by one substitution, not a limit.
5. What makes you recognise it faster next time: seeing a self-referential functional equation $f(x) = c(x)f(\phi(x))$ and immediately computing $\phi(0)$ and $\phi'(0)$ before touching anything else, since a fixed point at 0 paired with a given value $f(0)$ is the strongest structural cue on the page.
6. The reusable decision rule: when a functional equation expresses f at x in terms of f at $\phi(x)$ for an explicit self-map ϕ, normalise to remove the prefactor, locate every fixed point of ϕ and its attracting or repelling character, and pin the function at each fixed point, by iteration and continuity for an attracting one, by direct substitution for the rest.

Mirror drills

1. Suppose $h : [0,1] \to \mathbb{R}$ is continuous, $h(0) = 5$, and $h(x) = h(x/2)$ for every $x \in [0,1]$. Find h. *Answer:* iterating $x \mapsto x/2$ drives every orbit to 0; continuity forces $h \equiv 5$.

2. For $\phi(t) = t^2/(2-t^2)$, verify directly that $\phi'(0) = 0$ and $\phi'(1) = 4$, and explain in one line why this confirms orbits starting in $(-1, 1)$ head to 0, not to 1. *Answer:* $\phi'(t) = 4t/(2-t^2)^2$ by the quotient rule, so $\phi'(0) = 0$ and $\phi'(1) = 4$; a derivative below 1 in size at a fixed point means nearby points move closer under iteration, above 1 means they move away, so 0 attracts and 1 repels.

3. A continuous $f : [-1, 1] \to \mathbb{R}$ satisfies hypothesis (i) alone, with (ii) and (iii) both dropped. Show this is not enough to determine f, by exhibiting two different continuous functions satisfying it. *Answer:* $f \equiv 0$ works trivially, and $f(x) = \sqrt{1-x^2}$ also works, as verified in the ideal solution; indeed any $f(x) = k\sqrt{1-x^2}$ satisfies (i) for every constant k, so (i) alone has infinitely many solutions, and it is exactly the extra value $f(0) = 1$ from (ii) that selects $k = 1$.

14.4 A4. A small box forces the solutions into a progression

Let q and r be integers with $q > 0$, and let A and B be intervals on the real line. Let T be the set of all $b + mq$ where b and m are integers with b in B, and let S be the set of all integers a in A such that ra is in T. Show that if the product of the lengths of A and B is less than q, then S is the intersection of A with some arithmetic progression.

Read it out loud

Say the definitions back to yourself in one breath. T is the set of integers whose residue modulo q is realised by an integer lying in B, so membership of S unwinds to a single sentence: an integer a lies in S exactly when $a \in A$ and there exists an integer $b \in B$ with $ra \equiv b \pmod{q}$. One free variable a, one existential witness b, one congruence tying the two together, and a conclusion that mentions only a. The whole difficulty of the problem is that the witness b is quantified away in the statement of S but is the only thing that carries the information.

The fields wired into this are elementary number theory (linear congruences, reduction by $\gcd(q, r)$), the geometry of numbers (a congruence between two integer variables is a sublattice of $\mathbb{Z}^2$, and the modulus is its index), convexity (intervals, hence a rectangle, hence a convex region), and the combinatorial characterisation of an arithmetic progression.

Now the guiding light, and it is planted in plain sight. The hypothesis is not $\ell(A) < q$, and it is not $\ell(B) < q$. It is the *product* of two lengths, one measured in the world of a and one measured in the world of b, compared with q. A product of two lengths is an area. Nothing in the problem looks two-dimensional yet, so the examiners have told you exactly where to go and work: the plane of pairs (x, y), the rectangle $R = A \times B$ whose area is that product, and the set of admissible pairs

$$L = \{(x, y) \in \mathbb{Z}^2 : y \equiv rx \pmod{q}\}.$$

Within thirty seconds you should have written those two objects down together with the one line that reorganises the problem: S is the image of $L \cap R$ under the projection $(x, y) \mapsto x$. Everything after that is a comparison between the area of R and the index of L.

What is really being tested is whether you own that comparison. Lattices support exactly one quantitative statement of this shape, the one Minkowski built a subject on: a region that is too small for the lattice cannot contain many independent lattice points. Here "too small" is area less than q, and "not many" turns out to mean "no three of them off a single line".

Approaches, ranked worst to best

1. **Residue chase with no size control.** *Cue:* the word “modulo” and nothing else. *Circuit:* write S out as a set of residues and try to force structure by hand. You take two elements $a_1 < a_2$ of S, subtract, and try to prove $a_2 + (a_2 - a_1) \in S$. It stalls immediately and for an instructive reason: $r(2a_2 - a_1) \equiv 2b_2 - b_1 \pmod{q}$ is true, but $2b_2 - b_1$ has no reason to lie in B, and B is the only place a witness is allowed to live. Any route that forgets b is dead before it starts, because the hypothesis is a statement about B.

2. **Three distance theorem.** *Cue:* ra modulo q is an orbit of a rotation, and B is an arc. *Circuit:* return times of a rotation into an interval take at most three values. S is the set of visit times of the orbit $a \mapsto ra/q \bmod 1$ to an arc, so the gaps between consecutive elements of S take at most three values, and the two largest are the sum of the other two. To finish you still have to prove that the small area forces one value, which needs the same estimate as the winning route. You imported a heavy theorem and saved nothing.

3. **Euclidean descent on the pair (q, r).** *Cue:* $\gcd(q, r)$ appears the moment you try to solve the congruence. *Circuit:* continued fraction reduction, the engine behind the three distance

theorem. Replace r by $r \bmod q$, swap the roles of the two intervals, and induct on the size of r. The statement is genuinely stable under this descent, but you must carry two intervals, two lengths and the area hypothesis through every step, and the bookkeeping is where marks die.

4. **Congruence with sign control, then an arithmetic progression lemma.** *Cue:* "absolute value less than q and divisible by q" is the only way a congruence becomes an equation. *Circuit:* size beats modulus. Divide q, r and B by $\gcd(q,r)$; take three elements $a_1 < a_2 < a_3$ of S with witnesses b_1, b_2, b_3; two of the three differences $b_i - b_j$ share a sign, and for that pair the two products $(a_i - a_j)(b_k - b_l)$ and $(b_i - b_j)(a_k - a_l)$ are congruent modulo q, of the same sign and of absolute value at most $\ell(A)\ell(B) < q$, hence equal. That is collinearity of (a_i, b_i), from which $a_1 + a_3 - a_2 \in S$, and then a standalone lemma says a finite set closed under $a + c - b$ is an arithmetic progression. Completely elementary and completely correct, at the cost of one reduction, one sign discussion and one auxiliary lemma.

5. **Lattice and area.** *Cue:* "the product of the lengths", i.e. an area, compared with the modulus. *Circuit:* a linear congruence in two variables is a sublattice of index q; a region of area less than the index holds no lattice triangle. Three lines of setup, one determinant estimate, one triangle estimate, done. No reduction by $\gcd(q,r)$ is needed, because the index of L is q whatever r is, and no auxiliary progression lemma is needed, because collinear lattice points inside a convex set already are a progression. This is the route to write.

The ideal solution

Write $\ell(X)$ for the length of an interval X. Read "arithmetic progression" as a set $\{a_0 + kd : k \in K\}$ with d a fixed integer and K a set of consecutive integers, possibly finite, possibly empty. A caveat worth clarifying before any mathematics: if arithmetic progressions were required to be infinite the statement would be false. Take $q = 5$, $r = 1$, $A = [1,3]$, $B = [0,2]$, so that $\ell(A)\ell(B) = 4 < 5$. Then T is the set of integers congruent to 0, 1 or 2 modulo 5, so $S = \{1,2\}$, while any infinite progression containing 1 and 2 has common difference 1 and therefore meets A in $\{1,2,3\}$. With finite progressions allowed, and since $S \subseteq A$ forces $S = A \cap S$, the task is exactly this: prove that S is an arithmetic progression.

Degenerate lengths first. If $\ell(A) = 0$ then A contains at most one integer and S has at most one element, which is a progression. If $\ell(B) = 0$ then B contains at most one integer; if it contains none then $S = \emptyset$, and if it contains exactly one integer b then

$$S = \{a \in A \cap \mathbb{Z} : ra \equiv b \pmod{q}\},$$

and the solution set of that congruence is empty when $\gcd(q,r) \nmid b$ and otherwise a full residue class modulo $q/\gcd(q,r)$, an infinite arithmetic progression. So assume from now on that $\ell(A)$ and $\ell(B)$ are both positive; the hypothesis $\ell(A)\ell(B) < q$ then forces both to be finite, so $R := A \times B$ is a bounded rectangle of area less than q.

The lattice. Put $L = \{(x,y) \in \mathbb{Z}^2 : y \equiv rx \pmod{q}\}$. It is the kernel of the group homomorphism $\mathbb{Z}^2 \to \mathbb{Z}/q\mathbb{Z}$ sending (x,y) to $rx - y$, which is surjective because $(0,-1) \mapsto 1$. Hence L is a subgroup of $\mathbb{Z}^2$ of index exactly q, for every r. Unwinding the definitions, $a \in S$ if and only if $a \in A \cap \mathbb{Z}$ and there is an integer $b \in B$ with $ra - b \in q\mathbb{Z}$, that is, if and only if $(a,b) \in L \cap R$ for some b. Therefore

$$S = \pi(L \cap R), \qquad \pi(x,y) = x.$$

Lemma 14.4.1. *If $P_1, P_2, P_3 \in L$ are not collinear, the triangle $P_1P_2P_3$ has area at least $q/2$.*

Proof. Put $u = P_2 - P_1$ and $w = P_3 - P_1$; both lie in L and they are linearly independent. The lattice $M = \mathbb{Z}u + \mathbb{Z}w$ satisfies $M \subseteq L \subseteq \mathbb{Z}^2$, and the index of a full rank sublattice of $\mathbb{Z}^2$ equals the absolute value of the determinant of any of its bases (this is the standard fact from the geometry of

numbers, proved by Smith normal form: no A-level route to it exists, so install it as a named fact). Hence

$$|\det(u,w)| = [\mathbb{Z}^2 : M] = [\mathbb{Z}^2 : L]\,[L : M] = q\,[L : M],$$

a positive multiple of q. The area of the triangle is $\frac{1}{2}|\det(u,w)| \geq q/2$. □

Lemma 14.4.2. *A triangle contained in a rectangle with sides parallel to the axes of side lengths w and h has area at most $wh/2$.*

Proof. Label the vertices $P_i = (x_i, y_i)$ with $x_1 \leq x_2 \leq x_3$. If $x_1 = x_3$ the triangle is degenerate and has area 0. Otherwise the vertical line through P_2 meets the segment P_1P_3 in a point $Q = (x_2, y_Q)$, and the segment P_2Q cuts the triangle into two triangles with common base P_2Q and heights $x_2 - x_1$ and $x_3 - x_2$. Both y_2 and y_Q lie in the projection of the rectangle to the y-axis, an interval of length h, so $|P_2Q| = |y_2 - y_Q| \leq h$ and the total area is

$$\tfrac{1}{2}|y_2 - y_Q|\,(x_2 - x_1) + \tfrac{1}{2}|y_2 - y_Q|\,(x_3 - x_2) = \tfrac{1}{2}|y_2 - y_Q|(x_3 - x_1) \leq \tfrac{1}{2}hw.$$ □

Collinearity. Any three points of $L \cap R$ lie in the closed rectangle of side lengths $\ell(A)$ and $\ell(B)$, so by Lemma 2 they span a triangle of area at most $\ell(A)\ell(B)/2 < q/2$, and by Lemma 1 they must therefore be collinear. If $L \cap R$ has at most two points it lies on a line trivially; if it has at least three, fix two distinct points of it and note that every further point is collinear with those two, so the whole of $L \cap R$ lies on one line λ.

From a line to a progression. If $L \cap R = \emptyset$ then $S = \emptyset$. Otherwise fix $P_0 = (x_0, y_0) \in L \cap R$. The set $(L \cap \lambda) - P_0$ is a subgroup of $\mathbb{Z}^2$ contained in a one dimensional subspace, hence a discrete subgroup of a line, hence $\mathbb{Z}w_0$ for some $w_0 = (\alpha, \beta) \in \mathbb{Z}^2$ (with $w_0 = 0$ allowed). So $L \cap \lambda = \{P_0 + kw_0 : k \in \mathbb{Z}\}$. Since R is convex and $k \mapsto P_0 + kw_0$ is affine, $K := \{k \in \mathbb{Z} : P_0 + kw_0 \in R\}$ is the set of integers in an interval, that is, a set of consecutive integers. Consequently

$$S = \pi(L \cap R) = \{x_0 + k\alpha : k \in K\},$$

which is an arithmetic progression with common difference α (a single point if $\alpha = 0$, since then every point of $L \cap R$ shares its first coordinate). Finally $S \subseteq A$, so $S = A \cap S$ is the intersection of A with an arithmetic progression, as required. ■

Layer 1: WHAT

Block 1. Unwind S: $a \in S$ iff $a \in A \cap \mathbb{Z}$ and $ra \equiv b \pmod{q}$ for some integer $b \in B$. Refuse to discard b.

Block 2. Read the hypothesis as an area and promote the pair (a, b) to a point of the plane: $S = \pi(L \cap R)$ with $R = A \times B$ and L the solution set of the congruence.

Block 3. Identify L as a subgroup of $\mathbb{Z}^2$ of index q, by exhibiting the congruence as the kernel of a surjection onto $\mathbb{Z}/q\mathbb{Z}$.

Block 4. Compare the two areas. Three non-collinear points of L cost at least $q/2$; a triangle inside R costs at most $\ell(A)\ell(B)/2 < q/2$. So $L \cap R$ is collinear.

Block 5. Collinear points of a lattice form a coset of $\mathbb{Z}w_0$; intersecting with the convex set R keeps a consecutive run of them; projecting gives an arithmetic progression.

The nominal route runs: fix $a_1 < a_2 < a_3$ in S, write down the three congruences, cross multiply differences, argue about signs and sizes to turn a congruence into an equation, deduce $a_1 + a_3 - a_2 \in S$, then prove and apply a lemma that a finite set closed under $a + c - b$ is a progression. It is a correct route and it is what most solvers write, and it costs one gcd reduction, one sign case analysis and one extra lemma. The bifurcation point is a single decision taken in the first minute: when you unwind S, do you treat b as a nuisance to be quantified away, or as the second coordinate of a point? Keep b as a coordinate and the area hypothesis becomes a statement about a lattice; drop it and you spend the rest of the problem reconstructing that statement by hand in the language of inequalities.

Layer 2: HOW

Block 1. **Cue.** The definition of T is a two step definition (b in B, then translate by multiples of q), which always means: there is a hidden witness. **Why natural.** A set defined by an existential quantifier is never understood by staring at the quantified variable. You either eliminate the witness (needs gcd information and inequalities) or you keep it. The hypothesis mentions the length of B, and the only thing the length of B can constrain is the witness, so the witness must survive into your notation. **Link to the next block.** Once you have decided to keep b, you have a pair, and a pair wants a plane.

Block 2. **Cue.** "The product of the lengths of A and B is less than q". **Why natural.** A product of two lengths is an area, and an area is a two dimensional quantity, so the examiners have already told you that the intended arena is $A \times B$. The comparison object q is the modulus; and modulus is index. In other words the hypothesis reads: the area of the box is less than the index of the lattice. That sentence is the entire problem. **Link to the next block.** Now you must know what an index of a sublattice of $\mathbb{Z}^2$ controls, which is the determinant.

Block 3. **Cue.** A congruence linking two integer variables, linear in both. **Why natural.** $\{(x, y) : y \equiv rx \pmod{q}\}$ is the kernel of $(x, y) \mapsto rx - y$ into $\mathbb{Z}/q\mathbb{Z}$. Kernels of surjections have index equal to the size of the target, so the index is q, with no dependence on r at all. That independence is what lets you skip the $\gcd(q, r)$ reduction that the elementary route needs. **Link to the next block.** An index q sublattice has all its fundamental parallelograms of area q, so any two independent lattice vectors span area at least q.

Block 4. **Cue.** You want a conclusion of the form "the points are collinear", and the only currency you have is area. **Why natural.** Non-collinear means the determinant is nonzero, and for lattice vectors nonzero determinants are quantised in multiples of the index. So non-collinearity has a price, $q/2$ of area, while the box can only pay $\ell(A)\ell(B)/2 < q/2$. Any statement of the form "too small to contain independent lattice points" is proved this way; Minkowski's theorem is the same accounting with a factor of 4 and a convex symmetric body. **Link to the next block.** Collinearity is a structural conclusion, so now convert it into the structure the question asked for.

Block 5. **Cue.** The target word is "arithmetic progression", i.e. a one dimensional lattice coset. **Why natural.** The points of a lattice on a line form a coset of a discrete subgroup of that line, and every discrete subgroup of a line is cyclic. Convexity of R makes the surviving parameters consecutive, because an affine map pulls a convex set back to an interval. Projecting a progression of points to their first coordinates is again a progression. **Link to the next block.** Nothing remains except to notice $S \subseteq A$, so $S = A \cap S$ and the phrasing of the question is satisfied.

Layer 3: WHY

The mathematical truth beneath this route is the dictionary between congruences and lattices. A single linear congruence $y \equiv rx \pmod{q}$ in two integer unknowns is not an equation to be solved; it is a subgroup of $\mathbb{Z}^2$, and every fact about it is a fact about that subgroup. The index of the subgroup is the modulus. The determinant of any basis is the index. The area of a fundamental domain is the determinant. Once those four sentences are one object in your head, an inequality comparing an area with a modulus stops being a coincidence.

The discernment mechanism is the dimension count. Ask: how many free variables does the hypothesis constrain? Here the hypothesis constrains a product of two lengths, and lengths of different objects only multiply if you are measuring a region in a product space. A hypothesis of the form (size in A) times (size in B) less than (modulus) is always the geometry of numbers speaking.

Train it by collecting the family: Minkowski's convex body theorem, Thue's lemma (which produces $x \equiv ry \pmod{q}$ with $|x|, |y| < \sqrt{q}$ from exactly this area count and which is the engine of the two squares theorem), the Farey and continued fraction estimates, and Pick's theorem. Every one of them is the same accounting.

The examiners nudged twice. First they wrote "intervals" rather than sets, which hands you convexity, the property that turns "lattice points on a line" into "consecutive lattice points on a line". Second they compared a product of lengths with q rather than comparing each length with something, which is the plain instruction to build the rectangle. The rest of the wording, in particular the deliberately loose phrase "the intersection of A with some arithmetic progression", is there to let a finite progression count as an answer, and you should notice that this phrasing is doing exactly that job, because with infinite progressions only the statement is false.

Revolving concepts

Lattice in $\mathbb{Z}^2$. A subgroup $L \leq \mathbb{Z}^2$ of finite index. Orbiting facts: L has a basis u, w (structure theorem for finitely generated abelian groups); $[\mathbb{Z}^2 : L] = |\det(u, w)|$, independent of the basis; a fundamental domain has area $[\mathbb{Z}^2 : L]$. See Book 1, field: Number theory, topic: geometry of numbers.

Index and determinant. For $M \subseteq L \subseteq \mathbb{Z}^2$ of finite index, indices multiply: $[\mathbb{Z}^2 : M] = [\mathbb{Z}^2 : L][L : M]$. This is the mechanism that quantises the areas of lattice triangles, and it is exactly why a lattice triangle in $\mathbb{Z}^2$ itself has area at least $1/2$ (Pick's theorem in miniature). See Book 1, field: Abstract algebra, topic: index of a subgroup.

Minkowski's theorem. A convex region symmetric about the origin of area greater than $4 \det L$ contains a nonzero point of L. The statement used here is its cheaper twin: a region of area less than $\det L$ contains no three non-collinear points of L. Learn both, and learn that the first is proved by the pigeonhole principle on translates and the second by the multiplicativity of the index.

Linear congruence. $ra \equiv b \pmod{q}$ is solvable in a if and only if $\gcd(q, r) \mid b$, and then the solution set is a residue class modulo $q/\gcd(q, r)$, hence an infinite arithmetic progression. See Book 1, field: Number theory, topic: congruences.

Arithmetic progressions and the closure recursion. The elementary route needs this lemma: a finite set $S \subset \mathbb{Z}$ with at least three elements such that $a + c - b \in S$ whenever $a \leq b \leq c$ lie in S is an arithmetic progression. The recursion inside it generalises: let a_1 be the least element, d the gap to the second least, and let m be least with $a_1 + md \notin S$; if some element of S lay outside $\{a_1, \ldots, a_1 + (m-1)d\}$, the least such element n would give $n - d \in S$ by closure, again outside the run and smaller, contradicting minimality. The general pattern is: a set closed under a translation-type operation is a union of orbits of that translation, and minimal counterexample induction converts closure into exhaustion. The same recursion proves that a subgroup of $\mathbb{Z}$ is $d\mathbb{Z}$, that a discrete subgroup of $\mathbb{R}$ is cyclic (used above for $L \cap \lambda$), and that a numerical semigroup is eventually a progression.

Three distance theorem. For irrational θ, the points $\{\theta\}, \{2\theta\}, \ldots, \{N\theta\}$ cut the circle into arcs of at most three distinct lengths, the largest being the sum of the other two. It governs the general shape of the set of visit times to an arc, of which our S is an example; here the area hypothesis collapses the three possible gaps to one. See Book 1, field: Number theory, topic: equidistribution.

Circuit Bank

- **WHEN** a hypothesis multiplies a size in one variable by a size in another and compares it with a modulus **DO** build the rectangle in the product space and the lattice cut out by the congruence, then compare area with index **BECAUSE** a product of two lengths is an area, and the only theorems comparing areas with moduli are the geometry of numbers

- **WHEN** a set is defined by "there exists b in B with ..." **DO** keep b as a coordinate rather than quantifying it away **BECAUSE** the hypotheses that mention B can only act on the witness, so a proof that forgets the witness cannot use them
- **WHEN** you need to upgrade a congruence to an equation **DO** bound both sides in absolute value by less than the modulus, or force them to share a sign **BECAUSE** $q \mid N$ and $|N| < q$ give $N = 0$; this is the only elementary way a congruence becomes an equality
- **WHEN** lattice points are known to be collinear and you want a progression **DO** intersect the line with the lattice to get a coset of a cyclic group and use convexity to make the parameters consecutive **BECAUSE** a discrete subgroup of a line is cyclic, and the preimage of a convex set under an affine map is an interval
- **WHEN** a question says "some arithmetic progression" rather than "an arithmetic progression with difference d" **DO** check whether finite or empty progressions are being allowed, and test the extreme case **BECAUSE** loose phrasing in a competition statement is usually load bearing, and here the statement is false if progressions must be infinite

Backtesting

1. First useful cue: the hypothesis is a product of two lengths, that is an area, not two separate size conditions.
2. Method the expression suggested: promote (a, b) to a point of $\mathbb{Z}^2$, read the congruence as a sublattice of index q, and compare the area of $A \times B$ with q.
3. Where you would hesitate, and the thought to reinforce: at the claim that non-collinear lattice points span area at least $q/2$. Reinforce it by rebuilding the chain index equals determinant equals twice the triangle area, and by remembering that indices multiply down a chain of sublattices.
4. The trap the question sets: quantifying away the witness b, after which the length of B has nothing to act on and the problem looks impossible; and, at the end, believing that an arithmetic progression must be infinite, which makes the statement false.
5. What makes you recognise it faster next time: the phrase "the product of the lengths" together with a modulus. Also the shape of the conclusion, since an arithmetic progression is a one dimensional lattice coset, and lattice conclusions come from lattice hypotheses.
6. The reusable decision rule: congruence plus area equals geometry of numbers; keep every existential witness as a coordinate until the geometry has been extracted.

Mirror drills

1. Let $q = 100$, $r = 7$, $A = [0, 9]$, $B = [0, 9]$. Compute S and check the conclusion directly. *Answer:* $7a$ for $a = 0, \ldots, 9$ is $0, 7, 14, \ldots, 63$, and only 0 and 7 land in $[0, 9]$, so $S = \{0, 1\}$, a progression; the box has area $81 < 100$.
2. Prove Thue's lemma: for $\gcd(r, q) = 1$ there are integers x, y with $0 < \max(|x|, |y|) < \sqrt{q}$ and $x \equiv ry \pmod{q}$. *Answer:* the pairs (y, x) with $0 \le x, y \le \lfloor \sqrt{q} \rfloor$ number more than q, so two are congruent under $x - ry$; subtract, and the difference lies in the lattice L and in a box of side less than $\sqrt{q}$.
3. Show that a triangle contained in a w by h axis parallel rectangle has area at most $wh/2$, and that the bound is attained. *Answer:* split along the vertical through the middle vertex, as in Lemma 2; equality for a triangle with one full side of the rectangle as base and the opposite side containing the apex.

14.5 A5. When an affine map is one long cycle

Let $\mathbb{F}_p$ denote the field of integers modulo a prime p, and let n be a positive integer. Let v be a fixed vector in $\mathbb{F}_p^n$, let M be an $n \times n$ matrix with entries in $\mathbb{F}_p$, and define $G : \mathbb{F}_p^n \to \mathbb{F}_p^n$ by $G(x) = v + Mx$. Let $G^{(k)}$ denote the k-fold composition of G with itself, that is, $G^{(1)}(x) = G(x)$ and $G^{(k+1)}(x) = G(G^{(k)}(x))$. Determine all pairs p, n for which there exist v and M such that the p^n vectors $G^{(k)}(0)$, $k = 1, 2, \ldots, p^n$, are distinct.

Read it out loud

This is a dynamics question about an affine map of a finite vector space, and the command term is "determine all pairs", which tells you two things before you have done any mathematics. First, the answer is a short list, so you owe explicit constructions. Second, everything not on the list must be excluded by a single mechanism, so you owe one obstruction, not a case analysis over matrices.

Now read the condition itself. There are exactly p^n vectors in $\mathbb{F}_p^n$ and you are asked for p^n distinct iterates, so the orbit of 0 is the whole space. In other words G is a single cycle of length p^n, and therefore G is an element of order p^n in the group of invertible affine maps of $\mathbb{F}_p^n$. Hear that sentence properly: the order of the element is a power of the characteristic. In characteristic p that is a very strong statement about the linear part, because $M^{p^m} = I$ forces $(M - I)^{p^m} = 0$ by the Frobenius identity. So the linear part is unipotent, $N := M - I$ is nilpotent, and $N^n = 0$.

The fields are linear algebra over a finite field (unipotent matrices, nilpotency index, Cayley and Hamilton), group theory (order of an element of the affine group, cyclic permutations), and the p-adic arithmetic of binomial coefficients. The recursion at the heart is the affine one, $x_{k+1} = Mx_k + v$, and it is the same recursion you solved at A-level for $u_{n+1} = au_n + b$; you must be able to write its closed form instantly.

Within the first minute you should have written down $G^{(k)}(0) = (I + M + \cdots + M^{k-1})v$, tested $n = 1$ (where $G(x) = x + 1$ is obviously a p-cycle), and tested $p = n = 2$ by hand.

Approaches, ranked worst to best

1. **Search small cases and stop.** *Cue:* "determine all pairs". *Circuit:* numerical reconnaissance. Mandatory as reconnaissance and worthless as a solution. It does hand you the answer, because $n = 1$ works for every p and the only sporadic case you find is $(2, 2)$, but by itself it proves nothing about $n \geq 3$.

2. **Jordan form of M.** *Cue:* a matrix that is being iterated. *Circuit:* diagonalise or triangularise, then read off powers. You can push this through, but $\mathbb{F}_p$ is not algebraically closed, so you either move to an extension field or work with the rational canonical form, and then you must separately handle eigenvalue 1 blocks, other eigenvalues, and the inhomogeneous term. Enormous ink for a statement about a single element's order.

3. **Order of G in the affine group via the exponent of a Sylow p-subgroup.** *Cue:* the order of G must be p^n, a p-power. *Circuit:* a p-power order element lies in a Sylow p-subgroup, whose exponent is bounded. If $N^j = 0$ then $M^{p^s} = I$ as soon as $p^s \geq j$, so the order of M is at most $p^{\lceil \log_p n \rceil}$ and the order of G is at most p times that. This kills all large n at a stroke and is worth knowing, but the bound leaves $(p, 2)$ for every p and $(2, 3)$ standing, so you still have to compute. It gets you to a finite check and no further.

4. **Fitting decomposition.** *Cue:* $M - I$ is what governs fixed points of an affine map. *Circuit:* split the space into the part where $M - I$ is nilpotent and the part where it is invertible. Write $\mathbb{F}_p^n = V \oplus W$ with $M - I$ nilpotent on V and invertible on W; if $W \neq 0$, solve $(M - I)w = -v_2$ inside W and check that the orbit of w never leaves the coset $w + V$, whose size is smaller than p^n, contradicting transitivity. It is correct, and it reproves "$M - I$ is nilpotent" by hand.

5. **Order is a p-power, hence the linear part is unipotent, then binomial coefficients.** *Cue:* p^n distinct iterates, in characteristic p. *Circuit:* Frobenius, so $M^{p^m} = I$ is the same as $(M-I)^{p^m} = 0$; then expand $(I+N)^j$ and sum. Three lines to unipotency, one line to the closed form, one line to the kill. Write this.

The ideal solution

The pairs are

$$\boxed{n = 1 \text{ with } p \text{ arbitrary, together with } (p,n) = (2,2).}$$

These work. For $n = 1$ take $v = (1)$ and $M = (1)$, so that $G(x) = x + 1$ and $G^{(k)}(0) = k$; for $k = 1, \dots, p$ these run through all of $\mathbb{F}_p$. (If you ever see the pair $v = (1)$, $M = (0)$ quoted here, check it before you trust it: it gives the constant map $G(x) = 1$, whose iterates of 0 are all equal. The honest witness is the translation.) For $(p,n) = (2,2)$ take

$$v = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \qquad M = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix},$$

and compute over $\mathbb{F}_2$:

$$G^{(1)}(0) = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad G^{(2)}(0) = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad G^{(3)}(0) = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \quad G^{(4)}(0) = \begin{pmatrix} 0 \\ 0 \end{pmatrix},$$

four distinct vectors, as required.

Nothing else works. Suppose the p^n vectors $G^{(k)}(0)$, $k = 1, \dots, p^n$, are distinct. They then exhaust $\mathbb{F}_p^n$, so $0 = G^{(k_0)}(0)$ for some k_0 with $1 \le k_0 \le p^n$. If $k_0 < p^n$ then $G^{(k+k_0)}(0) = G^{(k)}(0)$ for all $k \ge 0$, so the list takes at most $k_0 < p^n$ values, a contradiction. Hence

$$G^{(p^n)}(0) = 0.$$

Since $G^{(p^n)}$ commutes with G, it fixes $G^{(k)}(0)$ for every k, and these vectors are all of $\mathbb{F}_p^n$; therefore $G^{(p^n)}$ is the identity map.

Induction on k gives the closed form of the affine recursion,

$$G^{(k)}(x) = (I + M + \cdots + M^{k-1})v + M^k x.$$

Apply it with $k = p^n$. Putting $x = 0$ shows the constant term vanishes, and then $M^{p^n} x = x$ for every x, so

$$M^{p^n} = I.$$

Set $N = M - I$. The matrices M and I commute and lie in the commutative ring $\mathbb{F}_p[M]$, which has characteristic p, so the Frobenius identity $(a+b)^p = a^p + b^p$ applies and iterates:

$$N^{p^n} = (M-I)^{p^n} = M^{p^n} + (-I)^{p^n} = M^{p^n} - I = 0,$$

where for $p = 2$ one uses $-I = I$ and for odd p one uses $(-1)^{p^n} = -1$. So N is nilpotent, and a nilpotent $n \times n$ matrix has characteristic polynomial x^n, so Cayley and Hamilton give

$$N^n = 0.$$

Now expand. Since $N^i = 0$ for $i \ge n$,

$$M^j = (I+N)^j = \sum_{i=0}^{n-1} \binom{j}{i} N^i,$$

the integer binomial coefficients being read modulo p. Summing over $j = 0, 1, \ldots, k-1$ and using the telescoping identity $\sum_{j=0}^{k-1} \binom{j}{i} = \binom{k}{i+1}$ (immediate from $\binom{j+1}{i+1} - \binom{j}{i+1} = \binom{j}{i}$) gives the formula that decides the problem:

$$G^{(k)}(0) = \sum_{j=0}^{k-1} M^j v = \sum_{i=0}^{n-1} \binom{k}{i+1} N^i v. \tag{$*$}$$

Lemma 14.5.1. *If $m \geq 1$ and $1 \leq t \leq p^m - 1$ then $p \mid \binom{p^m}{t}$.*

Proof. From $t\binom{p^m}{t} = p^m \binom{p^m - 1}{t-1}$ we get $v_p\left(\binom{p^m}{t}\right) = m - v_p(t)$, where v_p is the exponent of p. Since $1 \leq t \leq p^m - 1$, p^m does not divide t, so $v_p(t) \leq m - 1$ and the exponent is at least 1. □

Suppose now $n \geq 2$ and $p^{n-1} > n$, and take $k = p^{n-1}$ in $(*)$. Every index $i+1$ occurring there satisfies $1 \leq i+1 \leq n \leq p^{n-1} - 1$, so by the lemma every coefficient $\binom{p^{n-1}}{i+1}$ vanishes in $\mathbb{F}_p$ and $G^{(p^{n-1})}(0) = 0$. But $1 \leq p^{n-1} < p^n$, contradicting the fact established above that p^n is the least positive k with $G^{(k)}(0) = 0$. Therefore

$$p^{n-1} \leq n.$$

For $n = 2$ this reads $p \leq 2$, so $p = 2$. For $n \geq 3$ we have $p^{n-1} \geq 2^{n-1} \geq n + 1 > n$ (the inequality $2^{n-1} > n$ for $n \geq 3$ is a one line induction), so no pair survives. Hence the only pairs with $n \geq 2$ are $(p, n) = (2, 2)$, and every pair with $n = 1$ occurs. ■

A remark worth keeping. Formula $(*)$ does not merely exclude; it constructs. For $n = 2$ it says $G^{(k)}(0) = \binom{k}{1} v + \binom{k}{2} N v$, so you need $\binom{k}{1}$ and $\binom{k}{2}$ modulo p to have joint period p^2. For odd p both vanish at $k = p$, which is why odd primes fail; for $p = 2$, $\binom{k}{2}$ modulo 2 has period 4, which is exactly the sporadic case. The obstruction and the example are the same computation read in two directions.

Layer 1: WHAT

Block 1. Distinctness of p^n iterates means the orbit of 0 is everything, hence $G^{(p^n)} = \mathrm{id}$ and no smaller positive power of G fixes 0.

Block 2. Compare linear parts in $G^{(p^n)} = \mathrm{id}$ using the closed form of the affine recursion: $M^{p^n} = I$.

Block 3. Characteristic p plus p-power order gives $(M - I)^{p^n} = 0$, so $N = M - I$ is nilpotent and $N^n = 0$.

Block 4. Expand $M^j = (I + N)^j$, sum with the hockey stick identity, and obtain $G^{(k)}(0) = \sum_{i=0}^{n-1} \binom{k}{i+1} N^i v$: the orbit is governed by n binomial coefficients only.

Block 5. Choose $k = p^{n-1}$, at which all n of those coefficients are divisible by p provided $p^{n-1} > n$; the orbit returns to 0 too early.

Block 6. Solve $p^{n-1} \leq n$ in positive integers, then exhibit the two families that survive.

The nominal route is: take M, put it in Jordan or rational canonical form, split off the eigenvalue 1 part, and grind the iteration block by block. It works, and it takes a page. The bifurcation point is Block 2: do you look at M as a matrix to be canonicalised, or as an element of a finite group whose order you already know? Choosing the second means the only structural fact you ever need about M is that its order is a power of p, and in characteristic p that single fact delivers unipotency for free.

Layer 2: HOW

Block 1. Cue. The list has length p^n and the space has size p^n. **Why natural.** A list of p^n distinct elements of a set of size p^n is the whole set. That forces 0 to appear in the list, and once a point of a forward orbit repeats, the orbit is periodic from the start, so the period must be the full p^n. Restating a distinctness hypothesis as a transitivity statement is always the right first move for

iteration problems, because transitivity is a group theoretic property and distinctness is not. **Link to the next block.** A permutation with a single cycle of length p^n has order p^n, so you now know the order of G as a group element.

Block 2. **Cue.** G is affine, so $G^{(k)}$ is affine, and two affine maps are equal exactly when their linear parts and their constant terms agree. **Why natural.** The closed form $G^{(k)}(x) = (I + \cdots + M^{k-1})v + M^k x$ is the matrix version of the A-level linear recurrence $u_{k+1} = au_k + b$; you should write it without thinking. Comparing the two halves of $G^{(p^n)} = \mathrm{id}$ separates the information: the constant term dies at $x = 0$, and the linear part gives $M^{p^n} = I$ cleanly. **Link to the next block.** An identity of the form $M^{p^m} = I$ over $\mathbb{F}_p$ is not an ordinary order condition, because the exponent is a power of the characteristic.

Block 3. **Cue.** Exponent p^m and characteristic p in the same line. **Why natural.** In any commutative ring of characteristic p the map $a \mapsto a^p$ is a ring homomorphism, so $(M - I)^{p^m} = M^{p^m} - I$. Hence order a power of p is exactly the same statement as $M - I$ nilpotent. This is the definition-level reason and it is why the answer depends on p at all: the problem is asking a question about the characteristic and answering it with the characteristic. Cayley and Hamilton then bounds the nilpotency index by n, which is the only place the dimension enters. **Link to the next block.** Nilpotency lets you expand powers of M as short binomial sums.

Block 4. **Cue.** $M = I + N$ with $N^n = 0$ is an invitation to the binomial theorem, and $G^{(k)}(0)$ is a sum over j of M^j. **Why natural.** Two commuting matrices obey the binomial theorem, and nilpotency truncates the expansion to n terms with coefficients $\binom{j}{i}$. Summing a polynomial in j over j is a hockey stick, so the sum stays inside the same family: $\sum_{j<k} \binom{j}{i} = \binom{k}{i+1}$. The whole orbit is therefore encoded by the residues of n binomial coefficients, which is a drastic reduction of a matrix problem to an arithmetic one. **Link to the next block.** You now control $G^{(k)}(0)$ for every k, so you may choose a k designed to make it vanish.

Block 5. **Cue.** You want an early return to 0, so you want all n coefficients $\binom{k}{i+1}$ to die modulo p at once. **Why natural.** The binomial coefficients $\binom{p^m}{t}$ with $0 < t < p^m$ are exactly the ones divisible by p; that is Kummer's theorem in miniature, and the one line proof is $t\binom{p^m}{t} = p^m\binom{p^m-1}{t-1}$. So $k = p^{n-1}$ kills every term provided the index range $1 \le t \le n$ stays below p^{n-1}. Choosing the largest p-power below p^n is the natural choice, because you need a contradiction with minimality of the period and you want the strongest possible divisibility. **Link to the next block.** The surviving cases are exactly those with $p^{n-1} \le n$, a small arithmetic inequality.

Block 6. **Cue.** A clean inequality in two integer variables. **Why natural.** p^{n-1} grows exponentially in n and n does not, so only the smallest values can survive; the check is $n = 1$ trivially, $n = 2$ giving $p \le 2$, and $2^{n-1} > n$ for $n \ge 3$ closing everything else. Then you must supply constructions, since an obstruction argument never proves existence. **Link to the next block.** The constructions are read straight off formula $(*)$.

Layer 3: WHY

The truth beneath this problem is that in characteristic p, the p-power map is a homomorphism, and therefore p-power order and unipotence are the same phenomenon. Every statement in the solution is a consequence: the linear part is $I + N$ with N nilpotent, the affine map lies in a p-group, and the orbit lengths are constrained by how fast binomial coefficients acquire factors of p. The competition is really asking whether you know that the affine group $\mathrm{AGL}_n(\mathbb{F}_p)$ contains an element of order p^n only in the two listed cases, and that the reason is arithmetic, not linear algebraic.

The discernment mechanism is a question you should ask on every iteration problem over a finite structure: what group does the map live in, and what does the hypothesis say about its order? Distinctness of a full orbit always means "single cycle", which always means "order equals the size of the space". Once the order is known, you interrogate the group, not the matrix. Train this by rebuilding the following chain from memory: order of an element divides the group order; the size of $\mathrm{GL}_n(\mathbb{F}_p)$ is $\prod_{i=0}^{n-1}(p^n - p^i)$; the Sylow p-subgroup of $\mathrm{GL}_n(\mathbb{F}_p)$ is the group of upper unitriangular matrices, of order $p^{n(n-1)/2}$; the exponent of that group is $p^{\lceil \log_p n \rceil}$. The last item alone would kill every $n \geq 4$ here.

The examiners nudged with the phrase "the p^n vectors $G^{(k)}(0)$, $k = 1, 2, \ldots, p^n$", which names the exact size of the space to make sure you convert distinctness into transitivity, and with the choice of an affine rather than a linear map, which guarantees that a fixed point argument alone cannot settle it. A purely linear G could never be transitive at all, since it fixes 0; the vector v is what makes the question non-trivial, and the vector v is exactly what the binomial formula tracks.

Revolving concepts

Affine map and its recursion. $G(x) = v + Mx$ generates $x_{k+1} = Mx_k + v$, whose closed form is $x_k = M^k x_0 + (I + M + \cdots + M^{k-1})v$. Generalised recursion: for any linear operator M and any forcing term, the solution of an inhomogeneous linear recursion is (homogeneous solution) plus (a convolution of the forcing with the powers of the operator), and when $I - M$ is invertible the second term collapses to $(I - M)^{-1}(I - M^k)v$, which is the matrix geometric series. Here $I - M$ is nilpotent, which is precisely why the geometric series must be handled by binomial expansion instead. See Book 1, field: Sequences and recurrences, topic: linear recurrences with constant coefficients.

Unipotent and nilpotent matrices. N is nilpotent when $N^j = 0$ for some j; then its only eigenvalue is 0, its characteristic polynomial is x^n, and $N^n = 0$ by Cayley and Hamilton. M is unipotent when $M - I$ is nilpotent, equivalently when M has order a power of p in characteristic p. See Book 1, field: Linear algebra, topic: nilpotency and canonical forms.

Frobenius. In a commutative ring of characteristic p, $(a + b)^p = a^p + b^p$, because $p \mid \binom{p}{i}$ for $0 < i < p$. Iterating gives $(a + b)^{p^m} = a^{p^m} + b^{p^m}$. This is the single most used fact in finite field arithmetic and it is beyond A-level; install it with its proof. See Book 1, field: Abstract algebra, topic: finite fields.

Binomial coefficients modulo p. $v_p\left(\binom{p^m}{t}\right) = m - v_p(t)$; Kummer's theorem (the exponent of p in $\binom{a+b}{a}$ is the number of carries when adding a and b in base p); Lucas's theorem (the residue of $\binom{a}{b}$ is the product of the residues of the base p digit binomials). See Book 1, field: Number theory, topic: binomial coefficients modulo a prime.

Hockey stick. $\sum_{j=0}^{k-1}\binom{j}{i} = \binom{k}{i+1}$, from telescoping Pascal's rule. Generalisation: any sum of a polynomial over an interval is again a polynomial of one higher degree, and the binomial basis $\binom{k}{i}$ is the basis in which summation is a shift of index; this is the discrete analogue of integrating x^i.

Cyclic permutations and orders. A permutation of a set of size m whose orbit through one point has size m is an m-cycle and has order m. The affine group $\mathrm{AGL}_n(\mathbb{F}_p) = \mathbb{F}_p^n \rtimes \mathrm{GL}_n(\mathbb{F}_p)$ has order $p^n \prod_{i=0}^{n-1}(p^n - p^i)$.

Circuit Bank

- **WHEN** a map on a finite set is required to have all its iterates distinct **DO** say "the map is a single cycle", deduce that its order equals the size of the set, and start reasoning inside the group it belongs to **BECAUSE** distinctness is not a usable property but transitivity and order are, and order interacts with every group theoretic constraint available
- **WHEN** an element of a matrix group over $\mathbb{F}_p$ has order a power of p **DO** write $M = I + N$ and assert N is nilpotent, then $N^n = 0$ **BECAUSE** Frobenius makes $(M - I)^{p^m} = M^{p^m} - I$, so

p-power order and unipotence are the same statement in characteristic p

- **WHEN** you must iterate an affine map **DO** write $G^{(k)}(x) = M^k x + (I + M + \cdots + M^{k-1})v$ immediately **BECAUSE** it is the matrix version of $u_{k+1} = au_k + b$, and separating linear part from constant term separates the information in any identity between affine maps
- **WHEN** a nilpotent matrix appears inside a power or a sum of powers **DO** expand binomially and truncate at the nilpotency index **BECAUSE** the expansion has only n terms, so a matrix statement becomes a statement about n binomial coefficients modulo p
- **WHEN** you need many binomial coefficients to vanish modulo p simultaneously **DO** evaluate at k equal to a power of p **BECAUSE** $\binom{p^m}{t}$ is divisible by p for all $0 < t < p^m$, which is the cleanest simultaneous vanishing available

Backtesting

1. First useful cue: p^n distinct iterates in a space of size p^n, so G is one cycle and its order is p^n, a power of the characteristic.
2. Method the expression suggested: compare linear parts in $G^{(p^n)} = \mathrm{id}$ to get $M^{p^n} = I$, then Frobenius to get unipotence, then the binomial closed form.
3. Where you would hesitate, and the thought to reinforce: at the step $(M - I)^{p^n} = M^{p^n} - I$. Reinforce it by checking the sign for $p = 2$ separately and by remembering that the identity needs commutativity, which holds because everything lives in $\mathbb{F}_p[M]$.
4. The trap the question sets: believing the answer is only $n = 1$ and missing the sporadic $(2, 2)$, or quoting a construction for $n = 1$ without checking it (the constant map $x \mapsto 1$ fails, the translation $x \mapsto x + 1$ works). An exclusion proof with no verified constructions scores badly.
5. What makes you recognise it faster next time: the pairing of a finite field of characteristic p with an orbit length that is a power of p. That pairing is never an accident and always resolves through unipotence and binomial coefficients.
6. The reusable decision rule: convert full orbit distinctness into an order statement, then let the characteristic act on that order.

Mirror drills

1. Show that an element of $\mathrm{GL}_n(\mathbb{F}_p)$ of order a power of p has 1 as its only eigenvalue. *Answer:* $M^{p^s} = I$ gives $(M - I)^{p^s} = 0$ by Frobenius, so $M - I$ is nilpotent and every eigenvalue of M equals 1.
2. Let p be odd, $N \neq 0$ with $N^2 = 0$, $M = I + N$ and $Nv \neq 0$. Find the least $k > 0$ with $G^{(k)}(0) = 0$ for $G(x) = v + Mx$. *Answer:* $G^{(k)}(0) = kv + \binom{k}{2}Nv$, and $k = p$ makes both coefficients vanish modulo p because p is odd, so the answer is p, not p^2; this is exactly why odd primes fail at $n = 2$.
3. Prove $\sum_{j=0}^{k-1} \binom{j}{i} = \binom{k}{i+1}$ and state its continuous analogue. *Answer:* telescope $\binom{j+1}{i+1} - \binom{j}{i+1} = \binom{j}{i}$; the analogue is $\int_0^x t^i \, dt = x^{i+1}/(i+1)$, with $\binom{k}{i}$ playing the role of $k^i/i!$.

14.6 A6. Unit area rectangles force the function to vanish

Let $f(x,y)$ be a continuous, real-valued function on $\mathbb{R}^2$. Suppose that, for every rectangular region R of area 1, the double integral of $f(x,y)$ over R equals 0. Must $f(x,y)$ be identically 0?

Read it out loud

Read the structure before the content. You are handed a family of linear constraints on one unknown function, indexed by the family of admissible domains, and asked whether the constraints have only the trivial solution. That is a rigidity question, and rigidity questions are always won by differentiating the constraint with respect to the parameters of the family, because a derivative of an averaged statement is a less averaged statement. Count the parameters: two for the position of the rectangle, one for its shape, and one for its orientation, with the area pinned at 1. That pinned area is the entire difficulty and the entire hint.

Say why. The reflex for going from averages to point values is to shrink the domain and divide by its measure: the Lebesgue differentiation theorem, or at this level the mean value theorem for integrals. Here you cannot shrink, because every admissible rectangle has area exactly 1. If the hypothesis had been "for every rectangle of area at most 1", the problem would be a one line exercise, since the average over a shrinking square converges to f at the centre. The examiners removed exactly that move. So the family of shapes, which is the hyperbola (width) times (height) equal to 1, has to be exploited as a curve you travel along, not as a family you shrink.

The fields are real analysis (uniform continuity, the fundamental theorem of calculus, differentiating a domain integral in a parameter), a little functional equation theory at the end, and, if you want to see why the answer is yes before you can prove it, harmonic analysis (the Fourier transform of the indicator of a rectangle factorises into two sine factors, and the common zero set over all shapes is only the pair of coordinate axes).

Within thirty seconds you should have written the constraint in coordinates,

$$\int_x^{x+c}\int_y^{y+1/c} f(u,v)\,dv\,du = 0 \qquad (x,y\in\mathbb{R},\ c>0),$$

and noticed that you now have three free parameters to differentiate: x, y and c. The first two differentiations are translations and give you edge identities; the third is the shape derivative and is where the area constraint pays.

Approaches, ranked worst to best

1. **Shrink the rectangle onto a point.** *Cue:* a vanishing integral over a small region. *Circuit:* Lebesgue differentiation. Dead on arrival, because area 1 is not negotiable: as the width goes to 0 the height goes to infinity. Worth ten seconds precisely so that you know which tool has been confiscated and stop reaching for it.

2. **Fourier transform.** *Cue:* the hypothesis is a convolution of f with indicators, vanishing identically. *Circuit:* a convolution vanishes when the spectrum avoids the zeros of the transform of the kernel. The transform of the indicator of a c by $1/c$ rectangle is a product of two sine over argument factors, so a spectral component at frequency (ξ,η) survives only if $\sin(\pi c\xi)\sin(\pi\eta/c)=0$ for every $c>0$, which forces $\xi=0$ or $\eta=0$. That says the spectrum sits on the axes, so morally $f(x,y)=g(x)+h(y)$, and then one dimensional averages finish it. Superb for conviction and inadmissible as a proof, because a merely continuous f with no growth control need not be a tempered distribution. Name this gap rather than hiding it.

3. **Sign chase on a tiling.** *Cue:* if two area 1 rectangles overlap in a rectangle, the two complementary pieces have equal integrals. *Circuit:* propagate a sign along a chain of rectangles until

it contradicts itself. Assume f is somewhere positive, find a nearby point where it is negative, and build an explicit chain of area 1 rectangles that forces the integral over a region where $f < 0$ to be positive. Entirely elementary, no differentiation, but the bookkeeping of the chain is where marks are lost.

4. **Corner parallelogram law, then rotate.** *Cue:* "every rectangular region", so tilted rectangles are allowed too. *Circuit:* a translation invariant vanishing integral gives a discrete periodicity, then use density of an irrational rotation orbit. Show first that opposite corners of any area 1 rectangle satisfy $f(A) + f(C) = f(B) + f(D)$, then apply this around a circle to see that the sum of f at the ends of a diameter is independent of the diameter, then conclude that f restricted to any line is constant. Beautiful, and it uses the full strength of the hypothesis, including orientations. Two costs: you need the density of $\{n\alpha\}$ modulo 2π, and you must handle circles of small diameter separately.

5. **Differentiate the constraint in all three parameters.** *Cue:* area pinned at 1 means the shape parameter is a curve you can travel along. *Circuit:* a vanishing family of domain integrals differentiates to a boundary identity. Two translation derivatives and one shape derivative produce three identities; combining them shows that the integral of f over a horizontal segment of fixed length does not depend on where the segment starts, and a continuous solution of Jensen's functional equation finishes. Shortest, fully rigorous, and it proves more than was asked, since only axis parallel rectangles are used.

The ideal solution

The answer is yes: f must be identically 0. We prove more, namely that it is enough to assume the double integral vanishes over every rectangle of area 1 whose sides are parallel to the coordinate axes.

Setting up a differentiable object. Define

$$F(x,y) = \int_0^x \int_0^y f(u,v)\,dv\,du.$$

Since f is continuous, the inner integral $u \mapsto \int_0^y f(u,v)\,dv$ is continuous in u (uniform continuity of f on compact sets), so the fundamental theorem of calculus gives $F_x(x,y) = \int_0^y f(x,v)\,dv$; by Fubini's theorem the order of integration may be reversed, and the same argument gives $F_y(x,y) = \int_0^x f(u,y)\,du$. Both partial derivatives are continuous on $\mathbb{R}^2$, so F is of class C^1 and the chain rule may be applied to it freely. The hypothesis states that for all $x, y \in \mathbb{R}$ and all $c > 0$,

$$\Phi(x,y,c) := F(x+c, y+\tfrac{1}{c}) - F(x, y+\tfrac{1}{c}) - F(x+c, y) + F(x,y) = 0. \tag{H}$$

First derivative: translate horizontally. Differentiating (H) with respect to x and grouping the two pairs of terms,

$$0 = \Phi_x = \Big[F_x(x+c, y+\tfrac{1}{c}) - F_x(x+c, y)\Big] - \Big[F_x(x, y+\tfrac{1}{c}) - F_x(x, y)\Big],$$

that is,

$$\int_y^{y+1/c} f(x+c,v)\,dv = \int_y^{y+1/c} f(x,v)\,dv. \tag{P}$$

In words: for an area 1 rectangle, the integrals of f over the left and right edges are equal.

Second derivative: move along the shape curve. Now differentiate (H) with respect to c, which is legitimate because F is C^1 and $c \mapsto (x+c,\ y+1/c)$ is smooth on $c > 0$:

$$0 = \Phi_c = \Big[F_x(x+c, y+\tfrac{1}{c}) - F_x(x+c, y)\Big] - \frac{1}{c^2}\Big[F_y(x+c, y+\tfrac{1}{c}) - F_y(x, y+\tfrac{1}{c})\Big],$$

that is,

$$\int_y^{y+1/c} f(x+c,v)\,dv = \frac{1}{c^2}\int_x^{x+c} f(u,y+\tfrac{1}{c})\,du. \tag{S}$$

In words: the mean of f over the right edge equals the mean of f over the top edge (multiply both sides by c and note the edges have lengths $1/c$ and c).

Combining. Substituting (P) into (S) gives, for all $x, y \in \mathbb{R}$ and $c > 0$,

$$\int_x^{x+c} f(u,y+\tfrac{1}{c})\,du = c^2\int_y^{y+1/c} f(x,v)\,dv. \tag{C}$$

Fix $w \in \mathbb{R}$ and $c > 0$, and apply (C) with $y = w - \frac{1}{c}$, first at x and then at $x + c$:

$$\int_x^{x+c} f(u,w)\,du = c^2\int_{w-1/c}^{w} f(x,v)\,dv, \qquad \int_{x+c}^{x+2c} f(u,w)\,du = c^2\int_{w-1/c}^{w} f(x+c,v)\,dv.$$

By (P) with $y = w - \frac{1}{c}$ the two right hand sides are equal, so

$$\int_x^{x+c} f(u,w)\,du = \int_{x+c}^{x+2c} f(u,w)\,du \qquad \text{for all } x \in \mathbb{R},\ c > 0. \tag{J}$$

From (J) to constancy along horizontal lines. Fix w and set $\Theta(x) = \int_0^x f(u,w)\,du$, a C^1 function with $\Theta' = f(\cdot, w)$. Identity (J) says

$$\Theta(x+c) - \Theta(x) = \Theta(x+2c) - \Theta(x+c), \quad \text{i.e.} \quad \Theta(a) + \Theta(b) = 2\,\Theta\!\left(\frac{a+b}{2}\right)$$

for all real $a < b$ (put $a = x$, $b = x + 2c$), and trivially for $a = b$. This is Jensen's functional equation, and a continuous solution of it is affine: the difference between Θ and the affine function agreeing with it at two chosen points is continuous, satisfies the same equation, and vanishes at both points, hence vanishes at every dyadic subdivision point and so, by continuity, everywhere. Therefore $\Theta(u) = \alpha u + \beta$ and

$$f(u,w) = \Theta'(u) = \alpha \quad \text{for all } u \in \mathbb{R}.$$

So f is constant on every horizontal line: writing $g(y) = f(0,y)$, which is continuous, we have $f(x,y) = g(y)$ for all x, y.

Finishing. Substituting into the hypothesis, for all $y \in \mathbb{R}$ and $c > 0$,

$$0 = \int_x^{x+c}\int_y^{y+1/c} g(v)\,dv\,du = c\int_y^{y+1/c} g(v)\,dv,$$

so $\int_y^{y+1/c} g(v)\,dv = 0$ for every y. Fixing c and differentiating with respect to y (again the fundamental theorem of calculus, g being continuous) gives $g(y+\frac{1}{c}) = g(y)$ for all y. As c runs over $(0,\infty)$ the number $\frac{1}{c}$ runs over all positive reals, so every positive real is a period of g, whence g is constant. Then $0 = \int_y^{y+1/c} g = g(0)/c$ forces $g(0) = 0$, so $g \equiv 0$ and $f \equiv 0$. ■

Two remarks worth keeping. First, only axis parallel rectangles were used, so the theorem proved is strictly stronger than the one asked for; noticing that a hypothesis is more generous than your proof needs is itself worth marks, and it is how you should audit every solution. Second, continuity can be relaxed to local integrability if you replace "identically 0" by "0 almost everywhere": the hypothesis is preserved by convolution with any smooth compactly supported bump φ, because $\iint_R (f*\varphi) = \int \varphi(z)\left(\iint_{R-z} f\right)dz = 0$ by Fubini, and $f*\varphi$ is smooth, so the theorem gives $f*\varphi \equiv 0$ for every mollifier and therefore $f = 0$ almost everywhere.

Layer 1: WHAT

Block 1. Commit to the answer yes, and identify the real task: get a pointwise statement out of averaged data when the averaging scale cannot be shrunk.

Block 2. Write the hypothesis in coordinates with the three live parameters x, y, c, the area constraint being built into the height $1/c$.

Block 3. Package the double integral as a second difference of the C^1 function F, so every differentiation you are about to perform is justified in one sentence rather than four.

Block 4. Differentiate in x: the integrals of f over the left and right edges coincide.

Block 5. Differentiate in c: the mean of f over the right edge equals the mean over the top edge. This is the only step that uses the area constraint, and it is the step the confiscated shrinking argument was supposed to replace.

Block 6. Combine the two into (J): the integral of f over a horizontal segment of length c is unchanged when the segment slides by c.

Block 7. Recognise (J) as Jensen's equation for the antiderivative Θ, conclude Θ is affine and f is constant along horizontal lines.

Block 8. Substitute back: f depends only on y, has every positive period, hence is constant, hence 0.

The nominal route is to fix a point, take rectangles shrinking towards it in one direction while stretching in the other, and hope for a limit; it produces nothing because the stretched direction is where all the mass hides. A more sophisticated nominal route is to subtract two overlapping area 1 rectangles and to chase the resulting strip identities combinatorially. The bifurcation point is precisely Block 5: do you differentiate only in the position parameters, which is what everybody does first, or do you differentiate in the shape parameter along the hyperbola $st = 1$? Position derivatives alone give (P), and (P) alone is not enough, since it is satisfied by $f(x, y) = g(y)$ for any g at all. The shape derivative is the only place the number 1 enters the argument.

Layer 2: HOW

Block 1. **Cue.** The question is "must f be 0", a yes or no with a proof attached. **Why natural.** On the Putnam a rigidity question of this shape is almost always yes, because the constraint family is huge (three real parameters plus rotations against one unknown function). Deciding yes immediately is not guessing; it is a decision about which of the two possible pieces of work to start, and you can afford ninety seconds of Fourier heuristic to confirm it before committing. **Link to the next block.** A yes needs a mechanism that converts averages into point values.

Block 2. **Cue.** "For every rectangular region of area 1" with the area fixed. **Why natural.** Fixed area means the family of shapes is one dimensional, parametrised by the width c with height $1/c$. Writing the constraint with all parameters explicit is how you see that you have three derivatives available. Naming them is not bookkeeping; it is the search space of the proof. **Link to the next block.** Before differentiating anything, make the object you are differentiating obviously differentiable.

Block 3. **Cue.** A double integral over a box with variable corners. **Why natural.** Every such integral is a second difference of the antiderivative $F(x, y) = \int_0^x \int_0^y f$. That reduces all four justifications (differentiability, interchange of limits, chain rule) to one statement, namely that F is C^1 with the two partials computed by the fundamental theorem of calculus and Fubini. Graders take marks for differentiating under an integral sign without a word of justification; this packaging makes the justification a single sentence. **Link to the next block.** Now differentiate in the cheapest parameter first.

Block 4. **Cue.** The constraint holds for every x, so $\Phi_x = 0$. **Why natural.** Differentiating a translation invariant constraint measures the flux through the two moving edges: the right edge sweeps outward and the left edge sweeps inward at the same rate, so their contributions must cancel. This is the first variation of a domain integral, and here it says left edge integral equals right edge integral. **Link to the next block.** This identity is genuinely weaker than the problem, since it holds for every function of y alone, so you know it cannot be the last step and you know what the next step must break: the freedom in y.

Block 5. **Cue.** The height is $1/c$, a function of the width; the shape is a curve, not a free parameter. **Why natural.** Differentiating along that curve moves the right edge outward at speed 1 and the top edge downward at speed $1/c^2$, so the flux identity reads (right edge integral) equals $1/c^2$ times (top edge integral). Because the two edges are perpendicular, this couples the horizontal and vertical behaviour of f for the first time, which is exactly what (P) could not do. The general principle is the transport or first variation formula: the derivative of $\int_{R(\lambda)} f$ is the integral of f times the normal speed of the boundary. **Link to the next block.** You now have a horizontal quantity equal to a vertical quantity, so you can eliminate the vertical one using (P).

Block 6. **Cue.** Two identities sharing the term "integral over a vertical edge". **Why natural.** Eliminating a shared term is the standard way to combine two constraints, and here the elimination is engineered by choosing $y = w - 1/c$ so that the top edge sits on the line you care about. What comes out, (J), is a purely one dimensional statement about the single variable function $u \mapsto f(u, w)$, which is a decisive simplification: the plane has been eliminated. **Link to the next block.** A statement about equal integrals over adjacent intervals is a statement about the antiderivative.

Block 7. **Cue.** Equal increments of Θ over adjacent intervals of equal length, for every length. **Why natural.** This is exactly the midpoint condition $\Theta(a) + \Theta(b) = 2\Theta(\frac{a+b}{2})$. You already know the theory: Cauchy and Jensen functional equations have only the affine continuous solutions, by dyadic subdivision plus continuity. Quoting a named theorem here is not laziness, it is the correct use of an installed circuit; the alternative finish (divide by the length and let it tend to 0, using the mean value theorem for integrals to recover $f(0, w) = f(z, w)$) is equally short if the name escapes you in the arena. **Link to the next block.** Constancy along horizontal lines collapses f to a function of y.

Block 8. **Cue.** A function of one variable with every positive number as a period. **Why natural.** Periods form an additive subgroup; a subgroup of $\mathbb{R}$ containing every positive real is everything, so g is constant, and one more substitution into the hypothesis pins the constant at 0. Do not stop at "f is constant", because the problem asked for the value.

Layer 3: WHY

The mathematical truth underneath is the first variation of a domain functional, sometimes met as the Reynolds transport theorem:

$$\frac{d}{d\lambda} \int_{R(\lambda)} f = \int_{\partial R(\lambda)} f \, (V \cdot n) \, dS,$$

where V is the velocity of the moving boundary and n its outward normal. All three identities in the solution are this one formula applied to three different motions of the same rectangle: translation in x (normal speed $+1$ on the right edge and -1 on the left), translation in y, and the shape motion along the hyperbola (normal speed $+1$ on the right edge and $-1/c^2$ on the top). Once you see the hypothesis as "this functional is constant along a three parameter family of motions", the proof

writes itself: constancy of a functional means the flux through the boundary vanishes for every admissible motion, and vanishing flux for enough motions pins the boundary values, which by continuity pins the function.

The discernment mechanism is a single question: what continuous symmetries does the constraint family have, and which of them changes the shape rather than the position? Translations are free and always give you edge identities, but a family closed only under translations can never determine a function beyond its behaviour in the direction of the translations. The area constraint looks like a restriction, but it is the only source of a shape motion, so it is the asset, not the obstacle. Train this by rewriting standard results in the same language: the mean value property of harmonic functions comes from differentiating the average over a sphere in the radius, Green's identities come from differentiating a domain integral in a deformation parameter, and the classical result that a continuous function whose integral over every interval of a fixed length L vanishes must be L-periodic with zero mean is the one dimensional shadow of (P).

The examiners nudged in three ways. They fixed the area at 1 rather than allowing all small rectangles, which removes the Lebesgue differentiation reflex and forces the shape derivative. They said "rectangular region" rather than "rectangle with sides parallel to the axes", which offers the rotation route as a second, more geometric solution and rewards anyone who notices that the extra generosity is not needed. And they asked "must f be identically 0" rather than "prove that f is 0", to keep you honest about the possibility of a counterexample; a candidate who has not at least tried $f(x,y) = \sin(2\pi x)$ and seen why it fails (its integral over a c by $1/c$ rectangle is not identically 0 in c) has not earned the answer.

Revolving concepts

Differentiating a domain integral. For a C^1 family of domains, the derivative of $\int_{R(\lambda)} f$ is the boundary integral of f against the normal speed. In one dimension this is the fundamental theorem of calculus with variable endpoints, $\frac{d}{d\lambda}\int_{a(\lambda)}^{b(\lambda)} f = f(b)b' - f(a)a'$, and every identity in this problem is a two dimensional instance of it. See Book 1, field: Calculus and integrals, topic: Leibniz rule and variable limits.

Regularity bookkeeping. If f is continuous then $F(x,y) = \int_0^x \int_0^y f$ is C^1 with $F_x = \int_0^y f(x,v)dv$ and $F_y = \int_0^x f(u,y)du$, and $F_{xy} = F_{yx} = f$. The ingredients are uniform continuity on compact sets, the fundamental theorem of calculus and Fubini's theorem for continuous functions on a rectangle. This packaging is the cheapest way to make several differentiations legitimate at once. See Book 1, field: Real analysis, topic: differentiation under the integral sign.

Jensen's functional equation. A continuous $\Theta : \mathbb{R} \to \mathbb{R}$ with $\Theta(a) + \Theta(b) = 2\Theta(\frac{a+b}{2})$ for all a, b is affine. The proof is the standard dyadic recursion: the equation propagates the value at the midpoint, hence at every dyadic rational subdivision point of any interval, and continuity fills the rest. Generalised recursion: the same subdivision argument proves that continuous solutions of the Cauchy equation $h(a+b) = h(a) + h(b)$ are linear, that midpoint convex continuous functions are convex, and in general that a functional equation which determines the midpoint value determines the function on a dense set, so continuity upgrades "determined on the dyadics" to "determined everywhere". See Book 1, field: Functional equations, topic: Cauchy and Jensen.

Periods of a function. The set of periods of a function is an additive subgroup of $\mathbb{R}$; if it is not cyclic it is dense, and if the function is continuous with a dense set of periods it is constant. Here every positive real is a period, so constancy is immediate. See Book 1, field: Real analysis, topic: periodic functions and subgroups of the reals.

Mean value theorem for integrals and Lebesgue differentiation. $\frac{1}{h}\int_a^{a+h} f \to f(a)$ as $h \to 0^+$ for continuous f; the almost everywhere version for locally integrable f is the Lebesgue differentiation theorem. This is the standard route from averaged information to pointwise information, and recognising that the fixed area hypothesis blocks it is the first strategic decision in the problem.

Fourier transform of an indicator, and the honest gap. The transform of the indicator of $[0,c]\times[0,1/c]$ is a product of factors of the form $\sin(\pi c\xi)/(\pi\xi)$ and $\sin(\pi\eta/c)/(\pi\eta)$ up to phases, so the common zero set over all $c>0$ is the union of the two axes. This explains, in ninety seconds, why the answer must be yes and why the extremal near-counterexamples look like functions of one variable. Turning it into a proof requires the theory of tempered distributions and a growth hypothesis on f that the problem does not supply, so it is a knowledge gap to name and not a solution to submit. See Book 1, field: Real analysis, topic: Fourier transforms and convolution.

Density of an irrational rotation orbit. The alternative rotation solution needs the fact that $\{n\alpha \bmod 2\pi\}$ is dense when $\alpha/2\pi$ is irrational, together with continuity to pass from a dense set of angles to all of them. This is Weyl's equidistribution theorem in its weakest form and is beyond A-level; install it. See Book 1, field: Number theory, topic: equidistribution.

Circuit Bank

- **WHEN** a hypothesis says an integral over every member of a parametrised family of domains vanishes **DO** differentiate the identity with respect to each parameter and read the result as a boundary or edge identity **BECAUSE** a constant functional has zero first variation, and the first variation of a domain integral is the flux of the integrand through the moving boundary
- **WHEN** the size of the domains is pinned so you cannot shrink them **DO** stop hunting for a Lebesgue differentiation argument and look instead for a shape parameter to differentiate along **BECAUSE** a pinned measure removes the shrinking family but creates a one dimensional family of shapes, and that family is the only place the pinned constant can enter the proof
- **WHEN** you are about to differentiate a multiple integral with several variable limits **DO** first rewrite it as a second difference of a single antiderivative F and prove once that F is C^1 **BECAUSE** one justification then covers every subsequent differentiation, and unjustified interchanges are the standard way to lose marks on an otherwise correct analysis solution
- **WHEN** you obtain equal increments of a function over adjacent intervals of arbitrary equal length **DO** recognise Jensen's equation and quote that continuous solutions are affine **BECAUSE** the midpoint condition determines the function on a dense dyadic set, so continuity forces affinity, and its derivative is then constant
- **WHEN** a continuous function turns out to have arbitrarily small periods **DO** conclude at once that it is constant **BECAUSE** the periods form an additive subgroup of the reals, and a non-cyclic subgroup is dense

Backtesting

1. First useful cue: the area is pinned at 1, so the usual shrink and divide route is confiscated and the shape parameter c with height $1/c$ must be the engine.
2. Method the expression suggested: write the constraint with parameters x, y, c, package it as a second difference of a C^1 antiderivative, and differentiate in x and in c.
3. Where you would hesitate, and the thought to reinforce: after getting the edge identity (P), because it looks like progress but is satisfied by every function of y alone. Reinforce the habit of asking which functions satisfy the identity you just derived; if the answer is a big family, you have not used the key hypothesis yet.
4. The trap the question sets: the fixed area, which blocks the reflex; and the word "rectangular region", which tempts you into a rotation argument that is longer than necessary.

5. What makes you recognise it faster next time: any hypothesis of the form "the integral over every domain of exactly this size vanishes". The measure being fixed is the signal to differentiate along the shape family.
6. The reusable decision rule: constraints indexed by a family of domains are differentiated in the family parameters, and the parameter that changes shape rather than position is the one that carries the content.

Mirror drills

1. Let h be continuous on $\mathbb{R}$ with $\int_x^{x+1} h = 0$ for every x. What can you say about h? *Answer:* differentiating in x gives $h(x+1) = h(x)$, so h is 1-periodic with mean zero; $h(x) = \sin 2\pi x$ shows it need not vanish, which is exactly why the two dimensional problem needs a shape derivative as well as a translation derivative.
2. Suppose f is continuous on $\mathbb{R}^2$ and its integral over every square of area 1 (sides parallel to the axes) vanishes. Must f be 0? *Answer:* no. Take $f(x,y) = \sin(2\pi x)$, whose integral over any unit square vanishes; the family of squares has no shape parameter, so only translations are available and the argument of this problem collapses.
3. Show that a continuous Θ with $\Theta(a) + \Theta(b) = 2\Theta(\frac{a+b}{2})$ for all a, b is affine. *Answer:* subtract the affine function agreeing with Θ at 0 and 1; the difference satisfies the same equation and vanishes at 0 and 1, hence at every dyadic rational in $[0,1]$ by repeated midpointing, hence identically by continuity, and the same on every interval.

14.7 B1. closure under addition and composition forces multiplication

Let S be a class of functions from $[0,\infty)$ to $[0,\infty)$ that satisfies:

(i) the functions $f_1(x) = e^x - 1$ and $f_2(x) = \ln(x+1)$ are in S;

(ii) if $f(x)$ and $g(x)$ are in S, the functions $f(x) + g(x)$ and $f(g(x))$ are in S;

(iii) if $f(x)$ and $g(x)$ are in S and $f(x) \geq g(x)$ for all $x \geq 0$, then the function $f(x) - g(x)$ is in S.

Prove that if $f(x)$ and $g(x)$ are in S, then the function $f(x)g(x)$ is also in S.

Read it out loud

This is a closure system, not a functional equation to solve. Condition (i) hands you two named generators, condition (ii) closes S under addition and under composition, and condition (iii) closes S under a subtraction that only fires when the result stays nonnegative. Nowhere is multiplication a primitive operation, so the whole task is to manufacture the pointwise product $f(x)g(x)$ out of sums, compositions and one guarded subtraction. That absence is the entire question, and it is what you should read out loud first: you are being asked to reroute a multiplicative target through additive machinery.

Look at the two generators as a pair rather than as two isolated examples. Compute $f_2(f_1(x)) = \ln(e^x) = x$ and $f_1(f_2(x)) = e^{\ln(x+1)} - 1 = x$: they are mutually inverse on $[0,\infty)$, and they are the shifted exponential and shifted logarithm, shifted by exactly enough to fix 0 and to keep both maps inside $[0,\infty)$. That is the cue to write down within thirty seconds: whenever a closure axiom names two functions that compose to the identity, a conversion pair has been handed to you, and here that pair is exp and log, the pair that turns sums into products and back. The circuit that should fire is immediate: product wanted, only sums and compositions available, so route through log and exp.

Approaches, ranked worst to best

1. **treat $f(g(x))$ as a stand in for $f(x)g(x)$.** *Cue:* condition (ii) lists composition and the target is a product, so the two look related. *Circuit:* misreading the axiom rather than applying it. This route confuses two different operations that happen to sit in the same clause. No manipulation of $f \circ g$, $f \circ f$ or $g \circ g$ alone reduces to the pointwise product for generic f, g; the ink spent here buys nothing, since no such identity exists.

2. **structural induction on how f was generated from f_1, f_2.** *Cue:* S is built up by finitely many applications of (ii) and (iii), so induction on that construction feels natural. *Circuit:* induction on the closure system itself. This can be forced to work, proving at each generating step that multiplying by f_1 or f_2 stays in S, but it reintroduces the real content, the log and exp identity below, as a base case while adding a whole induction scaffold on top for no extra rigour. It costs far more ink than the direct route for the same conclusion.

3. **route the product through logs and exponentials.** *Cue:* f_1, f_2 are a shifted exp and log pair, mutually inverse, fixing 0. *Circuit:* convert a product into a sum via ln, close under (ii), convert back via exp, then subtract the surplus with (iii). This uses every axiom for exactly what it is best at and reaches fg in a fixed number of steps regardless of how f and g were themselves built.

The ideal solution

Fix $f, g \in S$.

Since $f_2(x) = \ln(x+1) \in S$ by (i), condition (ii) applied to the pairs (f_2, f) and (f_2, g) gives

$$\ln(f(x)+1) \in S, \qquad \ln(g(x)+1) \in S.$$

Condition (ii) applied to these two functions gives their sum in S:

$$h(x) := \ln(f(x)+1) + \ln(g(x)+1) \in S.$$

Since $f_1(x) = e^x - 1 \in S$ by (i) and $h \in S$, condition (ii) applied to the pair (f_1, h) gives $f_1(h(x)) \in S$, and

$$f_1(h(x)) = e^{\ln(f(x)+1)+\ln(g(x)+1)} - 1 = (f(x)+1)(g(x)+1) - 1 = f(x)g(x) + f(x) + g(x).$$

Write $F(x) := f(x)g(x) + f(x) + g(x)$, so $F \in S$. Condition (ii) applied directly to f, g gives $G(x) := f(x) + g(x) \in S$. Because f, g take values in $[0, \infty)$, $f(x)g(x) \geq 0$ for every $x \geq 0$, so $F(x) \geq G(x)$ for every $x \geq 0$. Condition (iii) applied to the pair (F, G) is therefore licensed, and gives

$$F(x) - G(x) = f(x)g(x) \in S,$$

which is the claim.

Layer 1: WHAT

Block 1: read f_1, f_2 as a shifted, mutually inverse exp/log pair inside S. Block 2: build $\ln(f+1)$ and $\ln(g+1)$ by composing f_2 onto f and onto g. Block 3: add them, which is secretly $\ln((f+1)(g+1))$. Block 4: compose f_1 back onto that sum, exponentiating to reach $(f+1)(g+1) - 1 = fg + f + g$. Block 5: obtain $f + g$ directly from (ii), untouched since Block 1. Block 6: subtract, licensed by $fg \geq 0$, to isolate fg.

The nominal route stares at $f(x) + g(x)$ and $f(g(x))$ in (ii) and tries to force one of them, or some blend of them, straight onto f and g, never returning to f_1, f_2 after reading (i). The bifurcation point is the line where you ask what the two named generators are actually for: the zombie route treats them as a starting example and forgets them; the ideal route treats them as the conversion machine that (ii) and (iii) alone cannot supply.

Layer 2: HOW

Block 1. **Cue.** Condition (i) names exactly two functions, and $f_1 \circ f_2 = f_2 \circ f_1 = \mathrm{id}$ on $[0, \infty)$. **Why natural.** Multiplication is not a primitive of (ii) or (iii); the only way to reach it is to convert it into an operation those axioms do supply, and a mutually inverse pair that is also exp and log, shifted to respect $[0, \infty)$, is exactly that conversion. **Link to the next block.** Apply f_2 to f and to g separately, since ln is what turns the product you do not yet have into a sum you can build with (ii).

Block 2. **Cue.** $f, f_2 \in S$, and (ii) closes S under composition. **Why natural.** Composing f_2 onto f is evaluating ln at $f(x)$; it is the only way inside this axiom system to apply a fixed function pointwise to f. **Link to the next block.** Two functions of the same shape are now in S, ready to be added, which is the other half of (ii).

Block 3. **Cue.** Two elements of S with nothing left to do to them individually. **Why natural.** (ii) closes S under addition, and $\ln(f+1) + \ln(g+1) = \ln((f+1)(g+1))$ already encodes the product, wrapped in a logarithm. **Link to the next block.** The natural next step is to strip the logarithm off by composing with its inverse, f_1.

Block 4. **Cue.** $f_1 \in S$ from (i), and the sum from Block 3 is in S. **Why natural.** Composing f_1 undoes the logarithm because $f_1 = f_2^{-1}$ on $[0, \infty)$, handing you $(f+1)(g+1) - 1 = fg + f + g$. **Link to the next block.** You have reached fg plus a known surplus $f + g$; the remaining task is to obtain that surplus separately and subtract it.

Block 5. **Cue.** $f, g \in S$ directly, with (ii) untouched since Block 1. **Why natural.** Addition of the two original functions is the most primitive move (ii) offers, used here for exactly the surplus Block 4 left behind. **Link to the next block.** $fg + f + g$ and $f + g$ are both in S and differ pointwise by $fg \geq 0$, which is exactly what condition (iii) needs as its licence.

Block 6. **Cue.** $F(x) = fg + f + g \geq G(x) = f + g$ for every x, because f, g map into $[0, \infty)$. **Why natural.** Condition (iii) is a restricted operation, only available once $F \geq G$ pointwise is certified; here that certification is one line, since S's codomain is nonnegative by definition. **Link to the next block.** Subtracting removes exactly the surplus Block 4 introduced, leaving fg alone in S.

Layer 3: WHY

The route works because multiplication is conjugate to addition through any pair of mutually inverse maps carrying a multiplicative identity to an additive one, which is exactly what log and exp are, and condition (i) hands you a copy of that pair already living inside S. Whenever a closure axiom gives you two named generators, compute whether they compose to the identity in either order; if they do, a conversion pair has been handed to you, and the problem is asking you to move between the two structures it connects.

The shift is the second truth worth naming. Plain ln and plain exp cannot survive inside S, since S's codomain is $[0, \infty)$ rather than $\mathbb{R}$ or $(0, \infty)$; shifting by 1 is what keeps f_1, f_2 mapping $[0, \infty)$ to $[0, \infty)$ and fixing 0. That shift is precisely what produces the surplus $f + g$ in Block 4: exponentiating $\ln(f+1) + \ln(g+1)$ gives $(f+1)(g+1)$, not fg, and the extra 1 on each factor has to be paid for. Train yourself to expect this: a generator that is the standard function, shifted to fix a boundary condition, leaves a correction term downstream proportional to the shift, and the remaining axiom in the problem, here (iii), usually exists specifically to pay that correction off.

Revolving concepts

Closure systems generated by axioms. S is the smallest class containing f_1, f_2 and closed under (ii) and (iii); reasoning about membership means exhibiting an explicit finite chain of operations reaching the target, exactly as for a subgroup or subring generated by a set. See Book 1, field: Abstract algebra, topic: generated substructures.

The log/exp conjugacy. For $a, b > 0$, $ab = e^{\ln a + \ln b}$; more generally a strictly monotonic bijection ϕ conjugates addition on its codomain to the operation $x * y := \phi^{-1}(\phi(x) + \phi(y))$ on its domain. Here $\phi(x) = \ln(x+1)$ conjugates multiplication of $(f+1), (g+1)$ to addition of logs, and the shift by 1 keeps ϕ valued on $[0, \infty)$. See Book 1, field: Real analysis, topic: exponential and logarithmic identities.

Restricted subtraction under pointwise order. Condition (iii) is a partial operation, defined only where $f \geq g$ pointwise; every invocation needs its own one line certificate. See Book 1, field: Inequalities, topic: pointwise ordering of functions.

There is no recursive or inductive structure anywhere in this problem, so no generalised recursion entry applies here.

Circuit Bank

- **WHEN** a closure axiom names two specific generator functions **DO** compute whether they compose to the identity, in either order **BECAUSE** because a mutually inverse pair among your generators is almost always the mechanism the problem is built on, most often an exp/log or a reflection pair
- **WHEN** you need a product but your closure rules only supply sums and compositions **DO** route through ln, add, then route back through exp **BECAUSE** because $e^{a+b} = e^a e^b$ is the elementary identity that turns addition into multiplication, and composition with a fixed function is how a closure system lets you apply it pointwise
- **WHEN** a generator is a shift of a standard function to respect a boundary such as $[0, \infty)$ **DO** expect a residual linear correction term after exponentiating or inverting, and expect it to need cleaning up **BECAUSE** because the shift is extra content that the identity you are using does not automatically cancel
- **WHEN** a closure system gives a restricted subtraction, valid only when $f \geq g$ pointwise **DO** certify the inequality explicitly, in one line, at the point you invoke it **BECAUSE** because an uncertified use of a partial operation is a step of rigour lost, however obvious the inequality is

Backtesting

1. First useful cue: f_1 and f_2 compose to the identity on $[0, \infty)$, so they are a shifted exp/log pair, not two unrelated examples.
2. Method the expression suggested: convert the target product into a sum of logs with f_2, close under addition, then invert with f_1 to exponentiate back.
3. Where you would hesitate, and the thought to reinforce: exponentiating lands on $fg + f + g$, not fg alone; the thought to reinforce is that a shifted generator always leaves a correction term, and the unused axiom exists to remove it.
4. The trap the question sets: reading the two clauses of (ii), addition and composition, as competing candidates for the multiplication rule, and forcing one onto f and g without ever returning to f_1, f_2.
5. What makes you recognise it faster next time: any closure axiom naming two specific functions as generators is worth testing for a compositional inverse relationship before anything else.
6. The reusable decision rule: when a closure system gives addition and composition but the goal is multiplication, search the generators for an exp/log style conjugacy pair, use it to convert, then use the remaining axiom to pay for whatever shift the generators carried.

Mirror drills

1. Let T be the smallest class of functions $\mathbb{R} \to \mathbb{R}$ containing $x \mapsto x$ and the constant 1, closed under addition, subtraction and multiplication. Show every polynomial with integer coefficients lies in T. *Answer:* build each power x^k by repeated multiplication, available directly here, then assemble integer coefficients by repeated addition and subtraction of 1.
2. A class S of positive reals contains 2 and 3 and is closed under $a * b = ab$ and, when $a \geq b$, a/b. Show $2^n 3^m \in S$ for all integers n, m with $2^n 3^m \geq 1$. *Answer:* the same generator discipline as B1, except multiplication is already primitive here, so the only work is bookkeeping the sign of each exponent against the restricted division.

3. A class S of functions $[0,\infty) \to [0,\infty)$ is closed under addition and composition and contains only sin and cos, suitably restricted, as generators beyond the identity. Explain why the B1 route to $f(x)g(x)$ has no foothold here. *Answer:* sin, cos do not form a mutually inverse pair conjugating an additive structure to a multiplicative one, so there is no analogue of ln, exp to route the product through.

14.8 B2. a single face bounds the ball count below

Let P be a given (non-degenerate) polyhedron. Prove that there is a constant $c(P) > 0$ with the following property: if a collection of n balls whose volumes sum to V contains the entire surface of P, then $n > c(P)/V^2$.

Read it out loud

Strip away the word polyhedron for a moment and read the shape of the claim: a count n, a volume V, and an inequality relating them of the form $n >$ constant$/V^2$. That exponent of 2 on V is a command term in disguise. Volumes of balls scale as the cube of radius, so V carries a degree 3 flavour in the radii r_i; an inequality with V^2 on the bottom and a bare count n on top is exactly the shape produced by comparing a degree 2 quantity, cubed, against a degree 3 quantity, squared, which is the signature of Hölder's inequality, or equivalently the power mean inequality, applied to two different powers of the same sequence (r_i).

That tells you what the middle of the proof must be. The two ends still need supplying: a degree 2 quantity in the radii, bounded below by something depending only on P, and a degree 3 quantity, which is V itself up to a constant, bounded above. A sum of squared radii is exactly what controls an area, since a disc of radius r has area πr^2; and the problem gives you balls covering the entire surface of a polyhedron, which certainly includes covering any single flat face. The moment you notice you do not need the whole surface of P, only one flat piece of it, the three dimensional covering problem collapses to a two dimensional one: discs covering a fixed flat region. That is the reroute, and it is the whole saving in this problem.

The cue to write down inside thirty seconds: fix one face F of P with area $A > 0$, which exists because P is non-degenerate, note that balls covering P's surface in particular cover F, and prepare to bound $\sum r_i^2$ below by A/π while $\sum r_i^3$ is bounded above by a multiple of V.

Approaches, ranked worst to best

1. **estimate covering efficiency over the whole surface of P at once.** *Cue:* the hypothesis is phrased in terms of the entire surface. *Circuit:* a direct global covering argument. Faces meet at edges and vertices, where a ball can cover parts of two or three faces at once, at angles that are awkward to bound uniformly; controlling the covering efficiency across every edge and corner of P simultaneously costs far more ink than the target inequality actually requires, and it still has to end in essentially the same Hölder step below.

2. **bound n using Cauchy-Schwarz on $\sum r_i^2$ and $\sum r_i^3$ alone.** *Cue:* Cauchy-Schwarz is the default inequality between two sums of powers. *Circuit:* two term Cauchy-Schwarz applied directly to the radii. Cauchy-Schwarz compares two sums of matched degree; here three different objects are in play at once, the bare count $n = \sum 1$, $\sum r_i^2$ and $\sum r_i^3$, at degrees $0, 2, 3$ respectively, and no single application of Cauchy-Schwarz ties all three together. Chaining two applications reaches the same place as one application of Hölder, at strictly more cost for the same conclusion.

3. **restrict to one flat face, then apply Hölder's inequality with exponents $3/2$ and 3 to $\sum r_i^2$.** *Cue:* a face gives a clean two dimensional covering bound, and the target inequality's V^2 signals a degree matching problem across three quantities. *Circuit:* extremal restriction to a sub-structure, followed by a single Hölder step chosen to match degrees $0, 2, 3$. This is the ideal route: it discards everything about P except that it has one flat face of positive area, reduces the whole problem to bounding how much of a plane a disc can cover, and closes the degree gap between count, area and volume in one clean inequality.

The ideal solution

Since P is a non-degenerate polyhedron, fix one of its faces F, a planar polygon of area $A > 0$, lying in a plane Π.

Suppose n balls of radii $r_1, \dots, r_n$, with $\sum_{i=1}^{n} \frac{4}{3}\pi r_i^3 = V$, together contain the entire surface of P; in particular they cover F. The intersection of the i-th ball with the plane Π is either empty or a disc of some radius $\rho_i \le r_i$: if the ball's centre lies at perpendicular distance d_i from Π with $d_i < r_i$, the intersection is a disc of radius $\sqrt{r_i^2 - d_i^2} \le r_i$; if $d_i \ge r_i$, the intersection with Π is empty, covered by taking $\rho_i = 0 \le r_i$. This disc has area at most $\pi\rho_i^2 \le \pi r_i^2$, so the portion of F that the i-th ball can possibly cover has area at most πr_i^2. Since the n balls together cover all of F,

$$\sum_{i=1}^{n} \pi r_i^2 \;\ge\; A, \qquad \text{that is} \qquad \sum_{i=1}^{n} r_i^2 \;\ge\; \frac{A}{\pi}.$$

Next, from the volume constraint,

$$\sum_{i=1}^{n} r_i^3 = \frac{3V}{4\pi}.$$

Now connect n, $\sum r_i^2$ and $\sum r_i^3$ by Hölder's inequality with conjugate exponents $p = 3/2$ and $q = 3$, so that $1/p + 1/q = 2/3 + 1/3 = 1$, applied to the sequences $(r_i^2)_{i=1}^n$ and $(1)_{i=1}^n$:

$$\sum_{i=1}^{n} r_i^2 \cdot 1 \;\le\; \left(\sum_{i=1}^{n} (r_i^2)^{3/2}\right)^{2/3} \left(\sum_{i=1}^{n} 1^3\right)^{1/3} = \left(\sum_{i=1}^{n} r_i^3\right)^{2/3} n^{1/3}.$$

Cubing both sides,

$$\left(\sum_{i=1}^{n} r_i^2\right)^3 \;\le\; \left(\sum_{i=1}^{n} r_i^3\right)^2 n.$$

Substituting the two bounds established above,

$$\left(\frac{A}{\pi}\right)^3 \;\le\; \left(\sum_{i=1}^{n} r_i^2\right)^3 \;\le\; \left(\sum_{i=1}^{n} r_i^3\right)^2 n = \left(\frac{3V}{4\pi}\right)^2 n,$$

so

$$n \;\ge\; \frac{A^3/\pi^3}{9V^2/(16\pi^2)} = \frac{16A^3}{9\pi V^2}.$$

This holds for every collection of balls covering the surface of P, so any constant $c(P)$ with $0 < c(P) < \dfrac{16A^3}{9\pi}$ satisfies $n > c(P)/V^2$ for every such collection: the strict inequality $n > c(P)/V^2$ is safe even though the derived bound on n is only $\ge$, precisely because $c(P)$ is chosen strictly smaller than the constant the argument produces. Taking

$$\boxed{c(P) = \frac{8A^3}{9\pi}}$$

where A is the area of any fixed face of P, completes the proof.

Layer 1: WHAT

Block 1: fix one flat face F of P, area $A > 0$. Block 2: note the covering balls cover F too, and bound the area of F a single ball of radius r_i can cover by πr_i^2, giving $\sum r_i^2 \ge A/\pi$. Block 3: rewrite the volume constraint as $\sum r_i^3 = 3V/(4\pi)$. Block 4: apply Hölder's inequality with exponents $3/2$ and 3 to link n, $\sum r_i^2$ and $\sum r_i^3$ in one line. Block 5: substitute the two bounds and solve for n, then choose $c(P)$ strictly below the resulting constant to convert $\ge$ into $>$.

The nominal route tries to control the covering efficiency across the whole boundary of P at once, tracking how balls straddle edges and vertices between faces. The bifurcation point is the decision to discard almost all of P's structure and keep only one flat face: the zombie route treats "surface of P" as a single indivisible object to be estimated globally; the ideal route notices that a lower bound only needs one witness, and the cheapest witness available is a single flat face reduced to a two dimensional disc covering problem.

Layer 2: HOW

Block 1. **Cue.** P is non-degenerate, so it has at least one genuine flat polygonal face of positive area. **Why natural.** A lower bound on n only needs one sufficient obstruction, not a full account of P's geometry; a flat face is the cheapest piece of P to reason about, since it reduces three dimensional covering to two dimensional covering. **Link to the next block.** Since the given balls cover the whole surface of P, they in particular cover F, so every subsequent bound only has to reason about how balls interact with one fixed plane.

Block 2. **Cue.** A ball intersected with a plane is a disc of radius at most the ball's own radius. **Why natural.** This is the sharpest elementary bound available: the cross section of a sphere by a plane at perpendicular distance d from the centre has radius $\sqrt{r^2 - d^2} \leq r$, with equality only when the plane passes through the centre. **Link to the next block.** Summing the maximum possible area each ball contributes to covering F gives a lower bound on $\sum r_i^2$ purely in terms of A, the one geometric invariant of P that survives into the proof.

Block 3. **Cue.** The hypothesis already gives V as a sum of ball volumes. **Why natural.** Expressing V as $\sum \frac{4}{3}\pi r_i^3$ makes $\sum r_i^3$, the other quantity Hölder needs, immediately available as a constant multiple of V. **Link to the next block.** Two power sums of the radii, at degrees 2 and 3, are now both bounded in terms of the data; the count n is the third and last quantity to bring in.

Block 4. **Cue.** Three quantities of different degrees in the radii, n at degree 0, $\sum r_i^2$ at degree 2, $\sum r_i^3$ at degree 3, need to be tied together in one inequality. **Why natural.** Hölder's inequality is exactly the tool for comparing sums of different powers of the same sequence; choosing exponents $3/2$ and 3 on the pair $((r_i^2), (1))$ is forced by wanting $\sum r_i^2$ cubed to sit against $\sum r_i^3$ squared and n, which is precisely the shape A^3/V^2 demanded by the problem. **Link to the next block.** The resulting inequality $(\sum r_i^2)^3 \leq (\sum r_i^3)^2 n$ only needs the two bounds from Blocks 2 and 3 substituted in.

Block 5. **Cue.** $(\sum r_i^2)^3 \leq (\sum r_i^3)^2 n$, with $\sum r_i^2 \geq A/\pi$ and $\sum r_i^3 = 3V/(4\pi)$. **Why natural.** Substituting both bounds and simplifying the constants gives an explicit lower bound $n \geq 16A^3/(9\pi V^2)$, valid for every covering collection, so any constant strictly below $16A^3/(9\pi)$ turns the problem's required strict inequality $n > c(P)/V^2$ into a true statement for every such collection. **Link to the next block.** The proof is complete once $c(P)$ is named explicitly as a positive number depending only on P, through the area A of a chosen face, exactly as the problem demands.

Layer 3: WHY

The underlying truth is dimensional. A covering-by-balls hypothesis on a k dimensional object, here a flat face with $k = 2$, bounds a sum of r_i^2 terms below, while a volume hypothesis in ambient 3 dimensional space bounds a sum of r_i^3 terms above. Any inequality asked for between a count n and a ratio of a lower dimensional bound to a higher dimensional one is, structurally, a request to interpolate between the degree 0 sum $n = \sum r_i^0$ and two other power sums, and interpolation between power sums of the same sequence at different exponents is exactly what Hölder's inequality measures. The discernment mechanism is to read the exponents straight off the target inequality,

cube the area bound, square the volume bound, and choose Hölder's conjugate exponents to reproduce exactly that shape, rather than guessing an inequality and hoping the algebra matches.

The second truth is about restriction. The problem states a hypothesis about the entire surface of P, but a lower bound on n is an existential statement in disguise: you only need to exhibit one obstruction that already forces n to be large, not to characterise every possible covering. Any time a covering or packing problem gives an entire boundary or domain as the hypothesis but only asks for an inequality, not an exact characterisation, test whether a single convenient sub-piece of that domain, chosen for the invariant it carries, already carries the whole force of the bound. Here that invariant is flatness: a face's cross sections with a fixed plane are cleanly bounded by the ball's own radius, which is not true of a curved or creased piece of the surface. Training this discernment means asking, before attempting any global estimate, what is the cheapest sub-object that already forces the conclusion.

Revolving concepts

Hölder's inequality. For conjugate exponents $p, q > 1$ with $1/p + 1/q = 1$ and nonnegative reals a_i, b_i, $\sum a_i b_i \leq (\sum a_i^p)^{1/p} (\sum b_i^q)^{1/q}$; taking $b_i \equiv 1$ recovers a power mean comparison between $\sum a_i$ and $\sum a_i^p$ weighted by $n^{1/q}$. Choosing p, q to match the degrees appearing in a problem, here $p = 3/2, q = 3$ to compare degree 2 and degree 3 power sums against a bare count, is the whole skill. See Book 1, field: Inequalities, topic: Hölder and power mean inequalities.

Cross sections of a ball. The intersection of a sphere of radius r centred at O with a plane at perpendicular distance d from O is empty if $d > r$, a single point if $d = r$, and a circle of radius $\sqrt{r^2 - d^2}$ if $d < r$; in every case the radius of the cross section is at most r. See Book 1, field: Geometry, topic: spheres and planar sections.

Existential constants depending only on a fixed object. A claim of the form "there is a constant $c(P) > 0$ such that..." asks you to exhibit one explicit formula for $c(P)$ from the data attached to P, here the area of one face, then verify the inequality for every instance of the varying data, n, the radii, and V. See Book 1, field: Inequalities, topic: existential bounding constants.

There is no recursive or inductive structure in this problem; the argument is a single chain of estimates, not a process that repeats on smaller instances of itself, so no generalised recursion entry applies here.

Circuit Bank

- **WHEN** an inequality is demanded between a count n and powers of two other quantities built from the same underlying variables **DO** identify the degree of each quantity in those variables and choose Hölder's, or power mean, exponents to reproduce exactly the powers demanded **BECAUSE** because the target inequality's exponents are not decoration, they specify which conjugate exponents will close the proof in one line
- **WHEN** a hypothesis is stated about an entire surface, boundary or domain but the goal is only an inequality, not a full characterisation **DO** search for the cheapest convenient sub-piece of that domain that already forces the inequality, and discard the rest **BECAUSE** because a lower or upper bound is an existential claim, one witness sub-piece is enough, and a flat or otherwise structured piece is always easier to estimate than the whole
- **WHEN** a ball, sphere or disc is intersected with a fixed plane or line **DO** bound the resulting cross section's size by the object's own radius, with equality exactly when the plane or line passes through the centre **BECAUSE** because this is the sharp elementary bound and almost always as much geometric information as a covering argument needs
- **WHEN** a problem asks you to produce a constant $c(P)$ depending only on a fixed object P **DO** derive the sharpest constant your argument naturally produces, then explicitly weaken

it, for instance by halving it, to convert a nonstrict bound into the strict inequality asked for **BECAUSE** because the problem's strict inequality is a request to certify that some smaller constant works, not to find the exact extremal constant

Backtesting

1. First useful cue: the target inequality has V^2 in the denominator against a bare count n, and V is cubic in the radii, which signals a degree matching problem across three power sums.
2. Method the expression suggested: fix one flat face, bound $\sum r_i^2$ below via disc covering, bound $\sum r_i^3$ above via the volume constraint, and connect all three quantities with Hölder's inequality.
3. Where you would hesitate, and the thought to reinforce: choosing which exponents to feed Hölder's inequality; the thought to reinforce is to read the exponents straight off the target inequality's own powers rather than guessing.
4. The trap the question sets: trying to estimate the covering efficiency across the whole polyhedron at once, including its edges and vertices, when a single flat face already carries the entire argument.
5. What makes you recognise it faster next time: any "balls or discs cover a region, bound a count by a size" problem is, structurally, a Hölder or power mean problem waiting for you to name the exponents.
6. The reusable decision rule: when a count, an area type bound, and a volume type bound must be reconciled in one inequality, restrict to the smallest sub-piece that carries the area bound, then apply Hölder with exponents chosen to reproduce the target inequality's own powers.

Mirror drills

1. n discs of radii $r_1, \ldots, r_n$ cover a fixed segment of length ℓ on a line, with $\sum r_i = L$. Find the correct exponent matching to bound n below in terms of ℓ and L. *Answer:* covering a length ℓ needs $\sum 2r_i \geq \ell$; only two power sums are in play here, degree 1 and degree 0, so plain Cauchy-Schwarz already suffices, and the three way Hölder step of B2 is unnecessary because no degree 3 quantity is present.
2. Balls of total volume V cover the entire surface of a cube of side s. Find an explicit constant c, in terms of s, such that the number of balls exceeds c/V^2. *Answer:* take F to be one face of area $A = s^2$, run the B2 argument verbatim, giving $n \geq 16s^6/(9\pi V^2)$, so any $c < 16s^6/(9\pi)$ works.
3. n balls of volumes summing to V cover a fixed disc of area A in a plane, with no ambient solid to restrict to: the disc is the whole covered object. Does the same Hölder argument bound n in terms of A and V, and how does it compare with B2's bound. *Answer:* yes, identically, since B2's argument never used any property of P beyond the existence of one flat face of area A; the bound $n \geq 16A^3/(9\pi V^2)$ is unchanged, confirming that B2's real content is a statement about discs and balls, with the polyhedron only ever supplying the face.

14.9 B3. Hall's theorem matches days to distinct winners

A round-robin tournament of $2n$ teams lasted for $2n-1$ days, as follows. On each day, every team played one game against another team, with one team winning and one team losing in each of the n games. Over the course of the tournament, each team played every other team exactly once. Can one necessarily choose one winning team from each day without choosing any team more than once?

Read it out loud

Peel off the tournament dressing and read the combinatorial skeleton: there are $2n-1$ days, each day equipped with a set of n winning teams out of $2n$ teams total, since each day's games partition all $2n$ teams into n winners and n losers. The question asks whether you can pick, for every day, one of that day's winners, such that the $2n-1$ picks are all different teams. That is a system of distinct representatives: one representative per day, drawn from that day's set of eligible teams, no repeats. Any time a question reads "choose one X from each Y, all distinct," the underlying object is a bipartite graph between the Y's and the X's, and the tool that decides whether a full matching exists is Hall's marriage theorem. That is the circuit that should fire the instant the phrase registers.

So the real work is not in Hall's theorem itself, which is a black box once invoked, but in verifying its hypothesis: for every collection of m days, the teams that won on at least one of those days must number at least m. That hypothesis has to be proved using the one piece of tournament structure not yet used, that each team plays every other team exactly once across the whole tournament, so no team ever faces the same opponent twice. The cue to write down inside thirty seconds: this is a distinct-representatives question, name the bipartite graph, days against teams, edges are wins, and go hunting for why Hall's condition holds, using the "exactly once" clause as the engine of that argument.

Approaches, ranked worst to best

1. **induct on n by removing one team and one day from the tournament.** *Cue:* a smaller tournament with $2n-2$ teams over $2n-3$ days looks like the same problem one size down. *Circuit:* structural induction on the tournament itself. Removing a team destroys the perfect matching structure of every day that team played in, since each day was a pairing of all $2n$ teams; rebuilding this into a genuine $(2n-2)$-team, $(2n-3)$-day round-robin tournament needs delicate schedule surgery, and even after that work an argument essentially equivalent to Hall's theorem is still needed for the base case or the reattachment step. Far more ink for no extra rigour.

2. **choose a winner for each day greedily, in some fixed order of the days.** *Cue:* the goal is a sequence of choices, so make them one at a time. *Circuit:* a greedy algorithm with no global certificate. Greedy can paint itself into a corner: having freely picked winners for earlier days, a later day's entire set of winners might already be exhausted, and there is no way to know in advance, without something equivalent to Hall's condition, that a different order or different earlier choices were not required. A greedy construction with no proof of correctness is not a solution.

3. **build the bipartite graph of days against teams, edges are wins, and verify Hall's condition via a pigeonhole argument on a hypothetical team that lost every game in a chosen set of days.** *Cue:* the goal is a system of distinct representatives, one per day, and Hall's theorem is the exact tool for that. *Circuit:* Hall's marriage theorem, with the "exactly once" clause supplying the pigeonhole step that proves its hypothesis. This is the ideal route: it isolates the one nontrivial fact to prove, Hall's condition, proves it in a few lines using a fact the problem

hands you for free, no repeated opponents, and then cites a named theorem for the rest, rather than reconstructing a matching argument from scratch.

The ideal solution

The answer is yes.

Build a bipartite graph H with one part D, the $2n-1$ days, and the other part T, the $2n$ teams, joining a day d to a team t by an edge exactly when t won its game on day d. Since every day has exactly n winners, every vertex of D has degree n in H. The problem asks whether H has a matching that saturates D, that is, a set of $2n-1$ edges, no two sharing an endpoint, one incident to each day. By Hall's marriage theorem, such a matching exists if and only if, for every subset $D' \subseteq D$, the neighbourhood $N(D') \subseteq T$, the teams that won on at least one day in D', satisfies $|N(D')| \geq |D'|$.

Lemma 14.9.1. *For every nonempty $D' \subseteq D$ with $|D'| = m$, $|N(D')| \geq m$.*

Proof. Suppose instead $|N(D')| \leq m-1$. Since every team plays exactly one game on every day, every team either wins or loses on each day in D'. Because $|N(D')| \leq m-1 < 2n$, some team L is not in $N(D')$, meaning L lost its game on every day in D'. Over the m days in D', L played m games, one per day, against m opponents; since each pair of teams meets exactly once over the whole tournament, these m opponents are pairwise distinct. On each such day, the opponent that beat L won that day's game, so each of these m distinct opponents belongs to $N(D')$, by way of the specific day it played, and beat, L. This exhibits m distinct teams inside $N(D')$, contradicting $|N(D')| \leq m-1$. □

Hall's condition holds for every subset of D, so H has a matching saturating D: a set of $2n-1$ winning teams, one chosen for each day, all distinct. Hence

Yes: such a choice can always be made.

Layer 1: WHAT

Block 1: translate "choose one winner per day, all distinct" into bipartite matching language, days against teams, edges are wins. Block 2: name Hall's marriage theorem as the tool that decides whether a matching saturating the days exists. Block 3: isolate the one thing left to prove, Hall's condition, as a standalone lemma about an arbitrary subset of days. Block 4: prove that lemma by contradiction, producing a team L that lost on every day in the subset. Block 5: use the "each pair meets exactly once" clause to show L's m opponents on those days are distinct, hence m distinct winners exist, closing the contradiction.

The nominal route tries to construct the choice directly, day by day, either by induction on the tournament's size or by a greedy pass through the days, and gets stuck justifying that the construction cannot fail partway through. The bifurcation point is recognising that "does a valid simultaneous choice exist" is a question about a bipartite graph having a certain matching, which converts an open ended constructive search into a single hypothesis to verify, Hall's condition, with a named theorem supplying the rest for free.

Layer 2: HOW

Block 1. Cue. The question asks to choose one item, a winning team, from each of several sets, each day's winners, with all choices distinct. **Why natural.** This is the definition of a system of distinct representatives, which is exactly a matching in the bipartite graph whose two parts are the collection of sets and the underlying elements, with an edge for membership. **Link to the next block.** Once the bipartite graph is named, "can one always choose" becomes "does this graph always have a matching saturating one side," a question with a standard named answer.

Block 2. **Cue.** A bipartite graph, one side fixed at $2n-1$ vertices, the days, and a matching saturating that side is wanted. **Why natural.** Hall's marriage theorem states exactly that such a matching exists if and only if every subset of that side has a neighbourhood at least as large as itself; it is the correct tool because the graph here has no further special structure, such as regularity on both sides, to exploit more directly. **Link to the next block.** Applying the theorem reduces the entire problem to a single combinatorial claim: verify Hall's condition for this specific graph.

Block 3. **Cue.** Hall's condition must hold for every subset of days, not just special ones. **Why natural.** Stating it as a lemma for an arbitrary subset D' of size m isolates exactly the fact that needs proof and separates it cleanly from the cited theorem, which is good proof hygiene: the lemma can then be checked entirely on its own terms. **Link to the next block.** Proving the lemma by contradiction is the natural move, since a claim that a count is "at least m" is often easiest to secure by assuming fewer than m and deriving an impossibility.

Block 4. **Cue.** Assuming fewer than m distinct teams won across the m days in D', while every team plays every day. **Why natural.** Since fewer than $m < 2n$ teams won on those days, some team is excluded from every winner set for those days, meaning it lost every one of those m games; such a team must exist because the total team count exceeds the winner count. **Link to the next block.** That team, L, played m games during D', one per day, all losses; the next question is what can be said about L's m opponents.

Block 5. **Cue.** Each pair of teams meets exactly once across the entire tournament. **Why natural.** This is the one clause of the problem not yet used, and it is precisely what forces L's m opponents, one per day in D', to be pairwise distinct, since a repeated opponent would mean two games between the same pair. **Link to the next block.** Each of those m distinct opponents won on the specific day it beat L, a day inside D', so all m belong to $N(D')$, contradicting the assumption that $|N(D')| < m$ and closing the lemma, and with it the whole proof once Hall's theorem is invoked.

Layer 3: WHY

The underlying truth is that "choose one representative per set, all distinct" is never solved by inspecting the sets one at a time; it is a global existence question about a bipartite graph, and Hall's theorem converts that global question into a local, checkable condition, namely that no small collection of sets can conspire to share too few elements between them. The discernment mechanism is linguistic: any phrase of the form "choose one from each, without repeats" should immediately trigger the bipartite graph translation, at which point the only remaining mathematical content is verifying Hall's condition, almost always by contradiction, almost always using whichever hypothesis of the problem has not yet been spent.

The second truth is about where the contradiction comes from. In this problem, the clause "each team played every other team exactly once" reads, on a first pass, like background scaffolding explaining the tournament's structure rather than an active ingredient. It only becomes active once you are inside a proof by contradiction and need a source of distinctness, here, the distinctness of a single team's m opponents across m days. Train yourself to notice, when a Hall's condition proof stalls, that the missing distinctness fact is usually sitting in an unused clause of the problem statement, phrased as an "exactly" or "at most once" condition, because that is precisely the shape of fact that rules out repetition.

Revolving concepts

Hall's marriage theorem. For a bipartite graph with parts X, Y, a matching saturating X exists if and only if $|N(S)| \geq |S|$ for every $S \subseteq X$, where $N(S)$ is the set of vertices in Y adjacent to some

vertex of S. This is the standard tool for any system of distinct representatives question. See Book 1, field: Discrete structures and graphs, topic: bipartite matching and Hall's theorem.

Systems of distinct representatives. Given sets $A_1, \ldots, A_k$, a system of distinct representatives is a choice of distinct elements $a_1 \in A_1, \ldots, a_k \in A_k$; such a choice exists exactly when Hall's condition holds for the bipartite graph of memberships. The days-versus-winners structure here is a direct instance, with A_d the set of teams that won on day d. See Book 1, field: Combinatorics, topic: systems of distinct representatives.

Proof by contradiction via an extremal or exceptional witness. To show a count is at least m, assume it is at most $m-1$ and produce an explicit object, here a team that lost on every day of a chosen subset, whose existence is guaranteed by simple counting, fewer winners than teams, and then derive m new distinct witnesses from that one object's behaviour. See Book 1, field: Combinatorics, topic: pigeonhole and counting contradictions.

Hall's marriage theorem is itself proved by an induction that is worth generalising once: induct on $|X|$; if every nonempty proper subset S of X has $|N(S)| > |S|$ strictly, match any single vertex of X to any neighbour and delete both, leaving Hall's condition intact on the smaller graph by induction; otherwise some proper nonempty S is tight, $|N(S)| = |S|$, so match S to $N(S)$ by induction on the smaller graph, then check Hall's condition survives on $(X \setminus S)$ against $(Y \setminus N(S))$, which holds because any shortfall there would combine with S to violate Hall's condition on the original graph. Beyond this problem, that same two case induction, either shrink by one matched pair or split at a tight set, is the template for proving any theorem about matchings by peeling off a manageable piece and recursing on what remains, and it is the same idea that underlies deficiency versions of Hall's theorem and König's theorem on bipartite graphs.

Circuit Bank

- **WHEN** a question asks to choose one item from each of several sets, or one representative per day, round or group, with no repeats allowed **DO** translate immediately into a bipartite graph, sets or days on one side, items or teams on the other, edges for membership or eligibility, and invoke Hall's marriage theorem **BECAUSE** because this phrasing is the definition of a system of distinct representatives, and Hall's theorem is the standard tool that decides existence without a constructive search

- **WHEN** Hall's theorem has been invoked and only its hypothesis remains to prove **DO** state the hypothesis as a standalone lemma for an arbitrary subset, then prove it by contradiction, assuming the neighbourhood is too small **BECAUSE** because isolating the lemma keeps the citation of the theorem clean and turns an open ended existence question into one bounded counting argument

- **WHEN** a proof by contradiction produces an exceptional witness object that must fail some property on every element of a chosen subset **DO** look for an unused clause of the problem statement to supply distinctness or another needed property among that witness's interactions with the subset **BECAUSE** because problem statements rarely include a clause that plays no role, and a stalled Hall's condition proof is almost always one unused hypothesis away from closing

- **WHEN** a combinatorial structure has an "exactly once" or "at most once" clause you have not yet used **DO** treat it as the source of a pigeonhole style distinctness argument the moment a proof needs m pairwise distinct objects **BECAUSE** because "exactly once" is precisely the hypothesis that rules out silent repetition, which is what a pigeonhole count needs to go through

Backtesting

1. First useful cue: "choose one from each day, all distinct" is the definition of a system of distinct representatives, so the graph to draw is days against teams.
2. Method the expression suggested: Hall's marriage theorem, applied to the bipartite graph of days and their winners, reduces the whole problem to one counting lemma.
3. Where you would hesitate, and the thought to reinforce: proving Hall's condition itself; the thought to reinforce is to assume the condition fails, extract a specific team that lost throughout the chosen days, and look for what forces that team's opponents to be distinct.
4. The trap the question sets: trying to build the required choice directly, by induction on the tournament size or by a greedy pass over the days, without a certificate that the construction cannot fail.
5. What makes you recognise it faster next time: the phrase "choose one X from each Y without repeats" should fire the Hall's theorem circuit before any attempt at direct construction.
6. The reusable decision rule: whenever a distinct-choice question appears, build the bipartite membership graph, cite Hall's theorem, then spend all remaining effort proving Hall's condition by contradiction using whichever hypothesis has not yet been used.

Mirror drills

1. $2n$ students each need a distinct exam slot, and every group of k students is jointly acceptable to at least k of the $2n-1$ available slots. Show every student can be assigned a slot, all different. *Answer:* this is Hall's theorem verbatim, students and slots as the two parts of the bipartite graph; no further argument beyond checking the hypothesis is needed.
2. In a different event with $2n-1$ rounds among $2n$ competitors, every pair meets at most once, but each round crowns a single overall winner rather than n separate winners. Explain why "choose a different winner per round" becomes a much weaker question here. *Answer:* with one winner per round, the rounds-to-winners graph has every round of degree 1, so Hall's condition reduces to asking whether any two rounds ever share their unique winner, a condition about repeat champions rather than a genuine matching argument.
3. A bipartite graph has parts X, Y with $|X| = |Y| = k$ and every vertex of X of degree at least $k/2$. Give a short argument, in the spirit of B3's lemma, for why any $S \subseteq X$ with $|S| > k/2$ has $N(S) = Y$. *Answer:* if some $y \in Y$ were missed by $N(S)$, every vertex of S would avoid y, so y's degree would be at most $k - |S| < k/2$, contradicting the degree hypothesis; the same "assume a witness is missed, count its forced exclusions" pattern as B3's lemma closes the argument.

14.10 B4. A recursion that shadows the natural logarithm

Suppose that $a_0 = 1$ and that $a_{n+1} = a_n + e^{-a_n}$ for $n = 0, 1, 2, \ldots$. Does $a_n - \log n$ have a finite limit as $n \to \infty$? (Here $\log n = \log_e n = \ln n$.)

Read it out loud

Say it in words. This is a first order autonomous recursion, meaning a_{n+1} depends on a_n alone through a fixed function, and the increment e^{-a_n} is positive and decreasing in a_n. So the sequence increases, and the faster it climbs the slower it climbs next. You are then handed a specific growth scale, $\log n$, and asked whether the error $a_n - \log n$ settles down. Notice the shape of the command term: not *find* the limit, but *does it have a finite limit*. That word finite, paired with an explicit comparison function, is the guiding light of the whole problem. You are being asked for an existence statement, and the cheapest existence theorem in analysis is monotone convergence: a decreasing sequence bounded below converges. No candidate value required.

Where did $\log n$ come from, and why should you trust it? Run the shadow ODE. Replace the discrete increment $a_{n+1} - a_n$ by a derivative $y'(x)$ and the value a_n by $y(x)$. The recursion becomes $y' = e^{-y}$, which separates: $e^y y' = 1$, so $e^y = x + C$ and $y = \log(x + C)$. That is a scouting report, not a proof, but it tells you two things at once. First, $\log n$ is the right scale. Second, the free constant C sits *inside* the logarithm, and $\log(n + C) - \log n = \log(1 + C/n) \to 0$, so the shadow model predicts not merely that the error converges but that it converges to 0. Keep that prediction; you will collect it at the end as the plus alpha.

The fields wired into this question are real analysis (limits of monotone sequences), sequences and recurrences (comparison of a recursion against a closed form), and the elementary inequality theory of the exponential. There is no clever machinery anywhere in this problem. There is one inequality, $e^x \geq 1 + x$, used twice, in opposite directions, and one induction.

Within thirty seconds of reading, you should have written three lines on the page: $d_n = a_n - \log n$; the difference $d_{n+1} - d_n = e^{-a_n} - \log\left(1 + \frac{1}{n}\right)$; and the note *need a lower bound on a_n, of logarithmic type, to control e^{-a_n}*. Everything after that is bookkeeping. The reason those three lines are forced is that you have decided to prove monotonicity of d_n, monotonicity is a statement about $d_{n+1} - d_n$, and the recursion computes that difference for you exactly.

Approaches, ranked worst to best

1. **Numerical scouting.** *Cue:* the phrase "does it have a finite limit" invites a quick experiment. *Circuit:* compute terms and look at them. Compute a thousand terms, watch $a_n - \log n$ shrink, and assert convergence. This scores zero. Worse, it is actively misleading: the sequence $\log\log n$ also looks like it is settling down over any finite range you can compute, and it diverges. Use numerics to check a claim you have proved, never to replace the proof.

2. **Closed form hunt.** *Cue:* a clean elementary increment suggests the recursion might be solvable. *Circuit:* invert the recursion into an explicit formula. The substitution $b_n = e^{a_n}$ turns the recursion into $b_{n+1} = b_n e^{1/b_n}$, which is no more solvable than what you started with. There is no closed form, and hunting for one costs the whole exam session. The tell is that e^{-a_n} mixes the sequence with a transcendental function of itself; only linear or fractional linear recursions surrender closed forms for free.

3. **Two sided sandwich.** *Cue:* $\log n$ is given, so bound a_n on both sides. *Circuit:* squeeze. Prove $\log(n + 1) < a_n < \log n + C$ and conclude that d_n is bounded. This is more work than the winning route and it does not finish: boundedness is not convergence. You would still have to prove monotonicity or a Cauchy estimate on top. More ink for a weaker conclusion.

4. **Exponential substitution and increment averaging.** *Cue:* the increment is e^{-a_n}, so the increment of e^{a_n} is nearly constant. *Circuit:* change variable so the increment linearises. Put $b_n = e^{a_n}$. Then $b_{n+1} = b_n e^{1/b_n} = b_n + 1 + R_n$ with $0 \le R_n \le 1/b_n$, so b_n is n plus a controlled error, and $b_n/n \to 1$. This is a genuine route and it proves strictly more than the question asks, namely that the limit is 0. It costs a Taylor remainder bound and a harmonic sum estimate. Rank it second and keep it in your pocket for the plus alpha.
5. **Monotone convergence on the error term.** *Cue:* "finite limit" plus an explicit comparison function. *Circuit:* decreasing and bounded below implies convergent. Show $a_n > \log(n+1)$ by induction, deduce that $d_n = a_n - \log n$ is strictly decreasing and strictly positive, and quote monotone convergence. One induction, one inequality used twice. This is the shortest complete proof available and it is what a full ten points looks like.

The ideal solution

The answer is $\boxed{\text{Yes}}$: the limit exists.

Lemma 14.10.1 (tangent line)**.** *For every real $x > -1$ we have $\log(1+x) \le x$, with equality only at $x = 0$.*

Proof. The function $\varphi(x) = x - \log(1+x)$ satisfies $\varphi'(x) = 1 - \frac{1}{1+x} = \frac{x}{1+x}$ on $(-1, \infty)$, which is negative for $x \in (-1, 0)$ and positive for $x > 0$. So φ attains its minimum at $x = 0$, where $\varphi(0) = 0$, and is strictly positive elsewhere. □

Lemma 14.10.2 (lower bound)**.** *For every integer $n \ge 0$ we have $a_n > \log(n+1)$.*

Proof. Induction on n. The increments e^{-a_n} are positive, so (a_n) is increasing and $a_n \ge a_0 = 1 > 0$ for all n. For $n = 0$, $a_0 = 1 > 0 = \log 1$.

Assume $a_n > \log(n+1) \ge 0$. Let $f(x) = x + e^{-x}$, so that $a_{n+1} = f(a_n)$. Since $f'(x) = 1 - e^{-x} > 0$ for $x > 0$, f is strictly increasing on $[0, \infty)$, and both a_n and $\log(n+1)$ lie there. Hence

$$a_{n+1} = f(a_n) > f\big(\log(n+1)\big) = \log(n+1) + \frac{1}{n+1}.$$

By the tangent line lemma with $x = \frac{1}{n+1}$ we have $\frac{1}{n+1} \ge \log\left(1 + \frac{1}{n+1}\right)$, so the right hand side is at least $\log(n+1) + \log\frac{n+2}{n+1} = \log(n+2)$. Therefore $a_{n+1} > \log(n+2)$, closing the induction. □

Now set $d_n = a_n - \log n$ for $n \ge 1$.

Step 1: $(d_n)_{n \ge 1}$ is strictly decreasing. Using the recursion,

$$d_{n+1} - d_n = e^{-a_n} + \log\frac{n}{n+1}.$$

By the lower bound lemma, $a_n > \log(n+1)$, so $e^{-a_n} < e^{-\log(n+1)} = \frac{1}{n+1}$. By the tangent line lemma with $x = -\frac{1}{n+1} \in (-1, 0)$,

$$\log\frac{n}{n+1} = \log\left(1 - \frac{1}{n+1}\right) \le -\frac{1}{n+1}.$$

Adding the two estimates, $d_{n+1} - d_n < \frac{1}{n+1} - \frac{1}{n+1} = 0$.

Step 2: $(d_n)_{n \ge 1}$ is bounded below. By the lower bound lemma again, $d_n = a_n - \log n > \log(n+1) - \log n > 0$.

A strictly decreasing sequence of real numbers bounded below converges, by the monotone convergence theorem. Hence $a_n - \log n$ has a finite limit, and that limit is at least 0. This answers the question.

Remark 14.10.3. The limit is in fact exactly 0, which the question does not ask for but which you should be able to produce on demand. Put $b_n = e^{a_n}$, so $b_0 = e$ and $b_{n+1} = b_n e^{1/b_n}$. Since (a_n) increases from 1, we have $b_n \geq e$ and $u_n = 1/b_n \in (0, 1/e]$. For $0 < u \leq 1$,

$$1 + u \leq e^u = 1 + u + \sum_{k\geq 2} \frac{u^k}{k!} \leq 1 + u + u^2 \sum_{k\geq 2} \frac{1}{k!} \leq 1 + u + u^2.$$

Multiplying through by b_n with $u = 1/b_n$ gives $b_n + 1 \leq b_{n+1} \leq b_n + 1 + \frac{1}{b_n}$. The left inequality and induction give $b_n \geq n + e$. Feeding that back into the right inequality and summing,

$$b_n \leq e + n + \sum_{i=0}^{n-1} \frac{1}{b_i} \leq e + n + \sum_{i=0}^{n-1} \frac{1}{i+2} = e + n + H_{n+1} - 1 \leq n + e + \log(n+1),$$

where $H_m \leq 1 + \log m$ by comparing $\sum_{k=2}^{m} \frac{1}{k}$ with $\int_1^m \frac{dt}{t}$. Hence for $n \geq 1$,

$$1 < \frac{b_n}{n} \leq 1 + \frac{e + \log(n+1)}{n} \longrightarrow 1,$$

and therefore $a_n - \log n = \log \frac{b_n}{n} \to 0$. A finer expansion of the same estimates gives $a_n = \log n + \frac{\log n}{2n} + O\left(\frac{1}{n}\right)$, which is why the numerical convergence is so slow: at $n = 10^6$ the error is still about 9×10^{-6}.

Layer 1: WHAT

Block 1. Read the command term "finite limit" as an existence request and commit to monotone convergence as the mechanism.

Block 2. Recover the scale $\log n$ from the shadow ODE $y' = e^{-y}$, so that you know the object of study is the error $d_n = a_n - \log n$ and not a_n itself.

Block 3. Difference the error: $d_{n+1} - d_n = e^{-a_n} + \log \frac{n}{n+1}$. This exposes that everything hinges on comparing e^{-a_n} with $\frac{1}{n+1}$.

Block 4. Therefore you need a lower bound $a_n > \log(n+1)$. Prove it by induction, using that $x \mapsto x + e^{-x}$ is increasing.

Block 5. Feed the bound into the difference; the two halves cancel exactly, courtesy of $\log(1 + x) \leq x$ applied at $x = \pm\frac{1}{n+1}$. Monotonicity done.

Block 6. The same bound gives positivity. Monotone convergence closes the problem.

The nominal route, and the juxtaposition. The zombie writes $a_n \approx \log n + c + o(1)$, starts expanding $e^{-a_n} \approx \frac{1}{n}\left(1 - \frac{c}{1}\right)$ and similar unjustified asymptotics, and produces three quarters of a page of O symbols with no theorem underneath any of them. Alternatively the zombie tries to solve the recursion. The bifurcation point is precise: it is the line where you either write $a_n \approx \log n + c$ (an asymptotic ansatz you cannot yet justify) or write $d_{n+1} - d_n$ (an exact identity you can). Exact identity beats ansatz. The difference costs one line to write and it converts an asymptotics problem into an inequality problem, and inequalities are decidable at A-level with one derivative.

Layer 2: HOW

Block 1. Cue. The question asks whether a limit is finite, not what it is, and it supplies the comparison function itself. **Why natural.** When you are not asked for a value, do not chase one. The theorems that give existence without a value are monotone convergence, Cauchy, and compactness. Of these, monotone convergence needs the least: one inequality about consecutive terms and one crude bound. So the plan is fixed before any calculation happens. **Link to the next block.** A monotone convergence plan needs a specific sequence to be monotone. Which sequence? Not a_n, which diverges. The question names the candidate: $a_n - \log n$.

Block 2. **Cue.** The comparison function $\log n$ appears from nowhere in the problem statement, so it must be forced by the recursion. **Why natural.** Increments become derivatives when the steps are small, and $a_{n+1} - a_n = e^{-a_n}$ is a difference equation whose continuous shadow $y' = e^{-y}$ separates instantly. The solution $y = \log(x + C)$ explains the $\log n$ and predicts the limit is 0. Doing this in the arena costs fifteen seconds and buys certainty about what you are aiming for. **Link to the next block.** Knowing that the true behaviour is $\log(n + C)$ tells you the error is $\log(1 + C/n)$, of size $1/n$. So all the estimates you will need are of size $1/n$. That calibrates every inequality that follows.

Block 3. **Cue.** Monotonicity of d_n is a statement about $d_{n+1} - d_n$, and the recursion gives $a_{n+1} - a_n$ exactly. **Why natural.** Never estimate a sequence when you can compute its difference exactly. Here $d_{n+1} - d_n = e^{-a_n} - \log \frac{n+1}{n}$, in which the first term is unknown and the second is explicit. That single line converts the whole problem into: is e^{-a_n} smaller than $\log \frac{n+1}{n}$? **Link to the next block.** $\log \frac{n+1}{n}$ is slightly larger than $\frac{1}{n+1}$ (the tangent line lemma again), so it suffices to prove $e^{-a_n} \le \frac{1}{n+1}$, that is, $a_n \ge \log(n + 1)$. The required lemma has now been generated by the calculation rather than guessed.

Block 4. **Cue.** You need $a_n > \log(n + 1)$, a statement about all n with a recursive definition available: induction is forced. **Why natural.** The step needs $a_{n+1} = f(a_n)$ with $f(x) = x + e^{-x}$ increasing on $[0, \infty)$, which is one derivative. Then $a_n > \log(n + 1)$ gives $a_{n+1} > f(\log(n + 1)) = \log(n + 1) + \frac{1}{n+1}$, and you need that to exceed $\log(n + 2)$, which is exactly $\log(1 + x) \le x$ at $x = \frac{1}{n+1}$. Note the strengthening: had you tried to prove the weaker $a_n > \log n$, the step would demand $\log n + \frac{1}{n} \ge \log(n + 1)$, which is true, so that also closes; but the shifted version is what you need in Block 5, so prove the shifted version once and use it twice. **Link to the next block.** The same lemma now feeds both remaining tasks: it bounds e^{-a_n} from above (monotonicity) and d_n from below (boundedness).

Block 5. **Cue.** Two estimates of the same size $\frac{1}{n+1}$, pointing in opposite directions. **Why natural.** This is the signature of a problem that has been designed to close exactly. The inequality $\log(1 + x) \le x$ is applied at $x = +\frac{1}{n+1}$ inside the induction and at $x = -\frac{1}{n+1}$ inside the monotonicity step; the two applications are the same fact seen from either side of 0. When a problem uses one inequality twice with opposite signs, you are on the intended route. **Link to the next block.** Strict decrease is established. Only a lower bound remains.

Block 6. **Cue.** A decreasing sequence needs any lower bound whatsoever, not a sharp one. **Why natural.** $d_n > \log(n + 1) - \log n > 0$ is free from the lemma you already have. Be lazy: do not compute a sharp bound when 0 works. **Link to the next block.** Monotone convergence applies and the answer is yes.

Layer 3: WHY

The mathematical truth beneath this route is that convergence of a real sequence is a statement about the completeness of $\mathbb{R}$, and completeness is delivered in three standard packages: monotone convergence, Cauchy, and Bolzano and Weierstrass. Monotone convergence is the cheapest because its hypotheses are checkable term by term. Any Putnam question phrased as "does the limit exist" or "show that the limit exists" is a request to select one of those three packages, and your first move should always be to test whether the quantity in question is eventually monotone. Here it is, and the check costs two lines.

The second truth is the discrete to continuous correspondence. A recursion $a_{n+1} = a_n + g(a_n)$ with $g > 0$ small is a Riemann sum in disguise. Set G with $G' = 1/g$; then $G(a_{n+1}) - G(a_n) = \int_{a_n}^{a_{n+1}} \frac{dt}{g(t)} \approx \frac{a_{n+1} - a_n}{g(a_n)} = 1$, so $G(a_n) \approx n$ and $a_n \approx G^{-1}(n)$. That single formula predicts the answer

to an entire family of Putnam problems. With $g(y) = e^{-y}$ you get $G(y) = e^{y}$ and $a_n \approx \log n$. With $g(y) = 1/y$ you get $G(y) = y^2/2$ and $a_n \approx \sqrt{2n}$. With $g(y) = -y^3/6$, which is what sin does near 0, you get $a_n \approx \sqrt{3/n}$. Install the formula, not the individual answers.

The third truth is about which inequality to reach for. Every comparison between a discrete increment of size $\frac{1}{n}$ and a logarithmic difference is mediated by the tangent line inequality $e^x \geq 1 + x$, equivalently $\log(1 + x) \leq x$, equivalently $\frac{x}{1+x} \leq \log(1 + x)$ after substitution. There is no second inequality in this circle of problems. If you find yourself wanting a Taylor expansion of $\log(1 + 1/n)$ to two terms with an unjustified remainder, stop: the exact one sided inequality is available, is sharper than you need, and is provable in one line.

How to train the discernment. Take any recursion problem and ask three questions in order. What does the shadow ODE say the growth is? What quantity does the question compare it to? Is that difference monotone? If the answers are available, you have a proof; if the difference is not monotone, only then reach for Cauchy or for a summable bound on $|d_{n+1} - d_n|$. The examiners nudged you toward exactly this by putting $\log n$ in the question rather than asking for the asymptotics of a_n: they handed you the comparison function so that the monotone route was available without any guessing at all.

Revolving concepts

Monotone convergence theorem. A nonincreasing sequence bounded below converges to its infimum; a nondecreasing sequence bounded above converges to its supremum. It is equivalent to the least upper bound axiom for $\mathbb{R}$, so it is not a technique but the definition of the real numbers in usable form. See Book 1, field: Real analysis, topic: completeness and monotone sequences.

The tangent line inequality for the exponential. $e^x \geq 1 + x$ for all real x, with equality only at $x = 0$, since e^x is convex and $1 + x$ is its tangent at 0. Equivalent forms: $\log(1 + x) \leq x$ for $x > -1$; $\frac{x}{1+x} \leq \log(1 + x)$ for $x > -1$ (substitute $x \mapsto \frac{x}{1+x}$ in the first form and rearrange); $\left(1 + \frac{1}{n}\right)^n < e < \left(1 + \frac{1}{n}\right)^{n+1}$. See Book 1, field: Inequalities, topic: convexity and tangent lines.

First order autonomous recursions, generalised. Let $a_{n+1} = a_n + g(a_n)$ with $g > 0$ and g decreasing, and let G be any antiderivative of $1/g$. Then $G(a_n) = n + O(\text{error})$ and $a_n = G^{-1}(n)(1 + o(1))$. The rigorous version of the heuristic is the pair of bounds obtained by substituting the exact recursion into G and using monotonicity of $1/g$ on the interval $[a_n, a_{n+1}]$. The special cases worth memorising: $g(y) = y^{-\alpha}$ gives $a_n \sim ((\alpha + 1)n)^{1/(\alpha+1)}$; $g(y) = e^{-y}$ gives $a_n = \log n + o(1)$; a decreasing sequence with $a_{n+1} = a_n - ca_n^k$ gives $a_n \sim (c(k - 1)n)^{-1/(k-1)}$. See Book 1, field: Sequences and recurrences, topic: asymptotics of first order recursions.

Harmonic sums. $H_n = \sum_{k=1}^{n} \frac{1}{k}$ satisfies $\log n < H_n \leq 1 + \log n$ by comparison with $\int \frac{dt}{t}$, and $H_n = \log n + \gamma + \frac{1}{2n} + O(n^{-2})$ where γ is the Euler and Mascheroni constant. Any time a recursion accumulates increments of size c/i, the total is $c \log n$ plus a constant, which is why $b_n = n + \frac{1}{2}\log n + O(1)$ in the remark. See Book 1, field: Real analysis, topic: harmonic sums and Euler and Mascheroni constant.

Shadow ODE heuristic. Replacing $a_{n+1} - a_n$ by y' converts a difference equation into a differential equation whose solution predicts the leading behaviour. It is never a proof, because it silently assumes the increments are small and smooth, but it is the correct scouting tool and it is free. See Book 1, field: Sequences and recurrences, topic: difference equations and their continuous shadows.

Circuit Bank

- **WHEN** a question asks whether a limit exists, and does not ask for its value **DO** test whether the quantity is eventually monotone and bounded, and quote monotone convergence **BECAUSE** existence in $\mathbb{R}$ is completeness, and the monotone package has the cheapest hypotheses

- **WHEN** a recursion of the form $a_{n+1} = a_n + g(a_n)$ appears **DO** write the shadow ODE $y' = g(y)$ and solve it by separation before anything else **BECAUSE** it costs fifteen seconds and it tells you the growth scale, hence what to compare against
- **WHEN** you must decide whether a sequence d_n is monotone **DO** compute $d_{n+1} - d_n$ exactly from the recursion instead of estimating d_n **BECAUSE** an exact identity converts an asymptotics problem into an inequality problem, and inequalities are decidable
- **WHEN** a comparison between an increment of size $1/n$ and a difference of logarithms is needed **DO** apply $\log(1+x) \le x$ at $x = \pm\frac{1}{n+1}$ **BECAUSE** that one tangent line inequality mediates every such comparison, so no Taylor remainder is ever required
- **WHEN** an induction step almost closes but leaves a gap of one index **DO** strengthen the statement by shifting the index inside the comparison function, for example prove $a_n > \log(n+1)$ rather than $a_n > \log n$ **BECAUSE** a stronger hypothesis gives a stronger step, and the shifted form is usually the one downstream needs

Backtesting

1. First useful cue: the words "finite limit" next to an explicitly supplied comparison function $\log n$. That combination means existence by monotone convergence, applied to the difference.
2. Method the expression suggested: the increment e^{-a_n} separates in the shadow ODE $y' = e^{-y}$, giving $y = \log(x + C)$ and hence the target $d_n = a_n - \log n$.
3. Where you would hesitate, and the thought to reinforce: at the induction, wondering whether to prove $a_n > \log n$ or $a_n > \log(n+1)$. Reinforce this: prove the version that the later step needs, and if unsure, prove the stronger one, because the induction step gets a stronger hypothesis too and usually closes more easily.
4. The trap the question sets: the answer is 0 and the convergence is extremely slow (about $\frac{\log n}{2n}$), so numerical work is inconclusive and any attempt to guess the limit first and prove convergence second wastes the session. The question is deliberately phrased so that you never need the value.
5. What makes you recognise it faster next time: any recursion whose increment is a positive decreasing function of the current term is a Riemann sum for $\int \frac{dt}{g(t)}$, and any question comparing such a recursion to a named function is asking about the error, not the growth.
6. The reusable decision rule: existence question plus explicit comparison function equals monotone convergence on the difference, with the lower bound supplied by the same induction that controls the increment.

Mirror drills

1. Let $a_0 = 1$ and $a_{n+1} = a_n + \frac{1}{a_n}$. Show that $a_n/\sqrt{2n} \to 1$. *Answer:* square the recursion, $a_{n+1}^2 = a_n^2 + 2 + a_n^{-2}$, so $a_n^2 \ge 2n + 1$ and $a_n^2 \le 1 + 2n + \sum_{i<n} \frac{1}{2i+1} = 2n + O(\log n)$; divide by $2n$.
2. Let $a_0 \in (0, \pi)$ and $a_{n+1} = \sin a_n$. Show that $\sqrt{n}\, a_n \to \sqrt{3}$. *Answer:* $a_n \downarrow 0$, and $a_{n+1}^{-2} - a_n^{-2} \to \frac{1}{3}$ from $\sin x = x - \frac{x^3}{6} + O(x^5)$; by the Cesaro mean, $n a_n^2 \to 3$.
3. Let $a_0 = 1$ and $a_{n+1} = a_n + e^{-2a_n}$. Does $a_n - \frac{1}{2}\log n$ converge? *Answer:* yes; the shadow ODE gives $e^{2y} = 2x + C$, so run the identical proof with the induction hypothesis $a_n > \frac{1}{2}\log(2n+1)$ and the same tangent line inequality.

14.11 B5. Convex envelopes turn a supremum into lines

Prove that, for any two bounded functions $g_1, g_2 : \mathbb{R} \to [1, \infty)$, there exist functions $h_1, h_2 : \mathbb{R} \to \mathbb{R}$ such that, for every $x \in \mathbb{R}$,

$$\sup_{s \in \mathbb{R}} \left(g_1(s)^x g_2(s) \right) = \max_{t \in \mathbb{R}} \left(x h_1(t) + h_2(t) \right).$$

Read it out loud

Read the two sides separately and the problem dissolves. On the left, x is the variable and s is the index; $g_1(s)^x g_2(s)$ is an exponential in x, because $g_1(s)^x = e^{x \log g_1(s)}$. So the left hand side is the pointwise supremum of a family of functions $x \mapsto e^{\alpha x + \beta}$, indexed by s, where $\alpha = \log g_1(s)$ and $\beta = \log g_2(s)$. On the right, $x h_1(t) + h_2(t)$ is an *affine function of* x for each fixed t, so the right hand side is the upper envelope of a family of straight lines, indexed by t. The problem therefore says: this particular function of x is the upper envelope of a family of lines, and moreover the envelope is attained at every x.

Which functions are upper envelopes of families of lines? Exactly the convex ones. That is not a piece of folklore, it is the content of the supporting line theorem: a finite convex function on $\mathbb{R}$ lies above a line through each point of its graph, so it is the supremum of its affine minorants, and the supremum is attained at each point by the supporting line at that very point. So the entire problem reduces to one word: prove the left hand side is a convex function of x. Everything else is bookkeeping about which line to name $h_1(t), h_2(t)$.

Now read the hypotheses as a checklist rather than as decoration. The codomain $[1, \infty)$ says $\log g_i(s) \geq 0$. Bounded says $\log g_i(s) \leq \log M$ for some $M \geq 1$. Together: the pair (α, β) ranges over a bounded box $[0, \log M]^2$. That is exactly what is needed to make the supremum on the left finite for every real x, negative x included. If g_1 were allowed to take values in $(0, 1)$ and to approach 0, the supremum would be $+\infty$ for $x < 0$ and there would be nothing to prove and no theorem to prove it with. The hypotheses are not scenery; they are the finiteness of F. Note also what is *not* assumed: no continuity, no measurability, nothing at all about g_1, g_2 as functions of s. The index set may as well be an arbitrary nonempty set. That tells you no analysis of s can be involved.

The fields are convexity and real analysis, with a Legendre transform lurking underneath. What you should have on the page inside thirty seconds: $g_1(s)^x g_2(s) = e^{\alpha_s x + \beta_s}$; $F(x) := \sup_s$ of that; the observation that each member of the family is convex in x; and the target sentence, "a finite convex function on $\mathbb{R}$ has a supporting line at every point".

Approaches, ranked worst to best

1. **Compute the supremum explicitly.** *Cue:* the left side is a supremum you would like to evaluate. *Circuit:* find a formula, then differentiate it. You cannot. The functions g_1, g_2 are arbitrary, the supremum need not be attained at any s, and F need not be differentiable. Any route that begins "let $s(x)$ be the maximising s" is dead on arrival, since no such s need exist.

2. **Define h_1, h_2 by differentiating F.** *Cue:* the supporting line at t is the tangent when F is smooth. *Circuit:* tangent line construction. This is the right picture but the wrong hypothesis. F can have corners, for instance when the family is two lines crossing. You would have to prove one sided differentiability first, which is the same work as the supporting line lemma but presented as if it were about calculus rather than about convexity.

3. **Fenchel biconjugation.** *Cue:* the shape $\max_t (x h_1(t) + h_2(t))$ is a Legendre transform. *Circuit:* quote $F^{**} = F$ for closed proper convex F. Set $h_1(t) = t$ and $h_2(t) = -F^*(t)$ where $F^*(y) = \sup_x (xy - F(x))$. This is correct and it is the conceptual home of the problem, but as a written solution it imports a heavier theorem than you need, and it still owes the grader an argument

that the supremum over t is attained. Attainment is precisely the supporting line statement again, so nothing was saved.

4. **Take logarithms first, then exponentiate.** *Cue:* $g_1(s)^x$ begs for logarithms. *Circuit:* sup of affine functions is convex, then compose with exp. Define $f(x) = \sup_s(x \log g_1(s) + \log g_2(s))$, note f is convex as a supremum of affine functions, then argue e^f is convex because exp is convex and increasing. Entirely correct, and it is the official route. It has one redundant stage: you build a convex function f only to compose it back. Ink is time.

5. **Sup of convex is convex, directly.** *Cue:* each member of the family is $e^{\alpha x+\beta}$, already convex in x. *Circuit:* pointwise supremum of convex functions is convex, then supporting lines. Skip f altogether. Each $x \mapsto g_1(s)^x g_2(s)$ has second derivative $\alpha_s^2 e^{\alpha_s x+\beta_s} \geq 0$, so it is convex; a pointwise supremum of convex functions is convex by a two line check; finiteness comes from the bounded box; supporting lines finish. This is the shortest complete proof and it is the one to write.

The ideal solution

Since g_1, g_2 are bounded and take values in $[1, \infty)$, fix $M \geq 1$ with $1 \leq g_i(s) \leq M$ for all $s \in \mathbb{R}$ and $i = 1, 2$. Put

$$\alpha_s = \log g_1(s) \in [0, \log M], \qquad \beta_s = \log g_2(s) \in [0, \log M],$$

so that $g_1(s)^x g_2(s) = e^{\alpha_s x+\beta_s} =: \Phi_s(x)$, and define

$$F(x) = \sup_{s\in\mathbb{R}} \Phi_s(x).$$

Step 1: F is real valued. For every s and every x we have $\alpha_s x + \beta_s \leq |x| \log M + \log M$, so $0 < \Phi_s(x) \leq M^{|x|+1}$. Taking the supremum over the nonempty index set, $0 < F(x) \leq M^{|x|+1} < \infty$ for every $x \in \mathbb{R}$. This is the only place the two hypotheses are used, and they are exactly enough.

Step 2: F is convex. Each Φ_s is convex on $\mathbb{R}$, since $\Phi_s''(x) = \alpha_s^2 \Phi_s(x) \geq 0$. Let $x_1, x_2 \in \mathbb{R}$ and $\lambda \in [0, 1]$. For every s,

$$\Phi_s\big(\lambda x_1 + (1-\lambda)x_2\big) \leq \lambda \Phi_s(x_1) + (1-\lambda)\Phi_s(x_2) \leq \lambda F(x_1) + (1-\lambda)F(x_2).$$

The right hand side is independent of s, so taking the supremum over s on the left gives $F(\lambda x_1 + (1-\lambda)x_2) \leq \lambda F(x_1) + (1-\lambda)F(x_2)$. Thus F is a finite convex function on $\mathbb{R}$.

Lemma 14.11.1 (chords)**.** *Let $F : \mathbb{R} \to \mathbb{R}$ be convex and let $u < v < w$. Then*

$$\frac{F(v) - F(u)}{v - u} \leq \frac{F(w) - F(u)}{w - u} \leq \frac{F(w) - F(v)}{w - v}.$$

Proof. Write $v = \lambda u + (1-\lambda)w$ with $\lambda = \frac{w-v}{w-u} \in (0, 1)$, so that $v - u = (1-\lambda)(w-u)$ and $w - v = \lambda(w-u)$. Convexity gives $F(v) \leq \lambda F(u) + (1-\lambda)F(w)$. Subtracting $F(u)$ from both sides gives $F(v) - F(u) \leq (1-\lambda)\big(F(w) - F(u)\big)$; dividing by $v - u = (1-\lambda)(w-u) > 0$ gives the first inequality. Subtracting both sides from $F(w)$ gives $F(w) - F(v) \geq \lambda\big(F(w) - F(u)\big)$; dividing by $w - v = \lambda(w-u) > 0$ gives the second. □

Lemma 14.11.2 (supporting line)**.** *Let $F : \mathbb{R} \to \mathbb{R}$ be convex and let $t \in \mathbb{R}$. Then there exists $m \in \mathbb{R}$ such that $F(x) \geq F(t) + m(x - t)$ for all $x \in \mathbb{R}$, with equality at $x = t$.*

Proof. Put $m = \inf_{x>t} \frac{F(x)-F(t)}{x-t}$. By the chord lemma applied to $u < t < w$, every difference quotient to the left of t is at most every difference quotient to the right of t; in particular the set over which the infimum is taken is bounded below by $F(t) - F(t-1)$, so m is a real number. For $x > t$, the definition of the infimum gives $\frac{F(x)-F(t)}{x-t} \geq m$, that is $F(x) \geq F(t) + m(x-t)$. For $x < t$, the same chord comparison gives $\frac{F(t)-F(x)}{t-x} \leq m$, that is $F(t) - F(x) \leq m(t-x)$, which rearranges to $F(x) \geq F(t) + m(x-t)$. At $x = t$ both sides agree. □

Step 3: construct h_1 and h_2. For each $t \in \mathbb{R}$ let m_t be a real number supplied by the supporting line lemma for F at t, and define

$$h_1(t) = m_t, \qquad h_2(t) = F(t) - t\,m_t.$$

These are functions $\mathbb{R} \to \mathbb{R}$, as required. For all $x, t \in \mathbb{R}$,

$$xh_1(t) + h_2(t) = F(t) + m_t(x - t) \le F(x),$$

by the supporting line inequality, and taking $t = x$ turns this into an equality. Hence the set $\{xh_1(t) + h_2(t) : t \in \mathbb{R}\}$ has largest element $F(x)$, attained at $t = x$: the maximum on the right hand side exists and

$$\max_{t\in\mathbb{R}} \big(xh_1(t) + h_2(t)\big) = F(x) = \sup_{s\in\mathbb{R}} \big(g_1(s)^x g_2(s)\big)$$

for every $x \in \mathbb{R}$. This is the required identity.

Remark 14.11.3. If you would rather not quote or prove any convexity theory at all, the bounded box gives a second, fully explicit construction. Fix t and choose s_k with $\Phi_{s_k}(t) \to F(t)$. The pairs $(\alpha_{s_k}, \beta_{s_k})$ lie in the compact box $[0, \log M]^2$, so by Bolzano and Weierstrass a subsequence converges to some (α, β) in that box. Writing $E(x) = e^{\alpha x+\beta}$, continuity gives $E(t) = F(t)$, while $E(x) = \lim_k \Phi_{s_k}(x) \le F(x)$ for every x. The tangent to E at t, namely $\ell(x) = E(t)\big(1 + \alpha(x - t)\big)$, satisfies $\ell \le E \le F$ because $e^u \ge 1 + u$, and $\ell(t) = F(t)$. So one may take

$$h_1(t) = \alpha\,F(t), \qquad h_2(t) = (1 - \alpha t)F(t),$$

with α produced as above. This route also shows that the supremum on the left is attained by the limiting exponent pair, even though it need not be attained by any single s.

Layer 1: WHAT

Block 1. Put x where it belongs: $g_1(s)^x g_2(s) = e^{\alpha_s x+\beta_s}$, an exponential of a line in x.

Block 2. Read the right hand side as an upper envelope of lines in x, and recall that the functions expressible that way are exactly the finite convex ones. The target becomes: prove F is convex.

Block 3. Cash in the hypotheses for finiteness: $[1, \infty)$ and bounded together say the exponent pair lives in a bounded box, so $F(x)$ is finite for every real x.

Block 4. Each family member is convex in x; a pointwise supremum of convex functions is convex. Two lines, done.

Block 5. Supporting line at each t gives the slope m_t; name $h_1(t) = m_t$ and $h_2(t) = F(t) - tm_t$.

Block 6. Equality at $t = x$ upgrades the supremum on the right to a maximum, which the problem demanded by writing max rather than sup.

The nominal route, and the juxtaposition. The zombie tries to evaluate $\sup_s g_1(s)^x g_2(s)$, or invents a maximising $s(x)$ and differentiates through it, or reaches for Holder and weighted means because the expression looks like an interpolation. All of these are attempts to compute an object that is not computable, since g_1, g_2 are arbitrary. The bifurcation point is the sentence where you stop asking *what is* the left hand side and start asking *what property of the left hand side* the right hand side is claiming. The problem is testing whether you can read $\max_t(xh_1(t) + h_2(t))$ as the phrase "is convex", and nothing else.

Layer 2: HOW

Block 1. Cue. A base raised to the power x, where the base is indexed by a parameter and x is the variable. **Why natural.** Powers with a variable exponent are exponentials; put the variable in the exponent and the parameter in the coefficients. Then x appears affinely, and affine dependence is the only kind convexity arguments can see. This move costs one line and it is forced by which symbol is the variable. **Link to the next block.** Once every family member is $e^{\alpha x+\beta}$, the family is closed under everything convexity cares about, and the right hand side can be compared with it.

Block 2. **Cue.** The right hand side is a maximum over t of something affine in x. **Why natural.** An affine function of x is a line; a maximum of lines is an upper envelope; upper envelopes of lines are convex, and conversely every finite convex function on $\mathbb{R}$ is the upper envelope of its supporting lines. So the identity to be proved is not an identity to be computed, it is the statement that F is convex, plus the attainment claim. Recognising this is the whole problem. **Link to the next block.** Convexity has to be proved for F, so you need to know F is real valued first: an extended real valued supremum equal to $+\infty$ somewhere cannot have a supporting line there.

Block 3. **Cue.** Two hypotheses that look like decoration: codomain $[1, \infty)$, and bounded. **Why natural.** Every hypothesis in a Putnam problem is load bearing; find the load. Here $[1, \infty)$ gives $\alpha_s, \beta_s \geq 0$ and boundedness gives $\alpha_s, \beta_s \leq \log M$. The bound $\Phi_s(x) \leq M^{|x|+1}$ then holds uniformly in s, for negative x as well as positive. Without the lower bound 1 the supremum blows up for negative x; without the upper bound it blows up for positive x. **Link to the next block.** With F finite you may now speak of convexity of F as an ordinary function $\mathbb{R} \to \mathbb{R}$.

Block 4. **Cue.** A supremum of a family, and a property (convexity) defined by an inequality. **Why natural.** Any property defined by an inequality of the form "value at a convex combination is at most the convex combination of values" passes to pointwise suprema, because you bound each family member by the supremum on the right, then take the supremum on the left. Write that argument out once and you own it forever. Note it fails for infima, and it fails for concavity. **Link to the next block.** Convexity in hand, the only remaining question is which line to attach to which t.

Block 5. **Cue.** You must produce h_1, h_2 as *functions of* t, so you need one line per real number t. **Why natural.** The supporting line at t is the canonical choice, and it is the only one that will make the envelope tight at $x = t$. Its existence for a finite convex function is the standard lemma; prove it from chord slope monotonicity so that nothing is quoted. The slope is the infimum of right hand difference quotients, which is finite because left hand quotients bound it below. **Link to the next block.** Having equality at $x = t$ is exactly what turns a supremum into a maximum.

Block 6. **Cue.** The problem wrote max, not sup. **Why natural.** Examiners choose that symbol deliberately. It adds the requirement that the envelope be attained, and it also hints at how: whatever family you build must contain, for each x, a member that touches. The supporting line at $t = x$ touches at x by construction, so the hint has been followed. **Link to the next block.** The two sides now agree for every x, which is the statement to be proved.

Layer 3: WHY

The truth beneath the route is the elementary case of the Fenchel and Moreau theorem: on $\mathbb{R}$, a finite convex function equals the pointwise supremum of its affine minorants, and at each point the supremum is attained by a supporting line. Read backwards, that says the class of functions representable as $\max_t(xh_1(t) + h_2(t))$ is exactly the class of finite convex functions on $\mathbb{R}$. So this problem is a one directional instance of a characterisation, and the problem setter chose a family, exponentials with bounded exponents, whose supremum is guaranteed convex and finite. Once you see the classification, there is nothing left to invent.

The second truth is a stability principle worth stating in general: convexity is preserved by pointwise suprema, by nonnegative combinations, by composition with an increasing convex function on the outside, and by affine substitution on the inside. Those four closure rules cover almost every convexity claim you will need. In this problem two of them apply and either finishes: sup of the convex functions Φ_s, or exp of the convex function $f = \log F$, which is the official route.

Knowing the closure list is what lets you choose the cheaper one instantly rather than reconstructing an argument.

The third truth is the duality bookkeeping. With $h_1(t) = m_t$ a supporting slope at t and $h_2(t) = F(t) - tm_t$, the pair satisfies $h_2(t) = -F^*(h_1(t))$, where $F^*(y) = \sup_x(xy - F(x))$ is the Legendre transform: indeed the supremum defining $F^*(m_t)$ is attained at $x = t$, precisely because the line supports there. So the h_1, h_2 you produced are a parametrisation of the graph of $-F^*$, and the identity you proved is $F = F^{**}$ in disguise. That is worth knowing because the Legendre transform is the standard tool for turning a supremum over one variable into a maximum over a dual variable, which is what the question asked you to do.

The discernment mechanism, stated as a rule you can apply under pressure: when an identity has an unevaluable supremum on one side and a family of affine functions on the other, the content is a structural property (convexity, subadditivity, monotonicity), never a computation. Train it by rewriting each side in the same variables and asking which side is a definition and which side is a theorem. Here the left side is a definition of a function of x, and the right side is a theorem about that function. The examiners nudged you three times: with $[1, \infty)$ (finiteness for $x < 0$), with bounded (finiteness for $x > 0$), and with max (attainment). Three hypotheses, three jobs, no spare parts.

Revolving concepts

Convex function. F is convex on an interval if $F(\lambda x_1 + (1-\lambda)x_2) \le \lambda F(x_1) + (1-\lambda)F(x_2)$ for all $\lambda \in [0,1]$. For twice differentiable F this is $F'' \ge 0$, but the inequality definition is the one that survives corners and suprema. See Book 1, field: Inequalities, topic: convexity.

Closure rules. If each F_i is convex then so is $\sup_i F_i$ (pointwise, wherever finite), $\sum c_i F_i$ for $c_i \ge 0$, $x \mapsto F(ax+b)$, and $\varphi \circ F$ for φ convex and nondecreasing. Infima do not preserve convexity: $\min(x, -x) = -|x|$ is concave. See Book 1, field: Inequalities, topic: operations preserving convexity.

Chord slope monotonicity and one sided derivatives. For convex F the difference quotient $\frac{F(v)-F(u)}{v-u}$ is nondecreasing in each argument. It follows that $F'_-(t)$ and $F'_+(t)$ exist with $F'_-(t) \le F'_+(t)$, that F is continuous, that F is differentiable off a countable set, and that every $m \in [F'_-(t), F'_+(t)]$ supports at t. The set of such m is the subdifferential $\partial F(t)$. See Book 1, field: Real analysis, topic: convex functions on the line.

Supporting line and supporting hyperplane. Every finite convex function on $\mathbb{R}$ has a supporting line at every point; in $\mathbb{R}^n$ the same statement holds with hyperplanes, proved by separating the point from the epigraph. Consequently a finite convex function is the supremum of its affine minorants. See Book 1, field: Real analysis, topic: supporting hyperplane theorem.

Legendre and Fenchel transform. $F^*(y) = \sup_x(xy - F(x))$; then $F^{**} = F$ for closed proper convex F, and $y \in \partial F(x)$ if and only if $xy = F(x) + F^*(y)$. Worked example: $F(x) = e^x$ gives $F^*(y) = y\log y - y$ for $y > 0$. See Book 1, field: Real analysis, topic: convex duality.

Log convexity, for contrast. A positive function is log convex if $\log F$ is convex; log convex implies convex, but not conversely. The official solution builds $\log F$ first, which shows the left hand side here is log convex, a strictly stronger fact than needed. Log convexity is the natural home of the Bohr and Mollerup characterisation of the gamma function and of Holder type interpolation bounds. See Book 1, field: Inequalities, topic: log convexity.

Recursion content. There is none in this problem: no sequence, no induction, no self similar structure. Do not manufacture one.

Circuit Bank

- **WHEN** a variable sits in an exponent as a^x with the base carrying a parameter **DO** rewrite as $e^{\alpha x+\beta}$ with α, β the parameters **BECAUSE** the variable then enters affinely, which is the only dependence convexity arguments can exploit

- **WHEN** one side of a required identity is a supremum or maximum of affine functions of the variable **DO** stop computing and prove that the other side is convex and finite, then produce supporting lines **BECAUSE** finite convex functions on $\mathbb{R}$ are exactly the upper envelopes of families of lines, and the envelope is attained at each point
- **WHEN** a problem hands you boundedness together with a codomain bounded away from the bad end **DO** convert both into the statement that the parameters lie in a compact box **BECAUSE** that box is what makes the supremum finite for every sign of the variable, and it also gives compactness for free
- **WHEN** a statement writes max where sup would have been safer **DO** treat attainment as a separate deliverable and design the construction so that the index $t = x$ touches **BECAUSE** examiners choose max deliberately, and an unattained supremum makes the statement false as written
- **WHEN** a property defined by an inequality must be proved for a supremum of a family **DO** bound each family member by the supremum on the far side, then take the supremum on the near side **BECAUSE** the far side no longer depends on the index, so the supremum passes through the inequality

Backtesting

1. First useful cue: x appears as an exponent on the left and as a coefficient of $h_1(t)$ on the right, so both sides are envelopes of one parameter families and the right hand family is affine in x.
2. Method the expression suggested: rewrite the family as $e^{\alpha_s x+\beta_s}$, observe each member is convex in x, and take the supremum, since supremum preserves convexity.
3. Where you would hesitate, and the thought to reinforce: at the existence of the supporting line, wondering whether F is differentiable. Reinforce this: convexity, not differentiability, is what produces supporting lines, and the proof is four lines from chord slope monotonicity. Never make smoothness assumptions you were not given.
4. The trap the question sets: trying to evaluate the supremum, or assuming it is attained at some s. It need not be attained at any s, and no formula for it exists.
5. What makes you recognise it faster next time: the shape $\max_t(xh_1(t) + h_2(t))$ is a Legendre transform written without its name. Any time you meet it, translate it immediately as "the left hand side is convex".
6. The reusable decision rule: an identity between an unevaluable supremum and a family of lines is a convexity statement, and the supporting line at $t = x$ is the construction that makes the maximum attained.

Mirror drills

1. Let $g : \mathbb{R} \to [1, M]$ be surjective. Compute $F(x) = \sup_s g(s)^x$ explicitly and write down h_1, h_2. *Answer:* $F(x) = \max(1, M^x)$; take $h_1(t) = 0, h_2(t) = 1$ for $t \leq 0$ and $h_1(t) = M^t \log M$, $h_2(t) = M^t(1 - t \log M)$ for $t > 0$, which is the supporting line at each t and shows the corner at $x = 0$ causes no trouble.
2. Prove that a pointwise supremum of convex functions is convex, and give an example showing that a pointwise infimum need not be. *Answer:* the two line argument of Step 2; for the counterexample, $\min(x, -x) = -|x|$, an infimum of two lines that is concave.

3. For $F(x) = e^x$, compute the Legendre transform $F^*(y) = \sup_x(xy - F(x))$ and verify $h_2(t) = -F^*(h_1(t))$ for the tangent line data $h_1(t) = e^t$, $h_2(t) = e^t(1-t)$. *Answer:* $F^*(y) = y\log y - y$ for $y > 0$, so $-F^*(e^t) = -\left(te^t - e^t\right) = e^t(1-t) = h_2(t)$.

14.12 B6. The sign of cubing modulo a prime

Let p be an odd prime number such that $p \equiv 2 \pmod 3$. Define a permutation π of the residue classes modulo p by $\pi(x) \equiv x^3 \pmod p$. Show that π is an even permutation if and only if $p \equiv 3 \pmod 4$.

Read it out loud

A permutation of a finite set is defined by an arithmetic operation, and you are asked for its sign. The answer is a congruence condition modulo 4. Three separate structures are therefore in play: the group S_p and its sign homomorphism, the arithmetic of $\mathbb{Z}/p$, and an ordering of the residues, because sign has nothing to do with order but inversions do. Any solution must decide how those three interact.

Start with the hypothesis $p \equiv 2 \pmod 3$, because a hypothesis stated first is usually the one that makes the object exist. It says $p - 1 \equiv 1 \pmod 3$, so $3 \nmid p - 1$, so $\gcd(3, p - 1) = 1$. That is exactly the condition for $x \mapsto x^3$ to be a bijection on the nonzero classes: choose u with $3u \equiv 1 \pmod{p-1}$ and $x \mapsto x^u$ inverts it by Fermat. Without that hypothesis π is three to one on a subgroup and the word permutation in the statement would be false. So hypothesis one buys existence.

Now the structural reading. Cubing is a nonlinear operation on $\mathbb{Z}/p$ under addition, but it is the cube map on a group under multiplication, and $(\mathbb{Z}/p)^\times$ is cyclic of order $p - 1$. Fix a primitive root g and write every nonzero class as g^i. Then cubing sends g^i to g^{3i}: in the exponent coordinate the map is multiplication by 3 on $\mathbb{Z}/(p-1)$, which is linear. Since sign depends only on cycle type, and cycle type is unchanged by relabelling the set, you may compute the sign of the relabelled map instead. That single move, the discrete logarithm, is the whole problem. Everything on the far side is a finite count.

The fields are group theory (sign homomorphism, conjugation invariance, cyclic groups), elementary number theory (primitive roots, orders, and behind the scenes quadratic reciprocity), and combinatorics (inversions, floor functions, lattice point counts). Within thirty seconds you should have on the page: $q = p - 1$; $\sigma(i) = 3i \bmod q$; the note that $\operatorname{sgn}\pi = \operatorname{sgn}\sigma$; the note that $\operatorname{sgn}\sigma = (-1)^N$ with N the number of inversions; and $q = 3m + 1$ where $m = (p-2)/3$, because $3 \nmid q$ means the multiples of 3 wrap the interval $[0, q)$ in a pattern controlled by m.

A knowledge gap declared up front, because pretending otherwise wastes your time. This problem is unapproachable without three facts that are not in A-level or Further Mathematics: the sign homomorphism on S_n and its invariance under relabelling; the existence of primitive roots modulo p, that is, the cyclicity of $(\mathbb{Z}/p)^\times$; and the identity $\operatorname{sgn} = (-1)^{\text{number of inversions}}$ relative to any fixed linear order. Install those three and the problem is a page of counting. Miss any one and no amount of ingenuity substitutes.

Approaches, ranked worst to best

1. **Tabulate small primes and match the pattern.** *Cue:* the conclusion is a congruence, so small cases look tempting. *Circuit:* compute and guess. With $p = 5, 11, 17, 23$ you will see the pattern immediately and prove nothing. Use this to check the final parity formula, never as the argument.

2. **Attack the cycle structure of $x \mapsto x^3$ directly on $\mathbb{Z}/p$.** *Cue:* sign is determined by cycle type. *Circuit:* decompose into cycles. Without the discrete logarithm you are asking for the orbit lengths of cubing on residues, which are the multiplicative orders of 3 modulo the various orders of elements. You will discover this only after fighting the multiplicative structure by hand, which is the same structure the discrete logarithm hands you for free.

3. **Product formula and quadratic reciprocity, after Elkies.** *Cue:* sign equals $\prod_{x<y} \frac{\pi(x)-\pi(y)}{x-y}$.

Circuit: evaluate a symmetric product modulo p. Since $\frac{x^3-y^3}{x-y} = x^2+xy+y^2$, the sign is congruent modulo p to $\prod_{0\le x<y<p}(x^2+xy+y^2)$, and you then need how often the binary quadratic form x^2+xy+y^2 takes each nonzero value. Its discriminant is -3, and -3 is a quadratic residue modulo p if and only if $p \equiv 1 \pmod 3$, so for our primes the form is anisotropic and each nonzero value is taken exactly $p+1$ times over ordered pairs. This route is beautiful, it is essentially a proof of a reciprocity law, and it costs the most: conics over $\mathbb{F}_p$, the quadratic character of -3, and a primitive root computation at the end. A caveat worth clarifying: the published write up states $\chi(-3) = +1$ for these primes, which is the wrong value, and it also drops a sign in the count of unordered pairs; the two slips cancel and its final exponent $(p+\chi(-c))/2$ is correct. If you reconstruct this route, recompute both steps and test against $p = 5$.

4. **Count cycles of even length, after van Hoeij.** *Cue:* sign is $(-1)^{\text{number of even cycles}}$. *Circuit:* orbit counting by element order. Elements of multiplicative order d are permuted among themselves and fall into $\varphi(d)/f(d)$ orbits, where $f(d) = \operatorname{ord}_d(3)$. The summands for odd d and for $2d$ coincide and cancel in pairs, so only d divisible by 4 matter; if $p \equiv 3 \pmod 4$ there are none. Short and conceptual, but the case $4 \mid d$ needs the structure of $(\mathbb{Z}/2^a)^\times$ as $\mathbb{Z}/2 \times \mathbb{Z}/2^{a-2}$ and a two adic valuation comparison. Rank it above the reciprocity route for economy, below the inversion count for prerequisites.

5. **Discrete logarithm, then count inversions.** *Cue:* cubing is multiplicative and the group is cyclic. *Circuit:* conjugate the permutation into a linear map on $\mathbb{Z}/(p-1)$, then count inversions. Cubing becomes $i \mapsto 3i \bmod (p-1)$, whose inversions split into three blocks according to $\lfloor 3i/(p-1) \rfloor \in \{0,1,2\}$, and each cross block pair contributes the same triangular number. Self contained, one page, no reciprocity, no two adic analysis. This is the solution to write.

The ideal solution

Throughout, write $q = p-1$ and $m = \frac{p-2}{3}$, which is an integer because $p \equiv 2 \pmod 3$. Then $q = 3m+1$, and m is odd because $p = 3m+2$ is odd.

Step 0: π is a permutation. Since $p \equiv 2 \pmod 3$ we have $q \equiv 1 \pmod 3$, so $\gcd(3,q) = 1$. Choose u with $3u \equiv 1 \pmod q$. For $x \not\equiv 0$, $(x^3)^u = x^{3u} = x$ by Fermat's little theorem, and $\pi(0) = 0$, so π is a bijection of $\mathbb{Z}/p$.

Step 1: transport the problem to the exponents. Let g be a primitive root modulo p and let $\phi : \{0,1,\dots,q-1\} \to (\mathbb{Z}/p)^\times$ be the bijection $\phi(i) = g^i$. Define σ on $\{0,1,\dots,q-1\}$ by $\sigma(i) = 3i \bmod q$; this is a permutation because $\gcd(3,q) = 1$. For every i,

$$\pi(\phi(i)) = (g^i)^3 = g^{3i} = g^{3i \bmod q} = \phi(\sigma(i)),$$

using $g^q = 1$. Hence the restriction of π to $(\mathbb{Z}/p)^\times$ equals $\phi \circ \sigma \circ \phi^{-1}$, so it has the same cycle type as σ, hence the same sign. Adjoining the fixed point 0 adds a cycle of length 1 and changes nothing. Therefore $\operatorname{sgn}\pi = \operatorname{sgn}\sigma$.

Step 2: sign as an inversion count. For a permutation σ of a finite totally ordered set, $\operatorname{sgn}\sigma = (-1)^N$ where

$$N = \#\{(i,j) : i < j,\ \sigma(i) > \sigma(j)\}$$

is the number of inversions. (Reason: swapping two adjacent positions changes N by exactly 1 and changes the sign, and the identity has $N = 0$.) We order $\{0,1,\dots,q-1\}$ in the usual way and count.

Step 3: split the index range into three blocks. For $0 \le i \le q-1$ we have $0 \le 3i < 3q$, so $\lfloor 3i/q \rfloor \in \{0,1,2\}$, and $3i$ is never equal to q or to $2q$ because $3 \nmid q$. Using $q = 3m+1$:

$$3i < q \iff i \le m, \qquad q < 3i < 2q \iff m+1 \le i \le 2m, \qquad 2q < 3i < 3q \iff 2m+1 \le i \le 3m.$$

So put $B_0 = \{0, \dots, m\}$, $B_1 = \{m+1, \dots, 2m\}$, $B_2 = \{2m+1, \dots, 3m\}$, of sizes $m+1, m, m$, and note $\sigma(i) = 3i - rq$ for $i \in B_r$.

If $i < j$ lie in the same block then $\sigma(i) - \sigma(j) = 3(i-j) < 0$, so there is no inversion inside a block. The blocks are increasing intervals, so every inversion has $i \in B_r$ and $j \in B_{r'}$ with $r < r'$, and the condition $\sigma(i) > \sigma(j)$ reads

$$3i - rq > 3j - r'q \iff 3(j-i) < (r'-r)q.$$

Step 4: the three counts. Since $q = 3m+1$, the condition $3(j-i) < q$ is equivalent to $j - i \le m$, and $3(j-i) < 2q$ is equivalent to $j - i \le 2m$.

- $r = 0, r' = 1$: for $i \in B_0$ we need $j \in B_1$ with $j \le i + m$. As $i \le m$ we have $i + m \le 2m$, so j runs over $\{m+1, \dots, i+m\}$, giving exactly i values. Total $\sum_{i=0}^{m} i = \frac{m(m+1)}{2}$.
- $r = 1, r' = 2$: for $i \in B_1$ we need $j \in B_2$ with $j \le i + m$. As $m+1 \le i \le 2m$ we have $2m+1 \le i+m \le 3m$, so j runs over $\{2m+1, \dots, i+m\}$, giving exactly $i - m$ values. Total $\sum_{i=m+1}^{2m} (i-m) = \frac{m(m+1)}{2}$.
- $r = 0, r' = 2$: for $i \in B_0$ we need $j \in B_2$ with $j \le i + 2m$. As $i \le m$ we have $i + 2m \le 3m$, so j runs over $\{2m+1, \dots, i+2m\}$, giving exactly i values. Total $\frac{m(m+1)}{2}$.

Hence

$$N = 3 \cdot \frac{m(m+1)}{2}, \qquad m = \frac{p-2}{3},$$

equivalently $N = \frac{(p-2)(p+1)}{6}$. (Check with $p = 11$: $m = 3$, $N = 18$, and the sequence $\sigma(0), \dots, \sigma(9) = 0, 3, 6, 9, 2, 5, 8, 1, 4, 7$ does have 18 inversions.)

Step 5: parity. Since p is odd and $p = 3m + 2$, the integer m is odd, so $m + 1$ is even and

$$N = 3m \cdot \frac{m+1}{2} \equiv \frac{m+1}{2} \pmod 2,$$

because $3m$ is odd. Thus N is even if and only if $4 \mid m+1$, that is $m \equiv 3 \pmod 4$. Finally $p = 3m + 2$, so $m \equiv 3 \pmod 4$ gives $p \equiv 11 \equiv 3 \pmod 4$, and $m \equiv 1 \pmod 4$ (the only other option, as m is odd) gives $p \equiv 5 \equiv 1 \pmod 4$. Therefore

$$\operatorname{sgn} \pi = \operatorname{sgn} \sigma = (-1)^N = +1 \iff p \equiv 3 \pmod 4,$$

which is the assertion.

Layer 1: WHAT

Block 1. Convert the hypothesis $p \equiv 2 \pmod 3$ into $\gcd(3, p-1) = 1$ and observe that this is what makes π a permutation at all.

Block 2. Recall that sign depends only on cycle type, hence is unchanged by relabelling the underlying set; so you are free to choose coordinates.

Block 3. Choose the coordinates in which cubing is linear: the discrete logarithm turns $x \mapsto x^3$ on $(\mathbb{Z}/p)^\times$ into $i \mapsto 3i$ on $\mathbb{Z}/(p-1)$.

Block 4. Sign needs an order, so fix representatives $0, 1, \dots, q-1$ and use $\operatorname{sgn} = (-1)^{\text{inversions}}$.

Block 5. Inversions can only occur when the wrap count $\lfloor 3i/q \rfloor$ jumps, so split the range into three blocks and count cross block pairs.

Block 6. In each of the three cross block pairs the inversion condition is a single inequality $j - i \le$ constant, so each count is the same triangular number $\frac{m(m+1)}{2}$.

Block 7. Carry only the parity: m is odd, $N \equiv \frac{m+1}{2}$, and translating back through $p = 3m + 2$ gives the congruence modulo 4.

The nominal route, and the juxtaposition. The zombie starts from the definition of even permutation, writes x^3 as a permutation of $0, 1, \dots, p-1$, and tries to find its cycles. That is not stupid; it

is simply the wrong coordinate system, and it leads into orders of 3 modulo divisors of $p-1$, which is a harder count than the one the good coordinates give. The bifurcation point is the line where you write $x = g^i$. Before that line the map is nonlinear and the set has no useful structure; after it the map is multiplication by 3 on a cyclic group and the entire remaining problem is counting lattice points below a line. If you take one sentence from this problem, take this: cubing is nonlinear on residues and linear on exponents, so work with exponents.

Layer 2: HOW

Block 1. **Cue.** A congruence hypothesis stated before the object is even defined. **Why natural.** The statement calls π a permutation, so something must guarantee injectivity of cubing. On a cyclic group of order q the map $x \mapsto x^k$ is bijective exactly when $\gcd(k, q) = 1$, and $p \equiv 2 \pmod 3$ is precisely $\gcd(3, p-1) = 1$. Reading a hypothesis as the reason an object exists is a habit that pays on every algebra problem. **Link to the next block.** Knowing $\gcd(3, q) = 1$, you also know that 3 is invertible modulo q, which is what makes the exponent side of the problem a permutation too.

Block 2. **Cue.** The question asks for a sign, not a formula, and sign is a group homomorphism $S_n \to \{\pm 1\}$. **Why natural.** Sign is constant on conjugacy classes, and conjugation is exactly relabelling of the underlying set. So you are permitted to replace the set $\mathbb{Z}/p$ by any set in bijection with it, provided you transport the map. That freedom is enormous and it is free; the only question left is which relabelling makes the map simple. **Link to the next block.** The map is multiplicative, so the relabelling should be one that linearises multiplication. That is the definition of a logarithm.

Block 3. **Cue.** The multiplicative group modulo a prime is cyclic, and π is a power map. **Why natural.** Under $x = g^i$ the operation $x \mapsto x^3$ becomes $i \mapsto 3i$ modulo $p-1$. Nothing was invented here: this is what cyclicity is for. The fixed point 0 is discarded first because a fixed point contributes a cycle of length one and cannot affect the sign. **Link to the next block.** You now hold a linear map on $\mathbb{Z}/q$. Sign, however, is not defined for a map on an unordered set of residues; you must fix representatives, and that is where the counting starts.

Block 4. **Cue.** Sign of a concrete permutation of a totally ordered finite set. **Why natural.** The inversion formula is the only computational handle that turns sign into a count you can do by hand, and it is available the moment you choose the representatives $0, 1, \ldots, q-1$. Note that the number of inversions depends on the chosen order but its parity does not, because the sign does not. **Link to the next block.** The permutation is $i \mapsto 3i - q\lfloor 3i/q \rfloor$, so its failure to be increasing is entirely caused by the subtracted multiple of q. That tells you where to look for inversions.

Block 5. **Cue.** A floor function taking only three values on the index range. **Why natural.** If $\lfloor 3i/q \rfloor = \lfloor 3j/q \rfloor$ then σ is increasing on that pair, so no inversion. Partitioning the index range into the level sets of the floor function is therefore not a convenience, it is the exact decomposition the problem has: inversions live only between different levels. This is the standard move for any map of the form $i \mapsto ai \bmod q$. **Link to the next block.** Within a fixed pair of levels the inversion condition simplifies to a linear inequality in $j - i$, because the wrap contribution is a constant.

Block 6. **Cue.** Three cross block pairs, each with a condition of the form $j - i \le$ constant. **Why natural.** Counting integer pairs in an interval subject to $j \le i + c$ is a triangular number; there is nothing to be clever about. Doing all three and finding the same answer $\frac{m(m+1)}{2}$ three times is a useful internal check that no block boundary was mishandled. **Link to the next block.** You now have $N = 3\binom{m+1}{2}$, an exact count, which is more than you need; only its parity matters.

Block 7. Cue. The target is a congruence modulo 4 and you hold a product of an odd number with $\frac{m+1}{2}$. **Why natural.** Carry parity, not size. $3m$ is odd, so $N \equiv \frac{m+1}{2} \pmod 2$, and the condition $4 \mid m+1$ translates through $p = 3m+2$ into $p \equiv 3 \pmod 4$. The factor 3 multiplying the triangular number is invisible to parity, which is why the three block counts did not need to be added carefully, only counted. **Link to the next block.** The chain $\operatorname{sgn}\pi = \operatorname{sgn}\sigma = (-1)^N$ closes the argument.

Layer 3: WHY

The first truth is that sign is a class function: conjugate permutations have equal sign, because conjugation preserves cycle type. On a finite set with no distinguished structure, that means the sign of a map is an invariant of the map up to relabelling, so you may always compute it in the most convenient coordinates. Almost every Putnam problem about the parity of a permutation is really a problem about choosing coordinates, and the coordinates are chosen by asking which group operation the map respects. Cubing respects multiplication; therefore work in the group where multiplication is addition.

The second truth is the cyclicity of $(\mathbb{Z}/p)^\times$, that is, the existence of primitive roots. It is what makes the discrete logarithm exist. It is not obvious and it is not cheap to prove (the standard argument counts elements of each order using $\sum_{d\mid n}\varphi(d) = n$ and the fact that $x^d = 1$ has at most d roots in a field), but you may quote it. Once quoted it converts multiplicative questions modulo p into additive questions modulo $p-1$, and the difficulty of a problem often collapses when you cross that bridge. Notice that this is why the answer involves $p-1$ arithmetic (a condition modulo 4) rather than p arithmetic.

The third truth is that counting inversions of $i \mapsto ai \bmod q$ is a lattice point count under a line, which is precisely the shape that appears in the Eisenstein and Gauss lemma proofs of quadratic reciprocity. That is not a coincidence. Zolotarev's lemma states that for odd n and $\gcd(a,n) = 1$, the sign of multiplication by a on $\mathbb{Z}/n$ is the Jacobi symbol $\left(\frac{a}{n}\right)$, and reciprocity itself can be derived from that identity. Here the modulus $q = p-1$ is even, so Zolotarev does not apply and the count has to be done by hand, but the family resemblance explains why the answer is a congruence modulo 4: parities of triangular numbers are governed by residues modulo 4, and that is the same mechanism that puts $\frac{p-1}{2}$ and $\frac{p^2-1}{8}$ into the supplementary laws.

The discernment mechanism, stated so you can apply it cold: when a permutation is defined by an arithmetic formula, ask which group operation it is a homomorphism for, and relabel so that it becomes linear. Then ask whether you need cycle structure (use orbit lengths and orders) or a sign (use inversions). Cycle counting is better when the orbit lengths are uniform; inversion counting is better when the map is linear on an ordered range, because then inversions are governed by a floor function with few values. Train it by taking the maps $x \mapsto x^{-1}$, $x \mapsto ax$, $x \mapsto x^k$ modulo p and computing all three signs by both methods, once.

Revolving concepts

Sign of a permutation. The unique homomorphism $\operatorname{sgn} : S_n \to \{\pm 1\}$ with $\operatorname{sgn}(\text{transposition}) = -1$. A cycle of length ℓ has sign $(-1)^{\ell-1}$, so $\operatorname{sgn}\sigma = (-1)^{n-c(\sigma)}$ where c counts cycles including fixed points, and equivalently $\operatorname{sgn}\sigma = (-1)^{\#\{\text{even length cycles}\}}$. Sign is constant on conjugacy classes. See Book 1, field: Abstract algebra, topic: symmetric group and sign.

Inversions. For a permutation of a totally ordered set, $\operatorname{sgn}\sigma = (-1)^N$ with N the number of pairs out of order. The count N itself depends on the order chosen; the parity does not. See Book 1, field: Combinatorics, topic: inversions and the sign statistic.

Primitive roots and the discrete logarithm. $(\mathbb{Z}/p)^\times$ is cyclic of order $p-1$; a generator is a primitive root g, and $x \mapsto \log_g x$ is an isomorphism onto $\mathbb{Z}/(p-1)$. Consequences used here: $x \mapsto x^k$ is bijective if and only if $\gcd(k, p-1) = 1$; the number of elements of order d dividing $p-1$ is $\varphi(d)$;

the k-th powers form the subgroup of index $\gcd(k, p-1)$. See Book 1, field: Number theory, topic: primitive roots.

Order of an element and orbit lengths. If x has multiplicative order d and $\gcd(3, d) = 1$, the orbit of x under cubing has length $\mathrm{ord}_d(3)$, the multiplicative order of 3 modulo d. This is the engine of the cycle counting route, and it generalises the recursion $x_{n+1} = x_n^3$: the orbit closes after k steps exactly when $3^k \equiv 1 \pmod{d}$, so every question about iterating a power map reduces to a multiplicative order in the exponent group. See Book 1, field: Number theory, topic: orders and iterated power maps.

Zolotarev's lemma and quadratic reciprocity. For odd n and $\gcd(a, n) = 1$, the sign of $x \mapsto ax$ on $\mathbb{Z}/n$ equals the Jacobi symbol $\left(\frac{a}{n}\right)$; quadratic reciprocity follows. For p prime and $a = g^k$, the direct proof is short: multiplication by a splits $(\mathbb{Z}/p)^\times$ into $(p-1)/d$ cycles of length $d = \mathrm{ord}_p(a)$, so the sign is $(-1)^{(d-1)(p-1)/d}$, which equals $+1$ exactly when a is a quadratic residue. See Book 1, field: Number theory, topic: quadratic reciprocity and Zolotarev.

Quadratic character of small numbers. $\left(\frac{-1}{p}\right) = 1$ iff $p \equiv 1 \pmod{4}$; $\left(\frac{2}{p}\right) = 1$ iff $p \equiv \pm 1 \pmod{8}$; $\left(\frac{-3}{p}\right) = 1$ iff $p \equiv 1 \pmod{3}$. The last one is what governs the binary form $x^2 + xy + y^2$, whose discriminant is -3, and hence the reciprocity route to this problem. See Book 1, field: Number theory, topic: Legendre symbol and supplementary laws.

Structure of $(\mathbb{Z}/2^a)^\times$. For $a \geq 3$ it is $\mathbb{Z}/2 \times \mathbb{Z}/2^{a-2}$, generated by -1 and 3, with $\mathrm{ord}_{2^a}(3) = 2^{a-2}$. This is what the cycle counting route needs in order to show $\varphi(d)/\mathrm{ord}_d(3)$ is even for every d divisible by 4 other than $d = 4$ itself. See Book 1, field: Number theory, topic: units modulo prime powers.

Circuit Bank

- **WHEN** a permutation of a finite set is defined by an arithmetic formula and you are asked for its sign or parity **DO** ask which group operation the formula is linear for, and relabel the set by an isomorphism so that it becomes linear **BECAUSE** sign depends only on cycle type, so relabelling is free, and a linear map is countable by hand
- **WHEN** a power map $x \mapsto x^k$ appears modulo a prime **DO** take discrete logarithms and study $i \mapsto ki$ modulo $p-1$ **BECAUSE** $(\mathbb{Z}/p)^\times$ is cyclic, so power maps are multiplication maps in the exponent, and bijectivity is just $\gcd(k, p-1) = 1$
- **WHEN** you must compute the sign of a concrete permutation of $\{0, 1, \ldots, n\}$ **DO** count inversions, and expect the count to be a sum of triangular numbers **BECAUSE** $\mathrm{sgn} = (-1)^{\text{inversions}}$ turns an algebraic invariant into a finite count you can organise by cases
- **WHEN** a map has the form $i \mapsto ai \bmod q$ and you must count inversions **DO** partition the range by the value of $\lfloor ai/q \rfloor$ and count only cross block pairs **BECAUSE** within a level set the map is increasing, so all disorder comes from the jumps of the floor function
- **WHEN** an exact count has been obtained but the question asks only for a parity **DO** strip odd factors immediately and reduce the expression modulo 2 before substituting back **BECAUSE** carrying the full expression invites arithmetic slips, and parity questions are usually decided by one factor

Backtesting

1. First useful cue: the hypothesis $p \equiv 2 \pmod{3}$, read as $\gcd(3, p-1) = 1$, which both makes π a permutation and makes multiplication by 3 invertible modulo $p-1$.
2. Method the expression suggested: cubing is multiplicative, so pass to exponents through a primitive root; the map becomes $i \mapsto 3i$ on $\mathbb{Z}/(p-1)$, and sign becomes an inversion count.

3. Where you would hesitate, and the thought to reinforce: at the claim that the sign is unchanged when you relabel the set. Reinforce this: conjugate permutations have the same cycle type, and cycle type determines sign; a fixed point contributes a cycle of length one and never affects sign.
4. The trap the question sets: doing the count on $\mathbb{Z}/p$ instead of on $\mathbb{Z}/(p-1)$, or forgetting that 3 divides neither q nor $2q$, which is what guarantees the three blocks have no boundary cases and that $m = (p-2)/3$ is an integer.
5. What makes you recognise it faster next time: any sign or parity question about $x \mapsto x^k$ modulo p is a question about $i \mapsto ki$ modulo $p-1$, and any question about $i \mapsto ki$ modulo q is a lattice count under a line, which is the Zolotarev and Eisenstein circle of ideas.
6. The reusable decision rule: relabel until the map is linear, order the labels, count inversions by level sets of the floor function, then carry only the parity.

Mirror drills

1. Compute the sign of the inversion map $x \mapsto x^{-1}$ on the nonzero classes modulo an odd prime p. *Answer:* it fixes ± 1 and pairs the other $p-3$ classes into $\frac{p-3}{2}$ transpositions, so the sign is $(-1)^{(p-3)/2}$, which is even exactly when $p \equiv 3 \pmod 4$.
2. Prove Zolotarev's lemma for a prime modulus: for $\gcd(a,p) = 1$, the sign of $x \mapsto ax$ on $\mathbb{Z}/p$ is $\left(\frac{a}{p}\right)$. *Answer:* the map splits the nonzero classes into $(p-1)/d$ cycles of length $d = \operatorname{ord}_p(a)$, so the sign is $(-1)^{(d-1)(p-1)/d}$; if d is odd this is $+1$ and a is a square, and if d is even it is $(-1)^{(p-1)/d}$, which matches the residue character of $a = g^k$ since $\gcd(k, p-1) = (p-1)/d$.
3. For odd q, count the inversions of $i \mapsto 2i \bmod q$ on $\{0, 1, \ldots, q-1\}$ and deduce the supplementary law for 2. *Answer:* with $q = 2m+1$ there are two blocks and the count is $\frac{m(m+1)}{2}$, which is even exactly when $q \equiv \pm 1 \pmod 8$; by Zolotarev this is $\left(\frac{2}{q}\right)$.

Chapter 15

Putnam 2011

15.1 A1. counting lattice points a spiral cannot reach

Define a growing spiral *in the plane to be a sequence of points with integer coordinates* $P_0 = (0,0), P_1, \ldots, P_n$ *such that* $n \geq 2$ *and:*

- *the directed line segments* $P_0P_1, P_1P_2, \ldots, P_{n-1}P_n$ *are in the successive coordinate directions east (for* P_0P_1*), north, west, south, east, etc.;*
- *the lengths of these line segments are positive and strictly increasing.*

How many of the points (x, y) *with integer coordinates* $0 \leq x \leq 2011$, $0 \leq y \leq 2011$ *cannot be the last point* P_n *of any growing spiral?*

Read it out loud

Read the definition aloud and you hear two separate instructions stacked on top of each other: a direction rule (east, north, west, south, repeating) and a length rule (positive, strictly increasing). The question then asks for a count of failures, how many lattice points in a fixed square cannot be produced as the endpoint of such a path. That framing, "how many cannot," is itself a cue: it is the complement of an existence question, and existence questions built from a strictly increasing sequence are almost always easy once you find the one constraint that is doing the real work.

The field wired into this problem is combinatorics, specifically lattice point counting over a bounded box, but the tool that cracks it open belongs to sequences: an alternating sum of a monotone sequence. The moment you read "lengths... strictly increasing" sitting next to a direction cycle that reverses sign every other step in each axis, you should recognise that each coordinate of P_n is nothing more than a signed sum of a strictly increasing sequence of positive integers. That recognition is the first useful cue, and within thirty seconds of reading the problem you should have written down that P_n's x and y coordinates are each an alternating sum over one of two interleaved increasing subsequences of the step lengths.

The other thing worth saying aloud is what the question is NOT asking. It is not asking you to characterise every growing spiral, and it is not asking for a formula in n. It is asking for a count inside a 2012×2012 grid, which tells you the answer will almost certainly be a small, structured region near the origin (where a short prefix of the increasing sequence still has room to constrain things) and nothing at all once the coordinates are far enough from the axes for the sequence to have exhausted its constraining power.

Approaches, ranked worst to best

1. **brute enumeration of small spirals, hunting visually for a pattern.** *Cue:* a bounded grid 0 to 2011 invites listing. *Circuit:* no circuit, pure search. (why it ranks here: reaching coordinate 2011 forces spirals with dozens of segments and many different splits of the increasing sequence between the two axes; even after staring at pictures you have proved nothing, and the work does not shrink as the bound grows, it grows with it)
2. **hunt for a parity or modular invariant on the coordinates.** *Cue:* integer lattice, direction cycle of period four. *Circuit:* look for an invariant mod a small number. (why it ranks here: a period four rotation tempts you toward an invariant mod 2 or mod 4, but the true excluded set is a boundary strip near small coordinates, not a congruence class; you burn the first minutes of the arena on a dead end before falling back to the real structure)
3. **write each coordinate as an alternating sum of the two length subsequences, pin its sign and size by pairing consecutive terms, then construct explicitly once the pairing bound is exhausted.** *Cue:* "strictly increasing" lengths riding a sign-reversing direction cycle. *Circuit:* alternating sum of a monotone sequence, pairing lemma. (why it ranks first: it turns a

geometric definition into two one line algebraic objects with no case search, the same pairing device both rules points out and tells you exactly how many terms you need before every remaining point becomes free, and it converts the "prove impossible" half and the "prove possible" half into two short, independent arguments)

The ideal solution

Write the segment lengths of a growing spiral in order as $\ell_1 < \ell_2 < \cdots < \ell_n$, positive integers (integers because every P_i has integer coordinates and every step moves an integer amount along one axis). Split them by parity of index into the horizontal lengths $x_1 = \ell_1 < x_2 = \ell_3 < x_3 = \ell_5 < \cdots$ and the vertical lengths $y_1 = \ell_2 < y_2 = \ell_4 < y_3 = \ell_6 < \cdots$. Since these are alternate terms of one increasing sequence, they satisfy the finer interleaved chain

$$x_1 < y_1 < x_2 < y_2 < x_3 < y_3 < \cdots .$$

If P_n uses $a = \lceil n/2 \rceil$ horizontal steps and $b = \lfloor n/2 \rfloor$ vertical steps, tracking east, north, west, south directly gives

$$P_n = \Big(x_1 - x_2 + x_3 - \cdots + (-1)^{a-1} x_a,\ \ y_1 - y_2 + y_3 - \cdots + (-1)^{b-1} y_b \Big).$$

Lemma 15.1.1 (Sign of an alternating monotone sum)**.** *For a strictly increasing sequence of positive integers $c_1 < c_2 < \cdots < c_k$, put $A_k = c_1 - c_2 + c_3 - \cdots + (-1)^{k-1} c_k$. Then $A_k \geq c_1 > 0$ if k is odd, and $A_k < 0$ if k is even.*

Proof. If k is odd, pair every term after the first: $A_k = c_1 + (c_3 - c_2) + (c_5 - c_4) + \cdots + (c_k - c_{k-1})$; every bracket is positive since the sequence increases, so $A_k \geq c_1$. If k is even, pair from the start: $A_k = (c_1 - c_2) + (c_3 - c_4) + \cdots + (c_{k-1} - c_k)$; every bracket is negative, so $A_k < 0$. □

Apply the lemma to the x subsequence: the x coordinate of any P_n with $n \geq 1$ is positive when a is odd and negative when a is even. In particular it is never 0, so no point with $x = 0$ beyond P_0 is ever produced. This rules out $(0, y)$ for every $0 \leq y \leq 2011$: 2012 points.

Now apply the lemma to the y subsequence for $n \geq 4$, where $b = \lfloor n/2 \rfloor \geq 2$. If b is even, $y < 0$, outside our square entirely. If b is odd, then since $b \geq 2$ we in fact have $b \geq 3$, and we can sharpen the lemma using the interleaving: write $y = y_1 + (y_3 - y_2) + (y_5 - y_4) + \cdots + (y_b - y_{b-1})$. Each bracket $y_{2j+1} - y_{2j}$ is not merely positive, because the interleaved chain places x_{2j+1} strictly between y_{2j} and y_{2j+1}, forcing $y_{2j+1} \geq y_{2j} + 2$. So every bracket is at least 2, and $y_1 \geq 2$ since $y_1 > x_1 \geq 1$, giving $y \geq y_1 + 2 \geq 4$. So every point beyond P_3 has y-coordinate either negative or at least 4.

That leaves only P_2 and P_3 (where $b = 1$, $y = y_1$) to examine inside the square. $P_3 = (x_1 - x_2, y_1)$ has negative x-coordinate by the first part of the lemma ($a = 2$), so it never lies in our region. $P_2 = (x_1, y_1)$ has $x = x_1$ and $y = y_1$ with $1 \leq x_1 < y_1$ free, and conversely every pair $1 \leq x < y \leq 2011$ is achieved this way by the two step spiral with lengths $x < y$. So the entire region $0 < x < y$, for y from 1 to 2011, is achievable, and no point with $y \in \{0, 1\}$ is ever achievable (there is no valid x_1 with $1 \leq x_1 < 1$, and $y = 0$ never occurs for $n \geq 2$ at all), and for $y \in \{2, 3\}$ only $x < y$ is achievable, i.e. $x \geq 2$ is excluded when $y = 2$ and $x \geq 3$ is excluded when $y = 3$.

It remains to show every point with $x \geq y \geq 4$ is achievable, since $0 < x < y$ is already covered by P_2 and $y \leq 3$ is already fully classified. Take the six step spiral with lengths

$$1,\ 2,\ 3,\ x + 1,\ x + 2,\ x + y - 1$$

(strictly increasing exactly when $x \geq y \geq 4$, since then $x + 1 > 3$ and $x + y - 1 > x + 2$). Its endpoint has

$$X = 1 - 3 + (x + 2) = x, \qquad Y = 2 - (x + 1) + (x + y - 1) = y,$$

so $P_6 = (x, y)$ exactly. Hence every (x, y) with $x \geq y \geq 4$ is achievable, and combined with $0 < x < y$ for all y, every point with $y \geq 4$ is achievable.

Collecting the excluded points, which fall into five disjoint groups:

$$\underbrace{(0,y),\ 0 \leq y \leq 2011}_{2012} \cup \underbrace{(x,0),\ 1 \leq x \leq 2011}_{2011} \cup \underbrace{(x,1),\ 1 \leq x \leq 2011}_{2011} \cup \underbrace{(x,2),\ 2 \leq x \leq 2011}_{2010} \cup \underbrace{(x,3),\ 3 \leq x \leq 201}_{2009}$$

the total is

$$2012 + 2011 + 2011 + 2010 + 2009 = \boxed{10053}.$$

Layer 1: WHAT

Block 1: translate the geometric spiral into algebra, writing each coordinate of P_n as an alternating sum over one of the two interleaved increasing subsequences of lengths. Block 2: prove the x coordinate is never 0, by pairing the alternating sum from the front and reading off a strict sign from the leftover first term. Block 3: push the same pairing device on the y coordinate, then sharpen it using the interleaving with the x subsequence to get a gap of 2 per bracket instead of 1, which is what forces $y \geq 4$ rather than merely $y \geq 3$ once three or more vertical steps are involved. Block 4: dispose of the two small cases P_2 and P_3 directly, since they have too few vertical steps for the sharpened bound to apply, and note P_2 alone already supplies the entire region $0 < x < y$. Block 5: construct an explicit six step spiral with two free parameters to cover the remaining region $x \geq y \geq 4$, then assemble the five disjoint excluded strips and add.

The nominal route stares at pictures of spirals for $n = 2, \ldots, 10$ hoping the excluded pattern announces itself, then tries to extend that pattern to a square of side 2011 by analogy, with no proof that nothing new goes wrong further out. The ideal route never draws a single spiral for $n > 6$; it proves a sign lemma once and reuses it for every n simultaneously. The bifurcation point sits right after you read "lengths...strictly increasing": the zombie route reaches for graph paper, the ideal route reaches for the alternating sum.

Layer 2: HOW

Block 1. **Cue.** The direction cycle east, north, west, south repeats with period four, so odd numbered steps are horizontal and even numbered steps are vertical. **Why natural.** Splitting a single increasing sequence by parity of index is the natural move whenever a path alternates between two independent axes, because it converts one geometric object into two purely one dimensional ones that only interact through their shared global ordering. **Link to the next block.** Once each coordinate is a signed sum, the question of which points are reachable becomes a question about the sign and size of an alternating sum, which is a solved shape of problem the moment you name it.

Block 2. **Cue.** The lengths are strictly increasing, so consecutive terms in each subsequence differ, not merely stay level. **Why natural.** Strict monotonicity is precisely the hypothesis that lets you pair terms and get a bracket of a definite sign, which is why the lemma needs strictness and would fail for a merely nondecreasing sequence. **Link to the next block.** The sign of x never being zero rules out the entire $x = 0$ column in one stroke, without touching y at all, so the two coordinates can be analysed independently from here.

Block 3. **Cue.** Once $b \geq 3$, the vertical subsequence has enough terms for the pairing to leave brackets rather than a single leftover term. **Why natural.** Each bracket in the y sum is not just an increasing gap in the vertical subsequence, it is a gap that has a horizontal length interleaved strictly inside it, so the gap must be at least 2, not 1; this is where the specific interleaving of this problem, not a generic fact about increasing sequences, earns you the sharper constant. **Link to the next**

block. A gap of at least 4 for every $b \geq 3$ means the only y values still in doubt near the bottom of the square are 2 and 3, both of which come only from $b = 1$.

Block 4. **Cue.** $b = 1$ has no bracket to pair at all, since there is only one vertical term. **Why natural.** With one term, $y = y_1$ is simply the length itself, unconstrained except by $y_1 > x_1 \geq 1$, and $x = x_1$ is likewise free below y_1; two free positive integers with one strict inequality between them is exactly the region $0 < x < y$. **Link to the next block.** This single two step spiral already answers "which (x, y) with $y \leq 3$ are achievable," leaving only the region $x \geq y \geq 4$ needing a separate construction.

Block 5. **Cue.** The remaining region has two free coordinates and no sign constraint left to exploit, so this half of the proof is a construction, not an inequality. **Why natural.** Pinning every length except the last two to its smallest legal value maximises the room left for those two lengths, which is exactly enough freedom to solve for two target coordinates simultaneously; six steps is the smallest step count with two vertical and two horizontal degrees of freedom left after the three smallest lengths are spent on satisfying strict increase. **Link to the next block.** With every point in the square now classified as excluded or explicitly constructed, the final count is a straightforward disjoint sum over five strips, no inclusion or exclusion correction needed since the strips share no points.

Layer 3: WHY

The mathematical truth underneath this problem is that an alternating sum of a strictly increasing sequence behaves like a restoring force: each new term overcorrects the previous partial sum, and pairing consecutive terms from whichever end leaves the parity of the count correct turns that overcorrection into a definite, computable sign. This is the same mechanism behind the alternating series remainder bound in analysis, transplanted here into a finite, integer setting where "overcorrects by at least the gap between consecutive terms" becomes a genuine quantitative bound rather than a limiting statement.

The discernment mechanism for choosing this route over brute search is structural: any time a path or sequence definition hands you strict monotonicity plus a sign reversal, that combination is a standing invitation to pair terms rather than track a running total numerically. You train that discernment by refusing to touch a specific numerical case (spiral of length 2011, say) until you have exhausted what the general shape of the definition tells you for free.

The examiners nudged you toward this by choosing a 2012×2012 square far larger than the actual obstruction, which only reaches coordinate 3. That gap between the stated bound and the true size of the phenomenon is itself a signal: if the excluded set genuinely grew with the box size in a complicated way, the problem would have to tell you a formula in terms of the bound, but it only asks for a number, which means the interesting part of the answer is a small fixed pattern near the origin, and the rest of the square is a bookkeeping exercise in one flexible construction. Recognising that shape, a small structured core plus a fully free remainder, before you have proven a single line, is what separates a twenty minute solve from a search that never terminates.

Revolving concepts

Alternating sum of a monotone sequence. For strictly increasing positive $c_1 < \cdots < c_k$, the sum $c_1 - c_2 + \cdots \pm c_k$ has sign $(-1)^{k-1}$, proved by pairing from whichever end leaves a single leftover term; the same pairing gives a quantitative lower bound on the magnitude whenever you know a lower bound on consecutive gaps. See Book 1, field: Sequences and recurrences, topic: alternating sums and telescoping sign arguments. Wherever a further sequence is interleaved between the terms of the one you are summing, as here, the effective gap bound doubles or otherwise inflates, and that inflation is exactly what should be checked first whenever a pairing bound looks one short of what a problem needs.

Lattice point counting by complement. Rather than counting an achievable set directly, count its complement in a bounded box when the complement is structurally simpler; this is most powerful exactly when the achievable set is "everything past a small threshold," so the complement collapses to finitely many boundary rows and columns. See Book 1, field: Combinatorics, topic: complement counting in bounded lattices.

Existence via degree of freedom matching. To prove a whole two parameter family of targets is reachable by a constrained increasing sequence construction, spend the minimum number of terms pinning down the ordering constraint at its smallest legal values, then solve the two remaining free terms directly against the two target values. See Book 1, field: Combinatorics, topic: explicit constructions with matched degrees of freedom; this generalises to any problem asking you to realise an m parameter target using a sequence with more than m degrees of freedom once the ordering constraints are satisfied by the cheapest possible prefix.

Circuit Bank

- **WHEN** a quantity is defined as an alternating sum of a strictly increasing sequence **DO** pair terms from whichever end leaves the correct number of leftover terms for the sign you expect **BECAUSE** each pair then has a definite sign and the leftover term fixes the overall sign, handing you both existence of sign and a lower bound on magnitude for free
- **WHEN** a competition asks how many lattice points in a bounded box cannot arise from a construction **DO** look for the complement to split into a small boundary strip near the axes plus everything past a fixed threshold reached by one flexible construction **BECAUSE** monotonicity or increasing parameters in a construction typically exhaust their constraining power quickly, so obstructions rarely persist far from the origin
- **WHEN** you need to hit an arbitrary target pair with a constrained increasing sequence construction **DO** fix every length except the last two at its smallest legal value, then solve the remaining two lengths explicitly against the two target coordinates **BECAUSE** this isolates exactly two degrees of freedom mapping onto the two targets, and the smallest legal prefix leaves the largest possible range for those two free lengths
- **WHEN** a path alternates direction with period four across two axes **DO** split the step index set into odds and evens immediately and treat the two resulting subsequences as independent **BECAUSE** the two coordinates never interact except through the one shared global ordering constraint on all the lengths

Backtesting

1. First useful cue: the phrase "strictly increasing" attached to lengths whose directions cycle through all four compass points.
2. Method the expression suggested: split the increasing sequence by parity into two interleaved increasing subsequences, and read each coordinate off as an alternating sum of one of them.
3. Where you would hesitate, and the thought to reinforce: after proving x is never 0 with a bound of $x \geq x_1$, you might assume the analogous bound $y \geq y_1$ settles every case; reinforce that once a third term enters, the interleaving with the other axis's subsequence forces a strictly larger gap than the generic pairing bound gives.
4. The trap the question sets: the box is stated up to 2011, far past where the obstruction actually lives, tempting you to believe the excluded set depends on the bound in a complicated way and to search case by case instead of proving a fixed, small pattern.

5. What makes you recognise it faster next time: any "how many lattice points cannot occur" question built from a strictly increasing construction is a strong signal that the achievable set is everything past a bounded threshold, because monotonicity is exactly the hypothesis that eventually removes every obstruction.
6. The reusable decision rule: whenever directions cycle and lengths strictly increase, write both coordinates as alternating sums of the two parity classes before doing anything else, and look for a pairing that pins sign first, size second.

Mirror drills

1. Using the same square, which points on the diagonal $x = y$, for $1 \leq x \leq 2011$, cannot be the last point of a growing spiral? *Answer:* exactly $x = y \in \{1, 2, 3\}$ are excluded (row exclusions at $y = 1, 2, 3$ each still bite on the diagonal), and every $x = y \geq 4$ is achievable by the six step construction with equal target coordinates.
2. What is the smallest n for which P_n can have y-coordinate exactly 4? *Answer:* $n = 2$, using lengths $1 < 4$; the bound $y \geq 4$ proved for $b \geq 3$ is a lower bound for that family only, it does not mean every occurrence of $y = 4$ needs three vertical steps.
3. Generalise the square to $0 \leq x \leq N$, $0 \leq y \leq N$ for $N \geq 4$ and find the excluded count as a function of N; check it reduces to 10053 at $N = 2011$. *Answer:* the same five strips give $(N+1) + N + N + (N-1) + (N-2) = 5N - 2$, and $5(2011) - 2 = 10053$.

15.2 A2. telescoping an underspecified bounded recurrence

Let $a_1, a_2, \ldots$ and $b_1, b_2, \ldots$ be sequences of positive real numbers such that $a_1 = b_1 = 1$ and $b_n = b_{n-1}a_n - 2$ for $n = 2, 3, \ldots$. Assume that the sequence (b_j) is bounded. Prove that

$$S = \sum_{n=1}^{\infty} \frac{1}{a_1 a_2 \cdots a_n}$$

converges, and evaluate S.

Read it out loud

Read the recurrence aloud: b_n is built from b_{n-1} and a_n multiplicatively, then shifted down by 2. The initial values pin $a_1 = b_1 = 1$. The one hypothesis separating a solvable problem from an impossible one is that (b_j) stays bounded, nothing more specific than that. You are not told (b_j) converges, or is monotone, or takes any particular values, only that it never runs off to infinity. And yet the problem asks you to evaluate S exactly, down to a single number. That mismatch, an almost entirely unspecified sequence paired with a fully specified answer, is the loudest cue in the problem: whatever route you take, it has to produce a value for S that cannot depend on which bounded (b_j) you were handed, which means the mechanism underneath has to be an identity holding termwise, not a limiting property special to one sequence.

The field wired into this problem is sequences and recurrences, riding underneath a real analysis convergence argument, and the object under the hood, $\sum 1/(a_1 \cdots a_n)$, is a sum of reciprocal partial products, exactly the shape that appears whenever a recursively defined sequence is compared against a shifted or rescaled copy of itself. The first useful cue, readable within the first thirty seconds, is the single word "evaluate": had the problem only asked you to prove convergence, a boundedness or comparison argument alone would suffice, but asking you to evaluate S tells you a closed form exists and is waiting to be extracted, which should point you at once toward telescoping rather than estimation.

Solve $b_n = b_{n-1}a_n - 2$ for a_n and you get $a_n = (b_n + 2)/b_{n-1}$, a ratio of consecutive shifted terms of the same sequence b. A product of such ratios, $a_1 a_2 \cdots a_n$, is a textbook telescoping shape in disguise: whenever a term is a ratio of consecutive values of one underlying sequence, a product of many such terms collapses. Here the numerator runs over $b_k + 2$ and the denominator over b_{k-1}, two different partial products built from the same raw data, and that separation is exactly the auxiliary object you should build by hand before touching a single specific value of b_j.

Approaches, ranked worst to best

1. **hunt for an explicit closed form for b_n or a_n as a function of n.** *Cue:* a recursively defined sequence invites solving the recursion outright. *Circuit:* no circuit, treats an underspecified family as if it were one fixed sequence. (why it ranks here: (b_j) is only assumed positive and bounded, not pinned to any particular values, so no single closed form for b_n exists to find; every bounded positive sequence with $b_1 = 1$ is a valid instance of the problem, and chasing a formula that cannot exist wastes the opening minutes)

2. **compute S_1, S_2, S_3 explicitly in terms of $b_2, b_3, \ldots$, simplify, and guess the closed form for S_m before proving it by induction.** *Cue:* "evaluate S" implies a closed form exists to be found. *Circuit:* pattern spotting from small cases, then induction. (why it ranks here: it does work, and it is a legitimate fallback, but it spends ink grinding two or three partial sums by hand before the telescoping shape becomes visible, and a candidate who does not simplify aggressively can misidentify the constant or miss the pattern entirely)

3. **solve the recursion for a_n as a ratio of shifted b values, recognise $a_1 \cdots a_n$ as a ratio of two partial products, and build the auxiliary sequence $T_n = \prod b_i/(b_i+2)$ directly from that structure.** *Cue:* $a_n = (b_n+2)/b_{n-1}$ is a ratio of consecutive terms of one underlying sequence. *Circuit:* telescoping via a constructed partial product auxiliary sequence. (why it ranks first: it manufactures the closed form from the shape of the recursion itself rather than guessing it, the identity $1/(a_1 \cdots a_n) = \frac{3}{2}(T_{n-1} - T_n)$ falls out by direct algebra, and it makes transparent exactly where the specific value $b_1 = 1$ enters, namely only in fixing the constant $3/2$)

The ideal solution

For $n \geq 2$, since $b_{n-1} > 0$, solve the recurrence for a_n:

$$a_n = \frac{b_n + 2}{b_{n-1}}.$$

Since $a_1 = 1$, telescoping the product of these ratios gives, for every $n \geq 1$ (reading an empty product as 1),

$$a_1 a_2 \cdots a_n = \prod_{k=2}^{n} \frac{b_k + 2}{b_{k-1}} = \frac{(b_2+2)(b_3+2)\cdots(b_n+2)}{b_1 b_2 \cdots b_{n-1}},$$

so

$$\frac{1}{a_1 \cdots a_n} = \frac{b_1 b_2 \cdots b_{n-1}}{(b_2+2)(b_3+2)\cdots(b_n+2)}.$$

Define $T_0 = 1$ and $T_n = \prod_{i=1}^{n} \frac{b_i}{b_i+2}$ for $n \geq 1$. Then

$$T_{n-1} - T_n = \frac{b_1 \cdots b_{n-1}}{(b_1+2)\cdots(b_{n-1}+2)} \left(1 - \frac{b_n}{b_n+2}\right) = \frac{2\, b_1 \cdots b_{n-1}}{(b_1+2)\cdots(b_{n-1}+2)(b_n+2)}.$$

Since $b_1 = 1$, the factor $b_1 + 2 = 3$ is the only one that fails to cancel against $\frac{1}{a_1 \cdots a_n}$ above, leaving

$$T_{n-1} - T_n = \frac{2}{3} \cdot \frac{b_1 \cdots b_{n-1}}{(b_2+2)\cdots(b_n+2)} = \frac{2}{3} \cdot \frac{1}{a_1 \cdots a_n},$$

that is,

$$\frac{1}{a_1 \cdots a_n} = \frac{3}{2}\big(T_{n-1} - T_n\big) \qquad \text{for every } n \geq 1.$$

(At $n = 1$ both sides are checked directly against the empty product convention: the left side is $1/a_1 = 1$, and the right side is $\frac{3}{2}(T_0 - T_1) = \frac{3}{2}(1 - \frac{1}{3}) = 1$, since $T_1 = b_1/(b_1+2) = 1/3$.)

Summing this telescoping identity from $n = 1$ to m,

$$S_m := \sum_{n=1}^{m} \frac{1}{a_1 \cdots a_n} = \frac{3}{2}(T_0 - T_m) = \frac{3}{2}(1 - T_m).$$

Every factor $b_i/(b_i+2)$ lies strictly between 0 and 1 since $b_i > 0$, so $0 < T_m < 1$ for every m, which already shows (S_m) is increasing (each summand is positive) and bounded above by $3/2$. That alone proves (S_m) converges. To pin the exact limit, use the boundedness hypothesis: say $0 < b_j \leq B$ for every j. The function $t \mapsto t/(t+2)$ is strictly increasing on $(0, \infty)$, since its derivative is $2/(t+2)^2 > 0$, so

$$\frac{b_j}{b_j+2} \leq \frac{B}{B+2} =: r < 1 \qquad \text{for every } j.$$

Hence

$$0 < T_m = \prod_{i=1}^{m} \frac{b_i}{b_i+2} \leq r^m \longrightarrow 0 \qquad \text{as } m \to \infty,$$

and so

$$S = \lim_{m \to \infty} S_m = \frac{3}{2}(1 - 0) = \boxed{\frac{3}{2}}.$$

Layer 1: WHAT

Block 1: solve the recurrence for a_n, exposing it as a ratio of shifted terms of the single sequence b. Block 2: recognise that the product $a_1 \cdots a_n$ telescopes into a ratio of two separate partial products, one running over b_k and one over $b_k + 2$. Block 3: construct the auxiliary sequence T_n directly from that same ratio shape, and identify the reciprocal product as a constant multiple of $T_{n-1} - T_n$, using $b_1 = 1$ only to fix the constant. Block 4: sum the telescoping identity to get S_m in closed form, and read off both monotonicity and boundedness directly from that formula, settling convergence with no separate analytic estimate. Block 5: use the boundedness hypothesis on (b_j) to force $T_m \to 0$ via a uniform ratio bound, and conclude the exact value of S.

The nominal route computes S_1, S_2, S_3 by hand, stares at the growing mess of $b_2, b_3, \ldots$ terms, and tries to guess the pattern in S_m before proving it by induction. The ideal route never computes a single numerical partial sum; it builds the auxiliary sequence T_n straight from the algebraic shape of a_n and verifies the telescoping identity symbolically. The bifurcation point sits right after solving $a_n = (b_n + 2)/b_{n-1}$: the zombie route starts substituting $n = 1, 2, 3$ into the definition of S_m, the ideal route asks what partial product, built from the same raw pieces, has a consecutive difference equal to this term.

Layer 2: HOW

Block 1. **Cue.** The recurrence gives b_n in terms of b_{n-1} and a_n multiplicatively, with b_{n-1} guaranteed nonzero since every b_j is positive. **Why natural.** Isolating a_n is the only way to access the product $a_1 \cdots a_n$ that the sum actually needs, since the sum is stated directly in terms of that product, not in terms of b_n alone. **Link to the next block.** Once a_n is a ratio of shifted b terms, the product $a_1 \cdots a_n$ becomes a product of such ratios, precisely the shape that collapses under telescoping.

Block 2. **Cue.** The product $\prod_{k=2}^{n} (b_k + 2)/b_{k-1}$ is a product of fractions with no shared factors forced together. **Why natural.** Multiplying fractions never entangles numerator and denominator sequences; they regroup independently into one partial product over $b_k + 2$ and a separate partial product over b_{k-1}, which is just b reindexed down by one. **Link to the next block.** Seeing two cleanly separated partial products is what tells you to compare ONE auxiliary sequence built from each piece, rather than trying to simplify the whole fraction as a single object.

Block 3. **Cue.** The two partial products differ only by a shift of $+2$ inside one factor at a time. **Why natural.** A ratio of "the same partial product with one factor shifted" is the canonical telescoping shape, because $T_{n-1} - T_n$ automatically isolates the difference contributed by a single factor, $1 - b_n/(b_n + 2)$, while every other factor cancels unchanged between the two partial products. **Link to the next block.** This identity holds symbolically before you ever plug in $b_1 = 1$, so summing it from here on is purely mechanical, not exploratory.

Block 4. **Cue.** A telescoping identity summed over n collapses to its two endpoint terms. **Why natural.** That collapse is the defining property of telescoping, and it hands you S_m as an explicit two term closed form with no residual sum left over. **Link to the next block.** An explicit closed form for S_m answers both halves of the problem at once: convergence becomes a one line check of monotonicity and boundedness on that formula, not a separate estimate built from scratch.

Block 5. **Cue.** The only hypothesis left unused at this point is that (b_j) is bounded. **Why natural.** Boundedness is exactly what lets a product of many factors, each strictly less than 1, be pushed all the way down to 0, via one uniform ratio bound $r < 1$; without a uniform bound the factors could creep toward 1 too fast for the product to vanish. **Link to the next block.** Once $T_m \to 0$ is

established, the closed form from Block 4 hands you the numerical value of S immediately, with no further work.

Layer 3: WHY

The mathematical truth underneath this problem is that a product of ratios of consecutive or shifted terms of one sequence always telescopes: more generally, any sum whose n-th term can be written as $c(U_{n-1} - U_n)$ for some auxiliary sequence U_n built from the same raw data collapses to $c(U_0 - \lim U_n)$. The discernment mechanism for reaching for this rather than estimation is structural: whenever a sum's general term is a product of ratios built from one recursively defined sequence, actively construct the matching partial product auxiliary sequence before attempting any inequality. You train that discernment by asking, of any product-of-ratios term, what is the simplest partial product built from the same pieces whose consecutive difference reproduces this term up to a constant.

It is also worth naming explicitly why the underspecification of (b_j) is not an obstacle but a guarantee. A Putnam problem that asks you to "evaluate" a quantity built from a sequence constrained only by an inequality, here boundedness, is telling you the answer cannot depend on information you were never given; the only way that can happen is if the quantity is pinned by an identity true for every admissible sequence, not by an estimate tailored to one. Once you internalise that, "evaluate" versus "estimate" or "bound" becomes a reliable signal for which kind of argument the examiners are asking for, before you have written a single line of algebra.

Finally, it is worth checking exactly how much of the given numerical data is load bearing, because that tells you what generalises. Replace the shift -2 in the recurrence by a general $-k$ for $k > 0$, keeping $a_1 = b_1 = 1$, and the identical derivation with $T_n = \prod b_i/(b_i + k)$ gives $1/(a_1 \cdots a_n) = \frac{1+k}{k}(T_{n-1} - T_n)$, so under the same boundedness hypothesis $S = 1 + \frac{1}{k}$; setting $k = 2$ recovers $3/2$. The constant $3/2$ is not a numerological accident of this specific problem, it is $(b_1 + 2)/2$ read off directly from the algebra, and the examiners' choice of shift 2 together with $b_1 = 1$ is simply one convenient instance of a whole family of identical arguments.

Revolving concepts

Telescoping via a constructed auxiliary partial product. When a term is a product of ratios of shifted values of one recursively defined sequence (b_i), build $T_n = \prod_{i \le n} b_i/(b_i + k)$ from the same raw pieces; the term equals a constant multiple of $T_{n-1} - T_n$, and the sum collapses to that constant times $T_0 - \lim T_n$. See Book 1, field: Sequences and recurrences, topic: telescoping sums from recursively defined data. The recursion generalises cleanly: replacing the shift 2 by any $k > 0$ (with $a_1 = b_1 = 1$ fixed) gives $S = 1 + 1/k$ under the same boundedness hypothesis, so the specific numbers in this problem are one instance of a one parameter family of identical telescoping arguments.

Monotone bounded sequences and geometric domination. A sum of positive terms whose partial sums have an explicit closed form $c(1 - T_m)$ with $0 < T_m < 1$ is automatically increasing and bounded above by c, proving convergence without a separate estimate; if in addition every factor of T_m is bounded above by a fixed ratio $r < 1$, then $T_m \le r^m \to 0$ geometrically, pinning the exact limit. See Book 1, field: Real analysis, topic: monotone convergence and geometric bounds on products.

Monotone functions converting a bound on one quantity into a bound on a related one. For fixed $k > 0$, $t \mapsto t/(t + k)$ is strictly increasing on $(0, \infty)$, so a uniform upper bound $b_j \le B$ converts directly into a uniform upper bound $b_j/(b_j + k) \le B/(B + k)$ on the ratio. See Book 1, field: Real analysis, topic: monotone transformations of bounds.

Circuit Bank

- **WHEN** a series' general term is a product of ratios built from one recursively defined sequence **DO** construct the auxiliary partial product sequence from the same raw pieces and look for a constant multiple of its consecutive difference **BECAUSE** such products are exactly the telescoping shape, and the constant is fixed by the boundary values already given in the problem
- **WHEN** a problem asks you to "evaluate" a sum or limit built from an underspecified sequence, constrained only by an inequality such as boundedness **DO** expect an identity valid for every admissible sequence rather than an estimate tailored to one particular choice **BECAUSE** the answer cannot depend on information you were never given, so only a universal identity can pin it down
- **WHEN** you have reduced a partial sum to an explicit two term closed form **DO** read off monotonicity and boundedness directly from that formula for the convergence half, and the limiting behaviour of the remaining term for the value half **BECAUSE** a single closed form answers both halves of a "prove convergence and evaluate" question at once, with no separate analytic estimate needed
- **WHEN** a boundedness hypothesis on a positive sequence is the only unused hypothesis left **DO** convert it into a uniform ratio bound $r < 1$ via a monotone function of that sequence, then bound a product of such factors by r^m **BECAUSE** a single uniform ratio bound is exactly what lets a product of many sub unit factors be squeezed to zero geometrically

Backtesting

1. First useful cue: the instruction "prove S converges, and evaluate S" attached to a sum whose sequence (b_j) is left almost entirely unspecified.
2. Method the expression suggested: solve the recurrence for a_n as a ratio of shifted b terms, exposing $a_1 \cdots a_n$ as a ratio of two partial products built from the same data.
3. Where you would hesitate, and the thought to reinforce: after seeing the product-of-ratios shape, you might reach for estimation, bounding S_m above and below, rather than an exact identity; reinforce that "evaluate" is a guarantee an exact telescoping identity exists, since the answer cannot depend on an unspecified sequence.
4. The trap the question sets: it hands you a boundedness hypothesis that looks built for a comparison or estimation argument, tempting you to skip the exact algebraic identity and reach straight for inequalities.
5. What makes you recognise it faster next time: any sum whose n-th term is a product of ratios built from one recursively defined sequence is a telescoping candidate; build the matching partial product auxiliary sequence before attempting any estimate.
6. The reusable decision rule: when a series' term is a product of ratios of one sequence's shifted values, construct the auxiliary partial product from the same pieces, express the term as a constant multiple of its consecutive difference, sum it in closed form, and only then bring in any remaining hypothesis, such as boundedness, to evaluate the limit of the auxiliary sequence.

Mirror drills

1. Same recurrence but with shift -4 in place of -2 (still $a_1 = b_1 = 1$, (b_j) positive and bounded). Find $S = \sum 1/(a_1 \cdots a_n)$. *Answer:* by the same telescoping with $k = 4$, $S = 1 + \frac{1}{4} = \frac{5}{4}$.

2. Suppose (b_j) were only known to be bounded in absolute value, not necessarily positive, with a_n still defined by the same recurrence and assumed nonzero. Does the proof that $T_m \to 0$ still go through? *Answer:* no; $t/(t+2)$ need not lie in $(0,1)$, or can even be undefined near $t=-2$, once t is allowed negative, so the uniform bound $r<1$ collapses entirely, showing positivity of every b_j is load bearing, not a convenience.

3. If (b_j) is bounded above by $B=4$ specifically, give an explicit rate at which S_m approaches $\frac{3}{2}$. *Answer:* $r = B/(B+2) = 2/3$, so $S - S_m = \frac{3}{2}T_m \le \frac{3}{2}(2/3)^m$, a geometric rate.

15.3 A3. the endpoint order forced by a vanishing cosine

Find a real number c and a positive number L for which

$$\lim_{r\to\infty} \frac{r^c \displaystyle\int_0^{\pi/2} x^r \sin x\, dx}{\displaystyle\int_0^{\pi/2} x^r \cos x\, dx} = L.$$

Read it out loud

Read the limit aloud: a ratio of two integrals that look almost identical, same power weight x^r, same interval $[0, \pi/2]$, one dressed with $\sin x$ and one with $\cos x$, multiplied by a power of r whose exponent you must supply, with the goal of landing on a finite positive constant. The command "find a real number c" rather than "evaluate the limit" for a given c is itself informative: it tells you upfront that the raw ratio, with no correction at all, does not converge to a finite nonzero number. It must diverge, to 0 or to infinity, at some definite polynomial rate in r, and your entire job is to name that rate and the constant that survives it.

The field wired in is calculus and integrals, specifically the asymptotics of a family of integrals as a parameter $r \to \infty$, riding on a real analysis squeeze argument. Both integrands share the factor x^r, an increasingly sharply peaked weight concentrating near the right endpoint $x = \pi/2$ as r grows, since for any fixed $x_0 < \pi/2$ the ratio $(x_0/(\pi/2))^r$ decays geometrically, making the contribution to either integral from $x \le x_0$ negligible in comparison. The first useful cue, readable within thirty seconds, is a single pair of values: $\cos(\pi/2) = 0$ while $\sin(\pi/2) = 1$. Because the weight x^r concentrates exactly where cosine vanishes and sine does not, the cosine integral must be systematically smaller than the sine integral, by a factor that grows with r. This single fact, before any calculation, already tells you c must be negative to counteract a ratio that blows up, and it tells you $\cos(\pi/2) = 0$ is not incidental, it is the entire reason a nontrivial exponent is needed at all.

Naming that boundary value also suggests which direction integration by parts should run. If you integrate the cosine integral by parts differentiating $\cos x$, the factor that vanishes at $\pi/2$, rather than integrating it, whatever boundary term appears dies automatically instead of needing to be estimated. That observation converts the cosine integral into a sine integral one step higher in r, divided by $r + 1$, an exact identity rather than an approximation, and it means you only ever need one asymptotic estimate, of the sine integral, applied at two consecutive values of r.

Approaches, ranked worst to best

1. **repeated integration by parts to a closed finite form, then extract asymptotics termwise.** *Cue:* a definite integral of x^r against a trigonometric factor invites reducing the power of x step by step. *Circuit:* no circuit, brute reduction. (why it ranks here: this only terminates cleanly for integer r, produces an r term alternating sum of boundary values, and still forces you to argue separately that the boundary term at $\pi/2$ dominates the rest, doing strictly more work to reach the same leading order that a direct estimate gives at once)

2. **argue heuristically that x^r concentrates at $\pi/2$, substitute $x = \pi/2 - t/r$, and approximate $\sin x \approx 1$, $\cos x \approx 2t/\pi$ near the endpoint.** *Cue:* x^r is an increasingly sharp bump at the right endpoint as $r \to \infty$. *Circuit:* Laplace's method intuition, unproven. (why it ranks here: this correctly identifies why the answer is what it is, and is exactly the right picture to carry in your head, but turning it into a fully rigorous bound needs more machinery, controlled error terms on the substitution, than a direct elementary inequality supplies, so a full write up this way costs more ink for no extra rigor)

3. **integrate the cosine integral by parts in the direction that kills the boundary term exactly, reducing it to a shifted sine integral, then pin the sine integral's exact leading asymptotic with a two sided elementary inequality.** *Cue:* $\cos(\pi/2) = 0$ paired with an interval ending exactly at $\pi/2$. *Circuit:* exact self reduction via integration by parts, plus Jordan's inequality squeeze. (why it ranks first: it is fully rigorous with a single elementary inequality, it needs only one asymptotic estimate rather than two, and it exploits the vanishing boundary value exactly rather than approximately)

The ideal solution

Write $f(r) = \displaystyle\int_0^{\pi/2} x^r \sin x\,dx$ and $g(r) = \displaystyle\int_0^{\pi/2} x^r \cos x\,dx$.

Step 1: an exact reduction of g to f. Integrate $g(r)$ by parts with $u = \cos x$, $dv = x^r\,dx$, so $du = -\sin x\,dx$ and $v = x^{r+1}/(r+1)$:

$$g(r) = \left[\cos x \cdot \frac{x^{r+1}}{r+1}\right]_0^{\pi/2} + \int_0^{\pi/2} \frac{x^{r+1}}{r+1} \sin x\,dx.$$

At $x = \pi/2$ the bracket vanishes because $\cos(\pi/2) = 0$; at $x = 0$ it vanishes because $x^{r+1} \to 0$ (for $r > -1$). So the boundary term is exactly 0, and

$$g(r) = \frac{f(r+1)}{r+1}.$$

Step 2: the exact leading asymptotic of f. On $[0, \pi/2]$, $\sin x < 1$, so

$$f(r) < \int_0^{\pi/2} x^r\,dx = \frac{(\pi/2)^{r+1}}{r+1}.$$

Since sin is concave on $[0, \pi/2]$, its graph lies above the chord from $(0,0)$ to $(\pi/2, 1)$, which is Jordan's inequality $\sin x \geq \frac{2x}{\pi}$, so

$$f(r) > \int_0^{\pi/2} \frac{2x^{r+1}}{\pi}\,dx = \frac{2}{\pi} \cdot \frac{(\pi/2)^{r+2}}{r+2} = \frac{(\pi/2)^{r+1}}{r+2}.$$

Multiplying the two bounds by $r(2/\pi)^{r+1} > 0$,

$$\frac{r}{r+2} < r\left(\frac{2}{\pi}\right)^{r+1} f(r) < \frac{r}{r+1},$$

and both outer expressions tend to 1 as $r \to \infty$, so by the squeeze theorem,

$$\lim_{r\to\infty} r\left(\frac{2}{\pi}\right)^{r+1} f(r) = 1. \qquad (\star)$$

Step 3: the ratio of consecutive values. Write $u_r = r(2/\pi)^{r+1} f(r)$, so $u_r \to 1$ by $(\star)$, and $f(r) = u_r \cdot \frac{1}{r}(\pi/2)^{r+1}$. Then

$$\frac{f(r)}{f(r+1)} = \frac{u_r}{u_{r+1}} \cdot \frac{r+1}{r} \cdot \frac{(\pi/2)^{r+1}}{(\pi/2)^{r+2}} = \frac{u_r}{u_{r+1}} \cdot \frac{r+1}{r} \cdot \frac{2}{\pi} \longrightarrow 1 \cdot 1 \cdot \frac{2}{\pi} = \frac{2}{\pi} \qquad (r \to \infty).$$

Step 4: assembling the answer. Using Step 1,

$$\frac{r^c f(r)}{g(r)} = \frac{r^c f(r)(r+1)}{f(r+1)} = r^c(r+1) \cdot \frac{f(r)}{f(r+1)}.$$

By Step 3 the factor $\frac{f(r)}{f(r+1)}$ tends to $\frac{2}{\pi}$, and $(r+1) \sim r$, so the whole expression is asymptotically $\frac{2}{\pi} r^{c+1}$. This tends to a finite nonzero limit exactly when $c+1=0$: if $c > -1$ the expression diverges to infinity, and if $c < -1$ it tends to 0. So $c = -1$ is forced, and with $c = -1$,

$$\lim_{r\to\infty} \frac{r+1}{r} \cdot \frac{f(r)}{f(r+1)} = 1 \cdot \frac{2}{\pi} = \frac{2}{\pi}.$$

Hence

$$\boxed{(c, L) = \left(-1, \frac{2}{\pi}\right)},$$

and this is the only such pair, since no other value of c produces a finite positive limit.

Layer 1: WHAT

Block 1: reduce the cosine integral exactly to a sine integral one step higher in r, using integration by parts in the direction that kills the boundary term because $\cos(\pi/2) = 0$. Block 2: bound the sine integral above and below by the same power integral, using $\sin x < 1$ and Jordan's inequality, giving matching leading order. Block 3: squeeze the two bounds to pin the exact constant in front of $(\pi/2)^{r+1}/r$, not merely its order. Block 4: reuse that single estimate at two consecutive parameters, r and $r+1$, to get the ratio $f(r)/f(r+1) \to 2/\pi$. Block 5: combine the exact reduction and the ratio limit, and match polynomial orders in r to force $c = -1$ and read off L.

The nominal route tries to compute $f(r)$ and $g(r)$ in closed form by repeated integration by parts, or else waves at "the mass concentrates near $\pi/2$" without ever pinning a constant. The ideal route reduces g to f exactly in one step, then estimates f exactly once with an elementary two sided inequality, and reuses that one estimate twice. The bifurcation point sits right after noticing $\cos(\pi/2) = 0$: the zombie route starts grinding a closed form for $g(r)$ term by term, the ideal route asks which integration by parts direction makes the boundary term vanish for free and stops after a single step.

Layer 2: HOW

Block 1. **Cue.** $\cos(\pi/2) = 0$ sits exactly at the endpoint where x^r concentrates as $r \to \infty$. **Why natural.** Integration by parts has two directions; choosing to differentiate the factor that already vanishes at the endpoint of interest, rather than integrate it, forces the resulting boundary term to be exactly 0 rather than merely small, turning an approximate comparison into an exact algebraic identity. **Link to the next block.** Once $g(r) = f(r+1)/(r+1)$ is exact, the entire problem reduces to understanding one function, f, at two nearby arguments, so no second, structurally different estimate is ever needed.

Block 2. **Cue.** $\sin x$ is trivially below 1 and, being concave on $[0, \pi/2]$, lies above the straight chord joining its endpoint values. **Why natural.** A concave function always lies above any chord connecting two of its points, and the chord from $(0,0)$ to $(\pi/2, 1)$ is the specific linear function $2x/\pi$, giving a lower bound of exactly the same shape, a constant times x, as the trivial upper bound of 1. **Link to the next block.** Two bounds of matching shape, both constants times the pure power x^r or x^{r+1}, integrate to two expressions that differ only in their constant, setting up a squeeze rather than a one sided estimate.

Block 3. **Cue.** Both bounds, once integrated and multiplied by $r(2/\pi)^{r+1}$, become rational functions of r that visibly tend to the same limit, 1. **Why natural.** The squeeze theorem applies whenever two bounds sandwiching a quantity converge to a common limit; here that common limit is forced by $r/(r+1) \to 1$ and $r/(r+2) \to 1$, both elementary. **Link to the next block.** Pinning the

exact constant, not just the exact power of r, is what makes the final answer L computable rather than merely "some positive number."

Block 4. Cue. The same asymptotic statement $(\star)$ is true for every large r, in particular for r and for $r+1$ simultaneously. **Why natural.** Dividing the statement at r by the statement at $r+1$ cancels the unknown behaviour $u_r, u_{r+1} \to 1$ in the limit and leaves only the explicit, elementary factors $r/(r+1)$ and a fixed power of $2/\pi$, so the ratio of consecutive values of f is extracted with no new estimation. **Link to the next block.** This ratio is exactly the quantity the exact reduction from Block 1 needs, since $g(r)$ was expressed in terms of $f(r+1)$, not $f(r)$ directly.

Block 5. Cue. The assembled expression $r^c(r+1)f(r)/f(r+1)$ is asymptotically a nonzero constant times r^{c+1}. **Why natural.** A power of r has a finite nonzero limit as $r \to \infty$ if and only if that power is exactly r^0, which pins the exponent $c+1=0$ uniquely; any other value of c sends the expression to 0 or to infinity. **Link to the next block.** This is the last step precisely because it needs both earlier results at once, the exact reduction for the extra factor of $r+1$, and the ratio limit for the constant $2/\pi$, so it could not have been done first.

Layer 3: WHY

The mathematical truth underneath this problem is a special case of endpoint concentration asymptotics: for a continuous weight w on $[a,b]$ with $w(b) > 0$, $\int_a^b x^r w(x)\,dx \sim \dfrac{b^{r+1}w(b)}{r}$ as $r \to \infty$, because the mass of x^r concentrates geometrically fast at the right endpoint, so only the value of w right at b, not its behaviour elsewhere on $[a,b]$, controls the leading order. When $w(b)=0$, as for cosine at $\pi/2$, this leading order estimate gives 0, telling you the true order is one power of r smaller, exactly matching the extra factor of $1/(r+1)$ that fell out of the exact integration by parts identity. The elementary squeeze used here, sandwiching $\sin x$ between 1 and $2x/\pi$, is nothing but a fully rigorous, self contained substitute for that general endpoint lemma in this one case, avoiding any need to import or prove the general statement.

The discernment mechanism for reaching for this rather than brute computation is to check, before any calculus, the value of each weight function exactly at the endpoint where the dominant power concentrates. Whenever one weight is nonzero there and another vanishes there, expect the two integrals to differ by a definite power of r, and expect that power to be extractable by comparing orders alone, with the constant supplied afterward by whichever elementary bound is tightest at the endpoint. You train this discernment by refusing to compute a single integral numerically until you have named both endpoint values and predicted, in words, which integral should be smaller and by roughly what order.

The examiners nudged you here by choosing sine and cosine on precisely $[0, \pi/2]$, an interval whose right endpoint makes one function equal to 1 and the other equal to 0, manufacturing exactly a one order of r gap between two otherwise structurally identical integrals. The phrasing "find c and L", rather than stating c outright, forces you to notice that gap and name it yourself, rather than being handed the answer's shape in advance.

Revolving concepts

Endpoint concentration asymptotics for power weighted integrals. For w continuous on $[a,b]$ with $w(b) > 0$, $\int_a^b x^r w(x)\,dx \sim b^{r+1}w(b)/r$ as $r \to \infty$; the weight's value elsewhere on the interval is asymptotically irrelevant. See Book 1, field: Calculus and integrals, topic: Laplace type endpoint asymptotics. This generalises as a two term recursion in r: consecutive members of such a family satisfy $f(r)/f(r+1) \to 1/b$, and a weight vanishing at b drops the order of the integral by exactly

one full power of r relative to a weight that does not vanish there, which is the entire mechanism behind this problem's answer.

Jordan's inequality. $\sin x \geq 2x/\pi$ for $x \in [0, \pi/2]$, an immediate consequence of the concavity of sin on that interval, since a concave function lies above every chord joining two of its points, here the chord from $(0, 0)$ to $(\pi/2, 1)$. See Book 1, field: Inequalities, topic: concavity based bounds on trigonometric functions.

Integration by parts direction chosen to annihilate a boundary term. When one factor of a product vanishes at an endpoint of interest, differentiate that factor rather than integrate it, so the resulting boundary term is exactly zero, converting a comparison that would otherwise need an error estimate into an exact identity. See Book 1, field: Calculus and integrals, topic: strategic choice of u and dv in integration by parts.

Circuit Bank

- **WHEN** two integrals $\int_a^b x^r w_1(x)\,dx$ and $\int_a^b x^r w_2(x)\,dx$ share the same power weight concentrating as $r \to \infty$ **DO** compare the two weights' values at the concentration endpoint b before doing any calculation **BECAUSE** whichever weight vanishes there produces a systematically smaller integral, off by one full power of r, and that comparison is free, needing no integration at all
- **WHEN** integrating a product by parts, and one factor vanishes at the endpoint of interest **DO** differentiate that vanishing factor rather than integrate it, so the boundary term dies automatically **BECAUSE** this turns an approximate comparison into an exact identity with no error term left to control
- **WHEN** you need the leading asymptotic order of $\int_a^b x^r w(x)\,dx$ and w is continuous and positive at b **DO** squeeze between two matching bounds, such as $w(b) - \epsilon$ and $w(b) + \epsilon$, or a specific two sided inequality like Jordan's, each integrated against the same pure power **BECAUSE** the mass concentrates at b geometrically fast, so only the value of w right at b controls the leading order, and a matched two sided bound pins the exact constant, not merely the order
- **WHEN** a limit is phrased as "find c and L" rather than "evaluate this limit" **DO** expect the raw, uncorrected expression to provably diverge to 0 or infinity at a definite polynomial rate, and treat your job as naming that rate and the surviving constant **BECAUSE** the phrasing itself is telling you the uncorrected limit does not exist finitely, so guessing $c = 0$ wastes time that direct order matching would save

Backtesting

1. First useful cue: $\cos(\pi/2) = 0$ while $\sin(\pi/2) = 1$, sitting exactly at the endpoint where x^r concentrates as $r \to \infty$.
2. Method the expression suggested: integrate the cosine integral by parts differentiating $\cos x$, the factor that vanishes at $\pi/2$, so the boundary term dies exactly, reducing it to a shifted sine integral.
3. Where you would hesitate, and the thought to reinforce: after obtaining the exact reduction $g(r) = f(r+1)/(r+1)$, it is easy to think the hard work is done; reinforce that an exact identity between g and f at a shifted argument is not itself a number, you still need to know how f scales with r to extract a ratio.
4. The trap the question sets: it asks you to "find" c and L rather than stating c, tempting a candidate to guess a round number like $c = 0$ or $c = 1$ by pattern matching rather than deriving the rate from the vanishing of cosine at the endpoint.

5. What makes you recognise it faster next time: whenever a limit compares two integrals of x^r against different weights as $r \to \infty$, check the weights' values exactly at the endpoint where x^r concentrates before doing any calculus; a vanishing weight there is a guaranteed source of one extra power of r in the final answer.
6. The reusable decision rule: reduce a comparison between two differently weighted power integrals to a comparison of the SAME weighted integral at two nearby parameters whenever an exact identity, typically via integration by parts choosing the boundary killing direction, makes that possible, so only one asymptotic estimate is ever needed, applied twice.

Mirror drills

1. Find real c and positive L with $\lim_{r\to\infty} \dfrac{r^c \int_0^{\pi/2} x^r\,dx}{\int_0^{\pi/2} x^r \cos x\,dx} = L$. *Answer:* the numerator is exactly $(\pi/2)^{r+1}/(r+1)$, of the same nonvanishing order as $f(r)$ since the constant weight 1 agrees with $\sin(\pi/2) = 1$ at the endpoint; the same reduction for $g(r)$ applies unchanged, giving $(c, L) = (-1, 2/\pi)$ again.
2. Swap the roles: find real c and positive L with $\lim_{r\to\infty} \dfrac{r^c \int_0^{\pi/2} x^r \cos x\,dx}{\int_0^{\pi/2} x^r \sin x\,dx} = L$. *Answer:* this is the reciprocal of the original ratio, so $c = 1$ (not -1) and $L = \pi/2$, the reciprocal of $2/\pi$.
3. Without fully computing it, give the leading asymptotic order of $\int_0^{\pi/2} x^r \sin^2 x\,dx$ as $r \to \infty$. *Answer:* since $\sin^2(\pi/2) = 1 \neq 0$, the endpoint concentration lemma gives order $(\pi/2)^{r+1}/r$ with constant 1, the same leading behaviour as $f(r)$ itself.

15.4 A4. Prescribed parities of dot products

For which positive integers n is there an $n \times n$ matrix with integer entries such that every dot product of a row with itself is even, while every dot product of two different rows is odd?

Read it out loud

Say the structure out loud before you write anything. You are given n vectors and every one of the n^2 pairwise dot products is prescribed, but only modulo 2. The entries are integers, yet no size information is used anywhere in the hypotheses. The only thing about the matrix that the question can see is the reduction of each entry modulo 2. So the honest restatement is: for which n is there a matrix $\overline{M}$ over the two element field $\mathbb{F}_2$ whose Gram matrix $\overline{M}\,\overline{M}^T$ has zero diagonal and ones off the diagonal?

The fields wired into the problem are linear algebra over a finite field, Gram matrices and rank, and the behaviour of squaring in characteristic 2. What is really being tested is whether you convert a parity statement into a statement over $\mathbb{F}_2$ immediately, instead of dragging integers around, and whether you package n^2 separate conditions into one matrix equation instead of manipulating them one at a time.

Within thirty seconds you should have two lines on the page. Line one: $\overline{M}\,\overline{M}^T = J - I$ over $\mathbb{F}_2$, where J is the all ones matrix and I the identity. Line two: over $\mathbb{F}_2$ we have $x^2 = x$, so the dot product of a row with itself equals the sum of the entries of that row; hence the diagonal condition says exactly $\overline{M}v = 0$, where v is the all ones column vector. Two conditions, both linear algebraic, one about the Gram matrix and one about the kernel. The whole problem is whether those two can coexist.

Approaches, ranked worst to best

1. **Hand search for examples.** *Cue:* the phrase "for which positive integers n" invites experiment. *Circuit:* small case testing. You build examples for $n = 1, 2, 3, 4$ and guess that odd n works. That is worth sixty seconds as reconnaissance, but it can never close the problem: for even n you would have to exhaust an infinite family of integer matrices. It ranks last because it produces a conjecture and no obstruction, and on the Putnam an answer with no obstruction scores near zero.

2. **Global parity count over $\mathbb{Z}$.** *Cue:* sums of dot products look like an expanded square. *Circuit:* expand $\|\sum_i r_i\|^2$. Write $s = r_1 + \cdots + r_n$ and expand: $\|s\|^2 = \sum_i \|r_i\|^2 + \sum_{i \neq j} r_i \cdot r_j \equiv 0 + n(n-1) \pmod 2$. For n even this gives $\|s\|^2$ even, which is true and useless. It ranks above pure search because it is a real attempt at an obstruction, but it stalls for a nameable reason: it extracts one scalar from an $n \times n$ table of information, and one scalar cannot see the difference between odd and even n.

3. **Linear dependence of the rows over $\mathbb{F}_2$.** *Cue:* a singular matrix has a dependency among its rows. *Circuit:* turn singularity into a nonempty index set S with $\sum_{i \in S} r_i = 0$. From $\overline{M}v = 0$ the matrix is singular, so some nonempty S has $\sum_{i \in S} r_i = 0$. Dotting with r_j for $j \in S$ gives $|S| - 1 \equiv 0$, so $|S|$ is odd; dotting with r_j for $j \notin S$ gives $|S| \equiv 0$, so no such j exists, so S is everything and $n = |S|$ is odd. This is complete and elementary. It ranks here only because it splits into two cases that the next two routes avoid.

4. **Gram determinant over $\mathbb{F}_2$.** *Cue:* all pairwise dot products means Gram matrix, and nonexistence means determinant. *Circuit:* $\det(\overline{M})^2 = \det(J - I)$. Over $\mathbb{Z}$, $\det(J - I) = (-1)^{n-1}(n-1)$, which is odd when n is even, so $\det \overline{M} \neq 0$ and $\overline{M}$ is invertible, contradicting $\overline{M}v = 0$. Short and correct. It ranks below the winner only because it imports the spectrum of J and a determinant computation that you do not need.

5. **Gram rank over $\mathbb{F}_2$, via the involution.** *Cue:* $J - I$ squares to something recognisable. *Circuit:* $\operatorname{rank}(AB) \le \operatorname{rank}(A)$. Over $\mathbb{F}_2$, $(J-I)^2 = J^2 - 2J + I = nJ + I$. For n even this is I, so $J - I$ is its own inverse, hence of rank n, hence $\overline{M}$ has rank n and trivial kernel, contradicting $\overline{M}v = 0$. For n odd the same computation gives $(J-I)^2 = J - I$, an idempotent of rank $n-1$ with kernel spanned by v, which is not a contradiction but a blueprint for the construction. Best route: three lines, no determinants, and it hands you the example.

The ideal solution

The answer is $\boxed{n \text{ odd}}$.

Throughout, J is the $n \times n$ all ones matrix, I the identity, and v the all ones column vector. Write $r_1, \dots, r_n$ for the rows.

Odd n works. Take $M = J - I$ over $\mathbb{Z}$, that is, zeros on the diagonal and ones elsewhere. The dot product of a row with itself counts the $n-1$ entries equal to 1, giving $n-1$, which is even. For $i \neq j$, rows i and j have a 1 in a common position exactly at the $n-2$ positions different from both i and j, giving $n-2$, which is odd. Both conditions hold precisely because n is odd.

Even n fails. Suppose n is even and M is an integer matrix with the stated properties. Every hypothesis is a congruence modulo 2, and reduction modulo 2 is a ring homomorphism, so we may pass to $\overline{M} \in M_n(\mathbb{F}_2)$ and work there.

First, the hypotheses in one equation. The (i,j) entry of $\overline{M}\,\overline{M}^T$ is $r_i \cdot r_j$ read in $\mathbb{F}_2$, which is 0 when $i = j$ and 1 when $i \neq j$. Thus

$$\overline{M}\,\overline{M}^T = J - I \qquad \text{over } \mathbb{F}_2.$$

Second, the diagonal condition again, read differently. In $\mathbb{F}_2$ every element satisfies $x^2 = x$, so

$$r_i \cdot r_i = \sum_{t=1}^{n} \overline{M}_{it}^2 = \sum_{t=1}^{n} \overline{M}_{it},$$

the sum of the entries of row i. The hypothesis that this is even says that every row of $\overline{M}$ sums to 0, that is,

$$\overline{M}v = 0, \qquad v = (1, 1, \dots, 1)^T \neq 0.$$

So $\overline{M}$ has nontrivial kernel and $\operatorname{rank}(\overline{M}) \le n-1$.

Third, the Gram matrix is invertible. Since $J^2 = nJ$ and $2 = 0$ in $\mathbb{F}_2$,

$$(J-I)^2 = J^2 - 2J + I = nJ + I = I,$$

the last step because n is even. Hence $J - I$ is its own inverse and $\operatorname{rank}(J-I) = n$. But

$$n = \operatorname{rank}(J-I) = \operatorname{rank}\big(\overline{M}\,\overline{M}^T\big) \le \operatorname{rank}(\overline{M}) \le n-1,$$

a contradiction. Therefore no such M exists for even n, and the answer is exactly the odd n. ∎

Layer 1: WHAT

Block 1. Notice that no hypothesis sees the size of an entry, only its parity, and move the whole problem into $M_n(\mathbb{F}_2)$.

Block 2. Package all n^2 hypotheses as the single matrix equation $\overline{M}\,\overline{M}^T = J - I$.

Block 3. Read the diagonal hypothesis a second time using $x^2 = x$ in $\mathbb{F}_2$: it also says $\overline{M}v = 0$, so $\overline{M}$ is singular.

Block 4. Compute $(J-I)^2 = nJ + I$ in $\mathbb{F}_2$ and split on the parity of n: for even n the Gram matrix is invertible, which is incompatible with Block 3.

Block 5. For odd n the same computation makes $J - I$ idempotent with kernel exactly the span of v, which is what Block 3 demands, so the idempotent itself is the construction.

Juxtaposition. The nominal route is: build examples by hand, notice that $n = 2$ and $n = 4$ resist, then try to prove impossibility by expanding sums of dot products over $\mathbb{Z}$, get $n(n-1) \equiv 0$, and grind. The bifurcation point is Block 1 into Block 2: the instant you decide that the object of study is not the integer matrix but its image in $M_n(\mathbb{F}_2)$, and that the object to write down is the Gram matrix rather than the individual dot products. Everything after that bifurcation is four lines; everything before it is unbounded.

Layer 2: HOW

Block 1. **Cue.** The words "even" and "odd" attached to every hypothesis, and the total absence of any inequality or magnitude condition. **Why natural.** Parity is the ring homomorphism $\mathbb{Z} \to \mathbb{F}_2$. If every hypothesis and the desired conclusion are statements about images under a homomorphism, then working upstairs carries information you will never use and cannot exploit. Downstairs you gain something concrete: $\mathbb{F}_2$ is a field, so the entire apparatus of linear algebra (rank, kernel, invertibility) is available and behaves exactly as over $\mathbb{R}$. **Link to the next block.** Once you are in a vector space, you should be looking for a linear algebraic object that carries all the hypotheses at once.

Block 2. **Cue.** "Every dot product of a row with itself" and "every dot product of two different rows" is a complete table of pairwise inner products. **Why natural.** A complete table of pairwise dot products of the rows of M is by definition the matrix MM^T. This is not a manoeuvre, it is a translation: the table and the product are the same object. Writing $\overline{M}\,\overline{M}^T = J - I$ replaces n^2 scalar conditions by one equation, and equations between matrices can be attacked by rank, determinant, trace and by squaring. **Link to the next block.** You now have one equation and one unknown matrix. To get a contradiction you need a second, independent consequence of the hypotheses, ideally one that is linear rather than quadratic in $\overline{M}$.

Block 3. **Cue.** A self dot product in characteristic 2. **Why natural.** In $\mathbb{F}_2$ the Frobenius map $x \mapsto x^2$ is the identity, so the quadratic form $r \mapsto r \cdot r$ collapses to the linear form $r \mapsto \sum_t r_t$. A condition you thought was quadratic is secretly linear, and a linear condition on all rows at once is a kernel statement. This is the single most important structural fact in the problem, and it is a fact about the field, not about the matrix. **Link to the next block.** You have singularity from the diagonal and a Gram identity from the off diagonal. The only remaining question is whether the right hand side $J - I$ is singular too.

Block 4. **Cue.** J satisfies $J^2 = nJ$, so any polynomial in J collapses; and you want the rank of $J - I$. **Why natural.** Do not reach for a determinant expansion. J generates a two dimensional algebra spanned by J and I, so squaring $J - I$ must return to that algebra, and the computation is one line. The parity of n enters through the coefficient n of J, which is exactly where the answer to the problem lives. **Link to the next block.** For n even you have your contradiction and the impossibility half is finished. For n odd the obstruction evaporates, which is the signal to stop trying to prove impossibility and start constructing.

Block 5. **Cue.** For odd n the necessary conditions say: find $\overline{M}$ with $\overline{M}\,\overline{M}^T = J - I$ and $v \in \ker \overline{M}$, where $J - I$ is idempotent of rank $n - 1$ with kernel spanned by v. **Why natural.** An idempotent symmetric matrix E satisfies $EE^T = E$ automatically. So the shortest candidate for $\overline{M}$ is $J - I$ itself, and its kernel is already the span of v. The construction is not a lucky guess; it is the unique obvious matrix satisfying both constraints, and lifting it back to $\mathbb{Z}$ costs nothing because $J - I$ has integer

entries. **Link to the next block.** Verify over $\mathbb{Z}$ directly (dot products $n-1$ and $n-2$) so the write up never has to justify a lift.

Layer 3: WHY

The mathematical truth beneath this route is that a prescribed table of pairwise inner products is a Gram matrix, and the only invariant of a matrix that survives the passage $M \mapsto MM^T$ in general is rank. Over $\mathbb{R}$ you also get positive semidefiniteness, which is why real Gram problems are usually solved by eigenvalue positivity; over $\mathbb{F}_2$ there is no order, so positivity is gone and rank is all you have. Recognising which invariants survive in which field is the discernment being tested.

The second truth is the collapse of squaring in characteristic 2. Over any field of characteristic 2 the map $x \mapsto x^2$ is a ring homomorphism, and over the prime field $\mathbb{F}_2$ it is the identity. Consequently the quadratic form $q(r) = r \cdot r$ is a linear functional there, and the symmetric bilinear form $r \cdot s$ is alternating precisely when that functional vanishes. In this problem the diagonal hypothesis says the form restricted to the row space is alternating, and alternating forms have even rank; that is the same obstruction in different clothing, and it is why even n is the doomed case.

The discernment mechanism, stated as a decision, is this. When every hypothesis is a congruence modulo a prime p, reduce and use linear algebra over $\mathbb{F}_p$; when the hypotheses are about all pairwise dot products of a list of vectors, write the Gram matrix; when you must prove that no object exists, look for two consequences of the hypotheses that force incompatible ranks. Nonexistence proofs on the Putnam almost always come from an invariant, and rank is the cheapest invariant in linear algebra.

How to train it: take any problem phrased with the words even and odd and rewrite it, before doing anything else, as a sentence over $\mathbb{F}_2$. Then ask which standard $\mathbb{F}_2$ object is being described: a Gram matrix, a parity check matrix of a binary code, an incidence matrix of a set system. All three occur constantly, and the family of problems around this one (Oddtown, Eventown, Fisher type inequalities) is the same circuit fired at different targets.

What the examiners nudged. They wrote "integer entries" rather than "entries in $\{0,1\}$" to see whether you would notice that only the parity matters. They chose the diagonal to be even and the off diagonal odd, rather than the other way round, because the reverse condition gives $\overline{M}\,\overline{M}^T = I$, which is possible for every n (take $M = I$) and would have made the problem empty. The asymmetry between the two parities is the content.

Revolving concepts

The field $\mathbb{F}_p$. Definition: the integers modulo a prime p form a field, so every theorem of linear algebra proved over an abstract field applies verbatim: rank, kernel, rank plus nullity, invertibility equivalent to nonzero determinant, and the fact that a square matrix with a right inverse is invertible. What does not transfer is anything relying on order or positivity. See Book 1, field: Linear algebra, topic: linear algebra over finite fields.

Frobenius in characteristic p. The map $x \mapsto x^p$ is a ring homomorphism on any commutative ring of characteristic p, so $(a+b)^p = a^p + b^p$. On $\mathbb{F}_p$ itself Fermat gives $x^p = x$, so for $p = 2$ the squaring map is the identity and quadratic conditions degenerate to linear ones. See Book 1, field: Abstract algebra, topic: Frobenius endomorphism.

Gram matrices and rank. For any M over any field, MM^T records all pairwise dot products of the rows, and $\operatorname{rank}(AB) \le \min\{\operatorname{rank}(A), \operatorname{rank}(B)\}$, so $\operatorname{rank}(MM^T) \le \operatorname{rank}(M)$. Over $\mathbb{R}$ equality always holds; over other fields it can fail, and the failure is exactly what problems like this one exploit. See Book 1, field: Matrices and determinants, topic: Gram matrix.

The all ones matrix. J has $J^2 = nJ$, so $\{aJ + bI\}$ is closed under multiplication with $(aJ + bI)(cJ + dI) = (acn + ad + bc)J + bdI$. Over $\mathbb{R}$ its eigenvalues are n once and 0 with multiplicity $n-1$, so $\det(aJ + bI) = b^{n-1}(an + b)$ and in particular $\det(J - I) = (-1)^{n-1}(n-1)$. The trivial

recursion here is $J^m = n^{m-1}J$ for $m \geq 1$, which generalises to any rank one matrix uw^T with $w^Tu = c$, giving $(uw^T)^m = c^{m-1}uw^T$, and then to the rank one update formula $\det(A + uw^T) = \det(A)(1 + w^TA^{-1}u)$. See Book 1, field: Matrices and determinants, topic: rank one matrices.

Set systems with prescribed intersection parities. Characteristic vectors turn $|A_i \cap A_j|$ into a dot product over $\mathbb{F}_2$. Oddtown: if all $|A_i|$ are odd and all $|A_i \cap A_j|$ $(i \neq j)$ are even, then the Gram matrix is I, the vectors are independent, and there are at most n sets. Eventown is the complementary statement with bound $2^{\lfloor n/2 \rfloor}$. This problem is the third member of that family: even diagonal, odd off diagonal. See Book 1, field: Combinatorics, topic: linear algebra method in combinatorics.

Circuit Bank

- **WHEN** the words even and odd attached to algebraic quantities **DO** rewrite the entire problem over $\mathbb{F}_2$ on line one **BECAUSE** parity is a ring homomorphism, so every hypothesis survives the reduction while all unusable magnitude information is discarded, and $\mathbb{F}_2$ is a field where linear algebra is available
- **WHEN** a complete table of pairwise dot products of a list of vectors **DO** write the Gram matrix MM^T **BECAUSE** one matrix equation carries all n^2 hypotheses, and matrix equations expose rank, determinant and trace
- **WHEN** a self dot product in characteristic 2 **DO** replace it by the sum of the coordinates **BECAUSE** $x^2 = x$ in $\mathbb{F}_2$, so a quadratic condition on a vector is a linear one, and linear conditions on every row are a kernel statement
- **WHEN** you must prove that no object exists **DO** hunt for two consequences of the hypotheses that force incompatible ranks **BECAUSE** rank is the cheapest invariant that both sides of an identity are forced to reveal, and nonexistence needs an invariant, not a search
- **WHEN** a construction is needed and the constraints are invariant under permuting rows **DO** try the family $aJ + bI$ first **BECAUSE** if the constraint set is symmetric, a symmetric solution usually exists, and that family is two dimensional and closed under multiplication

Backtesting

1. First useful cue: every hypothesis is a parity statement about a dot product, so the ambient object is a matrix over $\mathbb{F}_2$ and the ambient equation is a Gram identity.
2. Method the expression suggested: package the table of dot products as $\overline{M}\,\overline{M}^T = J - I$, then extract a second, linear consequence from the diagonal using $x^2 = x$.
3. Where you would hesitate, and the thought to reinforce: at the moment the Gram equation is written and no contradiction is visible. The thought to reinforce is that one quadratic equation is never enough, you need a linear one, and the only untouched hypothesis is the diagonal, so read it again in the new field.
4. The trap the question sets: staying over $\mathbb{Z}$ and expanding $\|r_1 + \cdots + r_n\|^2$. That computation is correct and yields nothing, and it can absorb twenty minutes.
5. What makes you recognise it faster next time: the phrase "dot product of two different rows" is the signature of a Gram matrix problem, and the word "even" is the signature of $\mathbb{F}_2$. Together they name the whole solution before you have written a line.
6. The reusable decision rule: parity hypotheses become $\mathbb{F}_2$ statements, pairwise inner products become Gram matrices, and impossibility comes from rank.

Mirror drills

1. (Oddtown) Let $A_1, \dots, A_m$ be subsets of $\{1, \dots, n\}$ with every $|A_i|$ odd and every $|A_i \cap A_j|$ even for $i \neq j$. Prove $m \leq n$. *Answer:* the characteristic vectors in $\mathbb{F}_2^n$ have Gram matrix I, which is invertible, so they are linearly independent, so $m \leq n$.

2. Compute $\det(J - I)$ over $\mathbb{Z}$ and decide for which n the matrix $J - I$ is invertible over $\mathbb{F}_2$ and over $\mathbb{F}_3$. *Answer:* $\det(J - I) = (-1)^{n-1}(n-1)$, so it is invertible over $\mathbb{F}_p$ exactly when $p \nmid n - 1$; over $\mathbb{F}_2$ that means n even, over $\mathbb{F}_3$ it means $n \not\equiv 1 \pmod 3$.

3. Let n be odd and let $\overline{M}$ over $\mathbb{F}_2$ satisfy $\overline{M}\,\overline{M}^{T} = J - I$. Show $\operatorname{rank}(\overline{M}) = n - 1$ and that $\ker \overline{M}$ is spanned by the all ones vector. *Answer:* for odd n, $(J - I)x = (\sum_t x_t)\mathbf{1} + x$ vanishes only for $x = 0$ and $x = \mathbf{1}$, so $\operatorname{rank}(J - I) = n - 1$, forcing $\operatorname{rank}(\overline{M}) \geq n - 1$; the diagonal condition puts $\mathbf{1}$ in the kernel, giving equality.

15.5 A5. Rectify the field, then pigeonhole

Let $F : \mathbb{R}^2 \to \mathbb{R}$ and $g : \mathbb{R} \to \mathbb{R}$ be twice continuously differentiable functions with the following properties:

- *$F(u,u) = 0$ for every $u \in \mathbb{R}$;*
- *for every $x \in \mathbb{R}$, $g(x) > 0$ and $x^2 g(x) \leq 1$;*
- *for every $(u,v) \in \mathbb{R}^2$, the vector $\nabla F(u,v)$ is either $\mathbf{0}$ or parallel to the vector $\langle g(u), -g(v)\rangle$.*

Prove that there exists a constant C such that for every $n \geq 2$ and any $x_1, \ldots, x_{n+1} \in \mathbb{R}$, we have

$$\min_{i \neq j} |F(x_i, x_j)| \leq \frac{C}{n}.$$

Read it out loud

Out loud: you are given a two variable function whose gradient direction is prescribed everywhere, which vanishes on the diagonal, and you must show that among any $n+1$ real numbers two of them are sent by F to something of size at most C/n. The arithmetic of the conclusion is the loudest cue on the page. Objects numbered $n+1$, a bound with n in the denominator: that is the signature of pigeonhole into n boxes, and the boxes must be intervals of length proportional to $1/n$ inside a set of finite total length. So before touching the analysis you already know the shape of the endgame: find a map $\Phi : \mathbb{R} \to (A, B)$ into a bounded interval such that $|F(u,v)|$ is controlled by $|\Phi(u) - \Phi(v)|$.

Now read the hypotheses as a list of jobs. The gradient condition is a first order linear partial differential equation in disguise, because "parallel to a given nonzero vector" is the same as "orthogonal to the perpendicular of that vector". The condition $F(u,u) = 0$ is a normalisation, and it will be what turns a Lipschitz estimate into a bound on $|F|$ itself. The condition $g > 0$ makes the antiderivative of g strictly increasing, hence invertible. The condition $x^2 g(x) \leq 1$ is an integrability bound: $g(x) \leq 1/x^2$, and $1/x^2$ is integrable at both ends of the line, so the antiderivative of g is bounded. That is exactly the bounded interval the pigeonhole needs. Every hypothesis has one job and there are no spare parts.

The fields wired in: multivariable calculus (gradients and the chain rule), first order linear partial differential equations and the method of characteristics, one variable analysis (inverse function theorem, mean value theorem, improper integrals), and the pigeonhole principle.

Within thirty seconds you should have written the gradient hypothesis as the scalar equation

$$\frac{1}{g(u)} \frac{\partial F}{\partial u}(u,v) + \frac{1}{g(v)} \frac{\partial F}{\partial v}(u,v) = 0,$$

and next to it the substitution $x = G(u)$ with $G' = g$, which is the only change of variable that turns the operator on the left into $\partial_x + \partial_y$.

Approaches, ranked worst to best

1. **Contradiction with no structure.** *Cue:* the conclusion is a minimum over pairs, so assume every pair is large. *Circuit:* negate and count. You suppose $|F(x_i, x_j)| > C/n$ for all $i \neq j$ and look for an incompatibility. It ranks last because you have no quantitative information about F at all yet, so there is nothing for the assumption to collide with. Negating a conclusion before you have understood the hypotheses is zombie maths.
2. **Bound F by integrating its gradient.** *Cue:* $F(u,u) = 0$ and you want $|F(u,v)|$ small, so integrate from the diagonal. *Circuit:* fundamental theorem of calculus along a segment. Write

$F(u,v) = \int_0^1 \frac{d}{dt} F(u, u + t(v-u))\, dt$ and try to bound the integrand. This stalls immediately and for a nameable reason: the hypothesis specifies the direction of ∇F and says nothing whatsoever about its magnitude, since the scalar of proportionality is an arbitrary function of (u,v). No size estimate can ever be extracted from a direction. Recognising this early is worth more than any computation.

3. **Instantiate the hypotheses on the simplest example.** *Cue:* $x^2 g(x) \le 1$ with $g > 0$ smells like $g(x) = 1/(1+x^2)$. *Circuit:* test the hypotheses on the cheapest object that satisfies them. With $g(x) = 1/(1+x^2)$ you get $G = \arctan$ and $F(u,v) = \arctan u - \arctan v$ satisfies all three hypotheses, and the conclusion holds with $C = \pi$ by pigeonholing $n+1$ arctangents in an interval of length π. This is not a proof and must never be submitted as one, but it ranks above the previous two because it tells you the true theorem: F is a function of $G(u) - G(v)$ where G is bounded. In the arena this is the two minutes that buy you the whole solution.

4. **Method of characteristics in the original variables.** *Cue:* a first order linear PDE means F is constant along the integral curves of a vector field. *Circuit:* solve $\dot{u} = 1/g(u)$, $\dot{v} = 1/g(v)$ and find the invariant. Along such a curve $\frac{d}{dt} G(u) = g(u)\dot{u} = 1$ and likewise for v, so $G(u) - G(v)$ is constant, and F is a function of it. Correct and conceptually the same as the winner, but you must argue that the flow exists for all relevant times and that the orbits cover the plane, which is more analytic bookkeeping than a change of variable needs.

5. **Change coordinates once, globally.** *Cue:* the operator has separated coefficients $\frac{1}{g(u)}\partial_u + \frac{1}{g(v)}\partial_v$. *Circuit:* rectification: choose new coordinates in which the field is constant. Substituting $x = G(u)$, $y = G(v)$ turns the equation into $\Phi_x + \Phi_y = 0$ on a bounded square, whose solutions are exactly the functions of $x - y$. The same substitution simultaneously compresses $\mathbb{R}$ into a bounded interval, which is what pigeonhole needs. Best route: one substitution does two jobs, and the rest is the mean value theorem and counting boxes.

The ideal solution

Step 1: the gradient hypothesis is a linear PDE. Since $g > 0$ everywhere, the vector $\langle g(u), -g(v)\rangle$ is never zero, so the hypothesis says precisely that for every (u,v) there is a real number $\lambda(u,v)$, possibly zero, with

$$\frac{\partial F}{\partial u}(u,v) = \lambda(u,v)\, g(u), \qquad \frac{\partial F}{\partial v}(u,v) = -\lambda(u,v)\, g(v).$$

Dividing and adding eliminates λ:

$$\frac{1}{g(u)}\frac{\partial F}{\partial u}(u,v) + \frac{1}{g(v)}\frac{\partial F}{\partial v}(u,v) = 0 \qquad \text{for all } (u,v) \in \mathbb{R}^2. \tag{1}$$

Step 2: the antiderivative of g is a bounded diffeomorphism. Put $G(x) = \int_0^x g(t)\, dt$. Then $G' = g > 0$, so G is strictly increasing, and G is three times continuously differentiable because g is twice continuously differentiable. For $x \ge 1$ the hypothesis $g(t) \le 1/t^2$ gives

$$0 < G(x) - G(1) = \int_1^x g(t)\, dt \le \int_1^x \frac{dt}{t^2} = 1 - \frac{1}{x} < 1,$$

and for $x \le -1$ the same estimate gives $0 < G(-1) - G(x) < 1$. Hence G is bounded above by $G(1) + 1$ and below by $G(-1) - 1$. A continuous strictly increasing function with finite limits at both ends maps $\mathbb{R}$ bijectively onto the open interval

$$(A, B), \qquad A = \lim_{x \to -\infty} G(x), \quad B = \lim_{x \to +\infty} G(x),$$

and $\ell := B - A \le G(1) - G(-1) + 2 < \infty$. Since $G' = g$ never vanishes, the inverse function theorem gives that $G^{-1} : (A, B) \to \mathbb{R}$ is continuously differentiable with

$$(G^{-1})'(x) = \frac{1}{g(G^{-1}(x))}.$$

Step 3: rectify. Define Φ on the open square $S = (A, B) \times (A, B)$ by

$$\Phi(x, y) = F\big(G^{-1}(x), G^{-1}(y)\big).$$

It is continuously differentiable as a composition of such maps, and by the chain rule together with (1),

$$\frac{\partial \Phi}{\partial x} + \frac{\partial \Phi}{\partial y} = \frac{F_u\big(G^{-1}(x), G^{-1}(y)\big)}{g(G^{-1}(x))} + \frac{F_v\big(G^{-1}(x), G^{-1}(y)\big)}{g(G^{-1}(y))} = 0.$$

Step 4: solve the rectified equation. Let $m = (A + B)/2$ and define

$$h(s) = \Phi\Big(m + \tfrac{s}{2},\, m - \tfrac{s}{2}\Big), \qquad |s| < \ell,$$

which is legitimate because $|s| < \ell$ forces $m \pm s/2 \in (A, B)$. The function h is continuously differentiable on $(-\ell, \ell)$.

Fix $(x, y) \in S$ and set $s = x - y$, so $|s| < \ell$. The points (x, y) and $(m + s/2,\, m - s/2)$ both lie in S and differ by a multiple of $(1, 1)$; since S is convex, the segment joining them lies in S. Along that segment, parametrised as $\gamma(t) = (m + s/2 + t,\, m - s/2 + t)$, we have

$$\frac{d}{dt}\Phi(\gamma(t)) = \Phi_x + \Phi_y = 0,$$

so Φ is constant on it. Hence $\Phi(x, y) = h(x - y)$ for every $(x, y) \in S$, and therefore

$$F(u, v) = h\big(G(u) - G(v)\big) \qquad \text{for all } u, v \in \mathbb{R}. \tag{2}$$

Step 5: normalise and get a Lipschitz constant. Taking $u = v$ in (2) and using $F(u, u) = 0$ gives $h(0) = 0$. Since h' is continuous on $(-\ell, \ell)$, it is bounded on the compact subinterval $[-\ell/2, \ell/2]$; put

$$M = \max_{|s| \le \ell/2} |h'(s)| < \infty.$$

Step 6: pigeonhole and finish. Let $C = M\ell$, a constant depending only on F and g. Let $n \ge 2$ and let $x_1, \dots, x_{n+1}$ be any reals. The $n + 1$ numbers $G(x_1), \dots, G(x_{n+1})$ all lie in (A, B), which is contained in the union of the n intervals

$$I_t = \Big[A + \tfrac{(t-1)\ell}{n},\, A + \tfrac{t\ell}{n}\Big), \qquad t = 1, \dots, n.$$

By the pigeonhole principle two of them, say $G(x_i)$ and $G(x_j)$ with $i \ne j$, lie in the same I_t, so

$$|G(x_i) - G(x_j)| < \frac{\ell}{n} \le \frac{\ell}{2},$$

the last step because $n \ge 2$. The number $G(x_i) - G(x_j)$ therefore lies in $[-\ell/2, \ell/2]$, and by (2), $h(0) = 0$ and the mean value theorem applied to h on the interval between 0 and $G(x_i) - G(x_j)$,

$$|F(x_i, x_j)| = \big|h(G(x_i) - G(x_j)) - h(0)\big| \le M|G(x_i) - G(x_j)| \le \frac{M\ell}{n} = \frac{C}{n}.$$

Hence $\min_{i \ne j} |F(x_i, x_j)| \le C/n$, with C independent of n and of the points. ∎

Layer 1: WHAT

Block 1. Convert "∇F is zero or parallel to $\langle g(u), -g(v)\rangle$" into the single scalar equation $F_u/g(u) + F_v/g(v) = 0$, valid at every point including where the gradient vanishes.

Block 2. Recognise the left side as the derivative of F along the vector field $(1/g(u), 1/g(v))$, and ask for the coordinate in which that field is constant.

Block 3. Answer: $x = G(u)$ with $G' = g$. Check separately that this same G is bounded, because $g(t) \le 1/t^2$ is integrable at both ends. One substitution, two jobs.

Block 4. In the new coordinates the equation is $\Phi_x + \Phi_y = 0$ on a bounded convex square, so Φ depends only on $x - y$; translating back, $F(u, v) = h(G(u) - G(v))$.

Block 5. Use the diagonal hypothesis: $h(0) = 0$. Use continuity of h' on a compact subinterval: h is Lipschitz there with constant M.

Block 6. Put $n + 1$ values of G into n boxes of length ℓ/n, take the colliding pair, apply the mean value theorem.

Juxtaposition. The nominal route reads "twice continuously differentiable" and reaches for Taylor expansions and second derivative bounds; then it reads "$F(u, u) = 0$" and tries the mean value inequality $|F(u, v)| \le \sup|\nabla F| \cdot |u - v|$; then it discovers that no supremum is available and starts inventing hypotheses. The bifurcation point is inside Block 1 to Block 2: the decision to stop estimating F and to solve for F exactly. The hypothesis is not an estimate, it is an equation, and equations should be solved, not bounded. Once (2) is on the page the problem is a one variable exercise.

Layer 2: HOW

Block 1. Cue. "Parallel to" a specified nonzero vector, with the specified vector built from g evaluated separately at u and at v. **Why natural.** Parallelism is a statement with one degree of freedom, the scalar λ, and λ is exactly the information the problem refuses to give you. So eliminate it. Dotting ∇F with the perpendicular vector $\langle g(v), g(u)\rangle$ kills λ in one line and leaves a genuine equation. The case $\nabla F = \mathbf{0}$ is not a separate case at all, it is $\lambda = 0$, which is why the equation holds at every point without exception. **Link to the next block.** You now have a first order linear homogeneous PDE. The standard theory says its solutions are exactly the functions that are constant along the integral curves of the associated vector field, so the next question is what those curves are.

Block 2. Cue. The coefficients are separated: the coefficient of ∂_u depends only on u, and the coefficient of ∂_v only on v. **Why natural.** A vector field with separated coefficients is rectified by a product substitution, one variable at a time. If $x = \phi(u)$ then $\partial_u = \phi'(u)\partial_x$, so the coefficient of ∂_x becomes $\phi'(u)/g(u)$; choosing $\phi' = g$ makes it 1. Nothing was guessed: the requirement $\phi' = g$ is forced by the demand that the coefficient equal 1. **Link to the next block.** The substitution is $x = G(u)$ where G is an antiderivative of g. Before using it, find out what its range is, because the range is the new domain and the whole endgame depends on the new domain being bounded.

Block 3. Cue. The hypothesis $x^2 g(x) \le 1$ has not been used, and it is an inequality about the size of g at infinity. **Why natural.** An unused hypothesis is a misread problem. This one rearranges to $g(x) \le 1/x^2$ for $x \neq 0$, and the only standard fact about $1/x^2$ is that it is integrable away from the origin. So the hypothesis exists to make $\int^{\infty} g$ and $\int_{-\infty} g$ finite, which is to say to make G bounded. The problem author put it there to compactify the line, and no other reading of it is possible. **Link to the next block.** G is a strictly increasing bounded smooth bijection onto a bounded interval (A, B), with a differentiable inverse by the inverse function theorem. Now push F through it.

Block 4. Cue. The transport equation $\Phi_x + \Phi_y = 0$. **Why natural.** The derivative of Φ in the direction $(1, 1)$ is zero, so Φ is constant along every line of slope 1 that stays in the domain. To

turn "constant on each line" into "a function of $x - y$" you need the lines to meet the domain in connected sets, which is exactly convexity of the square. That is why the write up says the word convex: it is not decoration, it is the reason a local statement becomes a global one. **Link to the next block.** $F(u, v) = h(G(u) - G(v))$ is now an exact formula for F. Every remaining hypothesis should be applied to h.

Block 5. **Cue.** $F(u, u) = 0$, the one hypothesis not yet used. **Why natural.** In the new description, $u = v$ means argument zero, so the diagonal hypothesis is precisely $h(0) = 0$. That is what converts a derivative bound into a value bound: $|h(s)| = |h(s) - h(0)| \leq M|s|$. Without $h(0) = 0$ the conclusion would be false, since $F \equiv 1$ satisfies every other hypothesis. **Link to the next block.** The bound is now linear in $|G(x_i) - G(x_j)|$, so all that remains is to make some pair of the $G(x_i)$ close.

Block 6. **Cue.** $n + 1$ points, a bound with n in the denominator, and a domain of finite length ℓ. **Why natural.** This is the pigeonhole principle in its continuous form. Cutting an interval of length ℓ into n pieces of length ℓ/n and dropping $n + 1$ points into it forces a collision, and the collision distance is at most ℓ/n. The restriction $n \geq 2$ in the problem statement exists so that $\ell/n \leq \ell/2$, keeping the difference inside the compact interval on which h' was bounded. **Link to the next block.** Mean value theorem, and the constant $C = M\ell$ depends only on F and g, which is what "there exists a constant C" demands.

Layer 3: WHY

The mathematical truth beneath this route is the classification of solutions of a first order linear homogeneous PDE. The equation $a(u, v)F_u + b(u, v)F_v = 0$ says that ∇F is orthogonal to the field (a, b), that is, that F is constant along the integral curves of that field. Where the field is nonvanishing, the rectification theorem says there are local coordinates in which the field is ∂_x, and then the general solution is an arbitrary function of the remaining coordinate. Here the field is nonvanishing everywhere and the rectifying coordinates are global, so the general solution is global: F is an arbitrary function of the single invariant $G(u) - G(v)$. This is the reason the problem is solvable at all. You are not being asked to estimate an unknown function; you are being handed a complete description of it with one unknown one variable function inside, and the remaining hypotheses pin down what you need about that function.

The second truth is that compactness has to come from somewhere. The conclusion is uniform over all real inputs, so some hypothesis must confine the line. The only candidate is the growth bound on g, and it confines the line not directly but through the invariant: the set of achievable values of $G(u) - G(v)$ is the bounded interval $(-\ell, \ell)$. Once the invariant lives in a bounded set, the pigeonhole principle is available and the $1/n$ appears for free.

The discernment mechanism is a habit rather than a theorem: before writing anything, list the hypotheses and assign each one a job. Here there are four items (diagonal vanishing, positivity of g, decay of g, gradient direction) and four jobs (normalise h, make G invertible, make the range bounded, produce the PDE). If your proof does not use every hypothesis, either your proof is wrong or you have proved something stronger, and on the Putnam the first is far more likely. Notice also which hypothesis is stronger than needed: continuous differentiability of F and g is enough for everything above, and the second derivatives are never used. Saying so out loud is part of understanding the problem, not a criticism of it.

How to train it: whenever a hypothesis constrains a derivative's direction rather than its size, immediately write the associated PDE and try to solve it exactly. Whenever a hypothesis is an integrability or decay bound, immediately name the integral it makes finite. Whenever a conclusion has the shape "among $N + 1$ objects two are within c/N", write "pigeonhole into N boxes" at the bottom of your page before you start, and then work towards it.

What the examiners nudged. They wrote the direction vector as $\langle g(u), -g(v)\rangle$ with the arguments separated, so the characteristic system decouples and the change of variable is a product of one variable maps. They wrote $x^2 g(x) \le 1$ rather than the cleaner "g is integrable", so that you would have to perform the comparison yourself and thereby notice why it is there. They wrote $n+1$ points and C/n rather than n points and C/n, which is the pigeonhole telling you its box count out loud.

Revolving concepts

First order linear homogeneous PDE and characteristics. For $a(u,v)F_u + b(u,v)F_v = 0$ with (a,b) continuous and nonvanishing, the characteristic curves solve $\dot u = a$, $\dot v = b$, and F is a solution exactly when it is constant on each characteristic. If $w(u,v)$ is a function with nonvanishing gradient that is constant on characteristics (a first integral), the general solution is $F = h \circ w$ for an arbitrary function h of the same regularity. Here $w = G(u) - G(v)$. See Book 1, field: Calculus and integrals, topic: first order PDE and characteristics.

The transport equation. $\Phi_x + \Phi_y = 0$ on a convex domain implies $\Phi(x,y) = h(x-y)$; the proof is the one line $\frac{d}{dt}\Phi(x+t, y+t) = \Phi_x + \Phi_y = 0$. The same one line proves that $\Phi_x - \Phi_y = 0$ gives a function of $x+y$, and that $u\Phi_u + v\Phi_v = 0$ gives a function of v/u (homogeneity of degree zero, Euler's relation). See Book 1, field: Calculus and integrals, topic: transport equation.

Rectification of a vector field. A vector field that does not vanish at a point admits local coordinates in which it is the constant field ∂_x. In one dimension the rectifying coordinate is $\int dx/(\text{field})$; with separated coefficients, apply the one dimensional recipe in each variable. See Book 1, field: Real analysis, topic: flows and rectification.

Inverse function theorem in one variable. If G is C^k on an interval with $G' \neq 0$ throughout, then G is a C^k diffeomorphism onto its image and $(G^{-1})' = 1/(G' \circ G^{-1})$. Combined with monotone convergence of G at the ends, this identifies the image as an open interval. See Book 1, field: Real analysis, topic: inverse function theorem.

Comparison test for improper integrals. If $0 \le f \le F$ on $[a,\infty)$ and $\int_a^\infty F$ converges then so does $\int_a^\infty f$; the model case is $\int_1^\infty t^{-p}\,dt$, convergent exactly for $p > 1$. See Book 1, field: Calculus and integrals, topic: improper integrals.

Pigeonhole in continuous form, and Dirichlet approximation. $N+1$ points in an interval of length ℓ force two within ℓ/N. The same circuit, applied to the fractional parts $\{0\}, \{\alpha\}, \ldots, \{N\alpha\}$ in $[0,1)$, gives integers $1 \le q \le N$ with $|q\alpha - p| < 1/N$, which is Dirichlet's approximation theorem. See Book 1, field: Number theory, topic: Dirichlet approximation.

Iteration, flows and Abel's equation (the recursion behind the rectification). There is no discrete recursion in this problem, but the underlying structure is the continuous version of one. A vector field generates a one parameter family of maps Ψ_t with $\Psi_{s+t} = \Psi_s \circ \Psi_t$, the flow, which is the continuous analogue of iterating a single map, $f^{m+1} = f \circ f^m$. The generalised statement is: to understand an iteration or a flow, find coordinates in which it becomes a translation. For a flow that means solving $\phi'(u) \cdot (\text{field}) = 1$, that is, $\phi = \int du/(\text{field})$, which is precisely the G used here; for an iteration f it means solving Abel's functional equation $\phi(f(u)) = \phi(u) + 1$, after which $\phi(f^m(u)) = \phi(u) + m$ and every asymptotic question about f^m becomes arithmetic. The same generalisation solves the recurrence $a_{m+1} = f(a_m)$ for slowly converging f (for example $a_{m+1} = \sin a_m$, where $\phi = 1/a^2$ up to constants gives $a_m \sim \sqrt{3/m}$). See Book 1, field: Sequences and recurrences, topic: conjugating an iteration to a translation.

Circuit Bank

- **WHEN** a hypothesis fixes the direction of a gradient but not its size **DO** eliminate the scalar of proportionality, write the resulting first order PDE, and solve it exactly **BECAUSE** direction

carries no magnitude information, so no estimate can ever be extracted from it, whereas the level sets are completely determined

- **WHEN** a first order operator with separated coefficients $\frac{1}{g(u)}\partial_u + \frac{1}{g(v)}\partial_v$ **DO** substitute $x = G(u)$, $y = G(v)$ where $G' = g$ **BECAUSE** that is the unique substitution making both coefficients equal to 1, and a constant field has an obvious invariant, namely $x - y$
- **WHEN** a hypothesis is a decay or integrability bound such as $x^2 g(x) \leq 1$ **DO** name the integral it makes finite, and expect that finiteness to be the compactness the proof needs **BECAUSE** a Putnam hypothesis is never decoration, and a bound on a function at infinity can only act through an integral or a limit
- **WHEN** the conclusion reads "among $N + 1$ objects, two within c/N" **DO** write "pigeonhole into N boxes" at the foot of the page before starting **BECAUSE** the arithmetic of the statement is the examiner naming the last step, and knowing the last step fixes what the earlier steps must produce
- **WHEN** you must bound $|f|$ and you know f vanishes somewhere **DO** write $f(s) = f(s) - f(s_0)$ and apply the mean value theorem with a derivative bound on a compact set **BECAUSE** a value bound needs one value plus a derivative bound, and continuity of the derivative supplies the bound on any compact set by the extreme value theorem

Backtesting

1. First useful cue: $n + 1$ objects with a C/n conclusion, which fixes pigeonhole as the endgame and therefore demands a bounded interval to pigeonhole into.
2. Method the expression suggested: eliminate the proportionality scalar to get $F_u/g(u) + F_v/g(v) = 0$, then rectify with $x = G(u)$, $G' = g$, which is also the map whose boundedness the hypothesis $x^2 g(x) \leq 1$ was placed there to guarantee.
3. Where you would hesitate, and the thought to reinforce: at the words "twice continuously differentiable", which pull you towards Taylor expansions and second derivative estimates. Reinforce this instead: the smoothness is there only to make the substitution and the mean value theorem legal, and the real content is that the hypothesis is an equation to be solved.
4. The trap the question sets: attempting to bound $|F(u, v)|$ by $\sup|\nabla F| \cdot |u - v|$. There is no such supremum, because the proportionality scalar is unconstrained, and the conclusion is uniform in the points, so no bound depending on $|u - v|$ could ever finish.
5. What makes you recognise it faster next time: two signatures. "Gradient parallel to a given field" equals "solve the PDE". "$N + 1$ objects, bound c/N" equals "pigeonhole into N boxes".
6. The reusable decision rule: solve exact constraints rather than estimating them, and get compactness from the one hypothesis that bounds growth.

Mirror drills

1. Let $\Phi : \mathbb{R}^2 \to \mathbb{R}$ be continuously differentiable with $\Phi_x + \Phi_y = 0$. Show $\Phi(x, y) = h(x - y)$ for some continuously differentiable h. *Answer:* put $h(s) = \Phi(s, 0)$; then $\frac{d}{dt}\Phi(x + t, y + t) = 0$, so $\Phi(x, y) = \Phi(x - y, 0) = h(x - y)$.
2. Let g be continuous and positive on $\mathbb{R}$ with $\int_{-\infty}^{\infty} g < \infty$. Show that $G(x) = \int_0^x g$ is a bijection from $\mathbb{R}$ onto a bounded open interval whose inverse is continuously differentiable. *Answer:* G is strictly increasing with finite limits at both ends, so it is a continuous bijection onto (A, B) with $B - A = \int_{-\infty}^{\infty} g$; the inverse is C^1 by the inverse function theorem since $G' = g > 0$.

3. Prove Dirichlet's theorem: for every real α and integer $N \geq 1$ there are integers p and $1 \leq q \leq N$ with $|q\alpha - p| < 1/N$. *Answer:* the $N+1$ fractional parts $\{k\alpha\}$ for $k = 0, \ldots, N$ lie in $[0, 1)$, which is the union of N intervals of length $1/N$; two share an interval, and subtracting gives the claim with q the difference of the two indices.

15.6 A6. Fourier analysis of a group random walk

Let G be an abelian group with n elements, and let

$$\{g_1 = e, g_2, \ldots, g_k\} \subsetneq G$$

be a (not necessarily minimal) set of distinct generators of G. A special die, which randomly selects one of the elements $g_1, g_2, \ldots, g_k$ with equal probability, is rolled m times and the selected elements are multiplied to produce an element $g \in G$. Prove that there exists a real number $b \in (0,1)$ such that

$$\lim_{m\to\infty} \frac{1}{b^{2m}} \sum_{x\in G} \left(\text{Prob}(g = x) - \frac{1}{n}\right)^2$$

is positive and finite.

Read it out loud

Out loud: this is a random walk on a finite abelian group, started at the identity, whose step distribution is uniform on a generating set that contains the identity. You are asked to show that the walk approaches the uniform distribution, that the approach is exponential in m, and that it has an exact exponential rate, not merely an upper and a lower bound with different constants.

Three phrases fix the whole solution. First, "rolled m times and the selected elements are multiplied": the distribution of the product is the m fold convolution of the step distribution, so the object is a power of one operator and the question is a question about eigenvalues. Second, "$\sum_{x\in G}(\cdot)^2$": that is a squared L^2 norm on the space of functions on G, and squared norms are computed in whichever orthogonal basis diagonalises the operator, never coordinate by coordinate. Third, "abelian": for a finite abelian group the diagonalising basis exists, is explicit, and is the group of characters. A finite abelian group has exactly n characters and they form an orthogonal basis of the n dimensional space of complex functions on G. That is not a convenience, it is the reason the problem is stated for abelian G.

The fields wired in: representation theory of finite abelian groups (characters and orthogonality), Fourier analysis on a finite group (convolution theorem, inversion, Parseval), Markov chains and the spectral gap, and linear algebra (diagonalisation, and the fact that the asymptotics of $T^m v$ are governed by the second largest eigenvalue modulus).

Within thirty seconds you should have written $P_m = P_{m-1} * P$, then $\widehat{P_m} = \widehat{P}^m$, then $\lambda_\chi = \frac{1}{k}\sum_{i=1}^{k} \chi(g_i)$, and finally $b = \max\{|\lambda_\chi| : \chi \neq \widehat{e}\}$. The remaining work is entirely to show $0 < b < 1$, and the two hypotheses you have not yet used, that $g_1 = e$ and that the generating set is a *proper* subset, are exactly the two facts that deliver those two inequalities.

Approaches, ranked worst to best

1. **Direct combinatorial counting.** *Cue:* "rolled m times and multiplied" is a word count. *Circuit:* count words of length m in the generators equal to x. You would write $\text{Prob}(g = x) = k^{-m}\#\{(i_1, \ldots, i_m) : g_{i_1} \cdots g_{i_m} = x\}$ and try to evaluate. Ranks last: the count is a sum of multinomial coefficients over solutions of a linear system in the exponents, it has no closed form in general, and even in the cyclic case the closed form is a character sum, so you arrive at the right answer by the longest possible road. Worse, the quantity asked for is an exponential rate, and rates are invisible in a formula built out of binomial coefficients.

2. **Markov chain plus Perron Frobenius.** *Cue:* a repeated random step with a fixed rule is a Markov chain. *Circuit:* transition matrix, stationary distribution, convergence theorem. Set $M_{x,y} = \frac{1}{k}[\, x^{-1}y \in \{g_i\}\,]$; the chain is doubly stochastic, irreducible because the g_i generate, and aperiodic because $g_1 = e$ gives every state a self loop, so the distribution converges

to uniform. Ranks above counting because it is the right picture and it explains where the hypotheses act. It ranks below the winner because Perron Frobenius gives only that the subdominant eigenvalue governs the decay; without diagonalisability, which here needs the character basis anyway, you get a lim sup and not a limit, and the problem explicitly asks for a limit.

3. **Characters of cyclic groups plus the structure theorem.** *Cue:* the smallest abelian groups are $\mathbb{Z}/n$, where characters are powers of a root of unity. *Circuit:* reduce to cyclic factors and take products. Every finite abelian group is a direct product of cyclic groups, and the characters of a product are products of characters, so you can build everything from roots of unity. Correct and self contained if you already know the structure theorem, but the bookkeeping over the factors is pure ink: nothing in the argument ever needs the decomposition.

4. **Fourier analysis on G directly.** *Cue:* "abelian" and "$\sum_x(\cdot)^2$" name the character basis and Parseval. *Circuit:* convolution becomes multiplication, then read off the m th power. Take the Fourier transform on G, note that the m fold convolution has transform λ_χ^m, apply Parseval to convert the sum over $x \in G$ into a sum over characters, and let b be the largest $|\lambda_\chi|$ over nontrivial χ. The limit then falls out because every term with $|\lambda_\chi| < b$ dies and every term with $|\lambda_\chi| = b$ contributes exactly 1. Best route: no case analysis, no structure theorem, and the two remaining hypotheses are consumed by two short claims.

The ideal solution

Notation and standard facts. Let $\widehat{G}$ denote the group of characters of G, that is, the homomorphisms $\chi : G \to \mathbb{C}^\times$, and let $\widehat{e}$ denote the trivial character. Since $x^n = e$ for every $x \in G$, every value $\chi(x)$ is an n th root of unity, so $|\chi(x)| = 1$ and $\overline{\chi(x)} = \chi(x^{-1})$. We use the standard facts that $|\widehat{G}| = n$ and that the two orthogonality relations hold:

$$\sum_{x\in G} \chi(x)\overline{\psi(x)} = n\,[\chi = \psi], \qquad \sum_{\chi\in\widehat{G}} \chi(x) = n\,[x = e].$$

For functions $\varphi, \psi : G \to \mathbb{C}$ write

$$\widehat{\varphi}(\chi) = \sum_{x\in G} \varphi(x)\chi(x), \qquad (\varphi * \psi)(x) = \sum_{y\in G} \varphi(y)\psi(y^{-1}x).$$

Three consequences are immediate from the orthogonality relations and will be used without further comment: inversion, $\varphi(x) = \frac{1}{n}\sum_\chi \widehat{\varphi}(\chi)\overline{\chi(x)}$; Parseval, $\sum_x|\varphi(x)|^2 = \frac{1}{n}\sum_\chi|\widehat{\varphi}(\chi)|^2$; and the convolution theorem, $\widehat{\varphi * \psi} = \widehat{\varphi}\,\widehat{\psi}$, the last because $\chi(x) = \chi(y)\chi(y^{-1}x)$.

Step 1: the walk is a convolution power. Let $S = \{g_1, \dots, g_k\}$ and let $P(x) = \frac{1}{k}$ for $x \in S$ and $P(x) = 0$ otherwise, the distribution of one roll. Let $P_m(x) = \mathrm{Prob}(g = x)$ after m rolls. Conditioning on the product of the first $m - 1$ rolls and using independence,

$$P_m(x) = \sum_{y\in G} P_{m-1}(y)\,P(y^{-1}x), \qquad \text{that is} \qquad P_m = P_{m-1} * P,$$

with $P_1 = P$. Taking Fourier transforms and iterating, $\widehat{P_m} = \widehat{P}^m$, so with

$$\lambda_\chi := \widehat{P}(\chi) = \frac{1}{k}\sum_{i=1}^{k} \chi(g_i)$$

we have $\widehat{P_m}(\chi) = \lambda_\chi^m$ for every $\chi \in \widehat{G}$ and every $m \geq 1$.

Step 2: Parseval turns the sum over G into a sum over characters. Let $U(x) = 1/n$ be the uniform distribution. Its transform is $\widehat{U}(\chi) = \frac{1}{n}\sum_x \chi(x) = [\chi = \widehat{e}]$, and $\lambda_{\widehat{e}} = \frac{1}{k}\cdot k = 1$, so $\widehat{P_m - U}(\chi) = 0$ for

$\chi = \widehat{e}$ and $= \lambda_\chi^m$ otherwise. Parseval therefore gives, for every $m \geq 1$,

$$D_m := \sum_{x \in G} \Big(P_m(x) - \frac{1}{n} \Big)^2 = \frac{1}{n} \sum_{\chi \neq \widehat{e}} |\lambda_\chi|^{2m}. \tag{1}$$

Step 3: the eigenvalues have modulus at most 1*, with equality only for* $\widehat{e}$*.* Each $\chi(g_i)$ is a complex number of modulus 1, so the triangle inequality gives $|\lambda_\chi| \leq 1$. Suppose $|\lambda_\chi| = 1$ for some χ, that is, $|z_1 + \cdots + z_k| = k$ with $z_i = \chi(g_i)$ of modulus 1. Equality in the triangle inequality forces all the z_i to be nonnegative real multiples of one common unit vector, and since each has modulus 1 they are all equal. Because $g_1 = e$ we have $z_1 = \chi(e) = 1$, hence $\chi(g_i) = 1$ for every i. The set of elements on which χ takes the value 1 is the kernel of χ, a subgroup; it contains all the g_i, which generate G, so it is all of G and $\chi = \widehat{e}$. Therefore

$$|\lambda_\chi| < 1 \quad \text{for every } \chi \neq \widehat{e}. \tag{2}$$

Step 4: the group has a nontrivial character and b *is positive.* Since $S \subsetneq G$ we have $k < n$, and $k \geq 1$, so $n \geq 2$ and $\widehat{G} \neq \{\widehat{e}\}$ because $|\widehat{G}| = n \geq 2$. Define

$$b := \max\{|\lambda_\chi| : \chi \in \widehat{G},\ \chi \neq \widehat{e}\},$$

a maximum over a finite nonempty set, so it is attained. By (2), $b < 1$. Suppose $b = 0$, so that $\lambda_\chi = 0$ for every $\chi \neq \widehat{e}$. Then inversion gives, for every $x \in G$,

$$P(x) = \frac{1}{n} \sum_{\chi} \lambda_\chi \overline{\chi(x)} = \frac{1}{n} \lambda_{\widehat{e}} = \frac{1}{n},$$

so P is the uniform distribution. But S is a proper subset of G, so there is an $x \notin S$, and for it $P(x) = 0 \neq 1/n$. This contradiction gives $b > 0$, so

$$b \in (0, 1).$$

Step 5: the limit. Let

$$N = \#\{\chi \in \widehat{G} : |\lambda_\chi| = b\},$$

noting that $\widehat{e}$ is not counted since $|\lambda_{\widehat{e}}| = 1 > b$, and that $1 \leq N \leq n - 1$ by the definition of b. Divide (1) by b^{2m}:

$$\frac{D_m}{b^{2m}} = \frac{1}{n} \sum_{\chi \neq \widehat{e}} \left(\frac{|\lambda_\chi|}{b} \right)^{2m}.$$

The sum is finite, with N terms equal to 1 for every m and every other term of the form r^{2m} with $0 \leq r < 1$, which tends to 0. Hence

$$\lim_{m \to \infty} \frac{1}{b^{2m}} \sum_{x \in G} \Big(\mathrm{Prob}(g = x) - \frac{1}{n} \Big)^2 = \frac{N}{n},$$

which is positive and finite, and $b \in (0, 1)$. ■

Two remarks worth carrying. First, the value of the limit is N/n and not N; the published solution loses the factor $1/n$ because it computes a squared norm of a vector of characters, each of which has squared norm n. The problem only asks for positive and finite, so nothing is lost, but you should compute constants correctly out of habit. Second, if you set the problem up with a transition matrix rather than with convolution, check which way your matrix multiplies: the natural matrix $M_{ij} = \frac{1}{k}[\, h_j = h_i g \text{ for some } g \in S\,]$ applied to the indicator of e produces the distribution of g^{-1}, not of g. Inversion is a bijection of G, so the sum in the problem is unchanged, but a grader is entitled to ask.

Layer 1: WHAT

Block 1. Name the object: $\text{Prob}(g = x)$ is the m fold convolution power of the uniform measure on the generating set, so the recursion is $P_m = P_{m-1} * P$, a linear recursion in the n dimensional space of functions on G.

Block 2. Diagonalise that linear recursion. Because G is abelian, the diagonalising basis is the character basis, and the eigenvalues are $\lambda_\chi = \frac{1}{k}\sum_i \chi(g_i)$.

Block 3. Convert the requested sum of squares into the character basis by Parseval, obtaining $D_m = \frac{1}{n}\sum_{\chi \neq \widehat{e}} |\lambda_\chi|^{2m}$, with the trivial character removed by the subtraction of $1/n$.

Block 4. Identify b as the largest nontrivial eigenvalue modulus, and spend the two unused hypotheses: $g_1 = e$ with generation gives $b < 1$, and properness of the generating set gives $b > 0$.

Block 5. Divide by b^{2m} and observe that a finite sum of terms r^{2m} with $r \leq 1$ converges to the number of terms with $r = 1$.

Juxtaposition. The nominal route tries to compute $\text{Prob}(g = x)$ for a general x, or fixes a small group such as $\mathbb{Z}/3$ to see a pattern, or quotes a convergence theorem for Markov chains and then tries to upgrade it to an exact rate by hand. The bifurcation point is Block 1 into Block 2: the decision that you will never compute a single value of $\text{Prob}(g = x)$, because the question does not ask for one. It asks for a squared norm, and squared norms are computed in the eigenbasis. Everything after that decision is forced.

Layer 2: HOW

Block 1. Cue. "Rolled m times and the selected elements are multiplied." **Why natural.** The distribution of a product of independent group valued random variables is the convolution of their distributions; that is the definition of convolution, not a theorem. Writing $P_m = P_{m-1} * P$ turns the words of the problem into a linear recursion $v_m = Tv_{m-1}$ on the n dimensional space of functions on G, and every linear recursion is solved by understanding T. **Link to the next block.** A power of a linear operator asks for an eigenbasis, so the next question is which basis diagonalises convolution by a fixed function.

Block 2. Cue. The word "abelian", which is doing no probabilistic work whatsoever, and therefore must be doing algebraic work. **Why natural.** Convolution operators commute with all translations of G. A commuting family of diagonalisable operators has a simultaneous eigenbasis, and for the translations of a finite abelian group that basis is exactly the set of characters: $\chi(y^{-1}x) = \overline{\chi(y)}\chi(x)$ says precisely that translating χ rescales it. So characters are eigenvectors of every convolution operator at once, with eigenvalue the Fourier coefficient of the convolving function. This is the single fact the problem is built on, and it fails for non abelian G because then the irreducible representations have dimension greater than one. **Link to the next block.** With eigenvalues named, the quantity to compute should be re expressed in the eigenbasis rather than in the standard basis.

Block 3. Cue. $\sum_{x \in G}(\cdot)^2$, a squared Euclidean norm over the whole group. **Why natural.** A squared norm is basis independent up to the normalisation of the basis, so compute it in whichever orthogonal basis makes the vector simple. Parseval is that statement for the character basis, and here it is decisive: in the standard basis $P_m - U$ has n complicated entries, while in the character basis it has entries λ_χ^m, which are literally m th powers. Subtracting the uniform distribution corresponds exactly to deleting the trivial character, because the uniform distribution is the projection of anything onto the constant function. **Link to the next block.** The expression $\frac{1}{n}\sum_{\chi \neq \widehat{e}} |\lambda_\chi|^{2m}$ is a finite sum of exponentials, and the asymptotics of such a sum are controlled by the largest base. That defines b with no choice involved.

Block 4. **Cue.** Two hypotheses remain unused: $g_1 = e$, and the generating set is a proper subset. The conclusion demands $b \in (0,1)$, two strict inequalities. **Why natural.** Count the unused hypotheses against the unproved claims: two and two. That pairing tells you what to prove with what before you have any idea how. The identity element in the list is what makes the walk aperiodic, and aperiodicity is exactly the statement that no nontrivial character has $|\lambda_\chi| = 1$; the properness is what stops the walk from being uniform already after one step, which is exactly $b > 0$. If the identity were absent the walk could be periodic: on $\mathbb{Z}/2$ with the single generator 1, the walk alternates deterministically, the nontrivial eigenvalue is -1, and the sum in the problem is constantly $1/2$, so no $b \in (0,1)$ can work. **Link to the next block.** The mechanism for $b < 1$ is equality in the triangle inequality; the mechanism for $b > 0$ is Fourier inversion, which turns "all nontrivial coefficients vanish" into "the function is constant".

Block 5. **Cue.** A finite sum of terms r_χ^{2m} divided by b^{2m} where $b = \max r_\chi$. **Why natural.** Each ratio $(r_\chi/b)^{2m}$ is either identically 1 or a geometric sequence with ratio less than 1. A finite sum of sequences may be passed to the limit term by term, so the limit is the count of maximisers. This is also the reason the problem is stated with b^{2m} rather than with a general normalisation: the ties must be allowed to count themselves, and they contribute an integer. **Link to the next block.** Positivity of the limit is the existence of at least one maximiser, which holds because $\widehat{G} \setminus \{\widehat{e}\}$ is nonempty; finiteness is the finiteness of $\widehat{G}$.

Layer 3: WHY

The truth beneath this route is that a convolution operator on a finite abelian group is a G circulant matrix, and every G circulant matrix is diagonalised by the same explicit unitary, the Fourier matrix. Concretely, if $M_{x,y} = f(x^{-1}y)$ then M commutes with every translation, the translations generate a commutative family of unitary operators, and a commuting family of unitary operators on a complex inner product space has a common orthogonal eigenbasis. For $G = \mathbb{Z}/n$ this is the familiar statement that circulant matrices are diagonalised by the discrete Fourier transform with eigenvalues $\sum_j c_j \omega^{jt}$. The Putnam problem is that statement dressed as a die roll.

The second truth is the general principle governing $T^m v$ for a diagonalisable T. Write $v = \sum_j c_j w_j$ in an eigenbasis with eigenvalues μ_j; then $T^m v = \sum_j c_j \mu_j^m w_j$. If exactly one eigenvalue has maximal modulus and it equals 1 with eigenvector w_0, then $T^m v \to c_0 w_0$ and the error is $\sum_{j \neq 0} c_j \mu_j^m w_j$, whose norm behaves like b^m where b is the second largest modulus. Dividing by b^{2m} and letting m grow keeps exactly the tying terms. This is the spectral gap principle: the gap $1 - b$ controls the mixing time of the walk, roughly $\log(n)/(1-b)$ steps to reach near uniformity, and the problem is asking you to prove that the gap is genuinely strictly between 0 and 1.

The discernment mechanism has three parts, and all three are transferable. First, when the quantity asked for is a norm rather than a value, change basis instead of computing entries. Second, when an operator is built from a group action, look for the representation theory that diagonalises it before doing anything analytic. Third, and most important here, audit your unused hypotheses against your unproved claims. This problem hands you two decorative looking conditions, $g_1 = e$ and $\subsetneq$, and asks for two strict inequalities, $b > 0$ and $b < 1$. That pairing is not a coincidence and it is visible before you know a single technique. Both conditions are sharp: dropping $g_1 = e$ allows periodic walks, and dropping properness allows the walk to be exactly uniform from the first step, which makes D_m identically zero and the limit 0 rather than positive.

How to train it: install the character theory of finite abelian groups as a reflex, then practise saying "convolution becomes multiplication" whenever you meet a sum over pairs whose indices multiply to something fixed. Then practise the audit: on every problem, list the hypotheses and cross them off as you spend them, and never submit a proof with an unspent hypothesis.

What the examiners nudged. They said abelian, which names the tool. They put e into the generating set explicitly, with the notation $g_1 = e$ rather than in prose, because it is the aperiodicity

hypothesis and they wanted it impossible to miss. They wrote $\subsetneqq$ with the strict symbol rather than saying "a set of generators", because properness is a hypothesis and not a description. And they asked for b^{2m} with a square, matching the square in the sum, so that b is the eigenvalue modulus rather than its square, which is the natural normalisation from the eigenvector expansion.

Revolving concepts

Characters and the dual group. A character of a finite abelian group G is a homomorphism $\chi : G \to \mathbb{C}^\times$; the values are n th roots of unity, the characters form a group $\widehat{G}$ under pointwise multiplication, and $\widehat{G} \cong G$ (not canonically). Explicitly, by the structure theorem $G \cong \mathbb{Z}/d_1 \times \cdots \times \mathbb{Z}/d_r$, and the characters are $\chi_{\mathbf{a}}(\mathbf{x}) = \prod_t \exp(2\pi i a_t x_t / d_t)$. See Book 1, field: Abstract algebra, topic: characters of finite abelian groups.

The two orthogonality relations. $\sum_x \chi(x)\overline{\psi(x)} = n[\chi = \psi]$ and $\sum_\chi \chi(x)\overline{\chi(y)} = n[x = y]$. The first says the characters are an orthogonal basis of the space of functions on G; the second is the first applied to $\widehat{G}$. Both follow from the one line argument: if $\chi \neq \widehat{e}$ pick y with $\chi(y) \neq 1$; then $\chi(y)\sum_x \chi(x) = \sum_x \chi(yx) = \sum_x \chi(x)$, so the sum vanishes. See Book 1, field: Abstract algebra, topic: orthogonality relations.

Fourier analysis on a finite abelian group. Transform $\widehat{\varphi}(\chi) = \sum_x \varphi(x)\chi(x)$; inversion $\varphi(x) = \frac{1}{n}\sum_\chi \widehat{\varphi}(\chi)\overline{\chi(x)}$; Parseval $\sum_x |\varphi|^2 = \frac{1}{n}\sum_\chi |\widehat{\varphi}|^2$; convolution theorem $\widehat{\varphi * \psi} = \widehat{\varphi}\widehat{\psi}$. For $G = \mathbb{Z}/n$ this is the discrete Fourier transform and the corresponding matrices are the circulants. See Book 1, field: Discrete structures and graphs, topic: Fourier analysis on finite groups.

Kernels and generation. The set where a homomorphism takes the value 1 is a subgroup, so a character trivial on a generating set is trivial. Conversely, for any proper subgroup $H \subsetneqq G$ there is a nontrivial character trivial on H, obtained by lifting a nontrivial character of G/H. See Book 1, field: Abstract algebra, topic: quotients and lifting characters.

Equality in the triangle inequality. If $z_1, \ldots, z_k \in \mathbb{C}$ and $|z_1 + \cdots + z_k| = |z_1| + \cdots + |z_k|$, then all nonzero z_i have the same argument; if in addition all have modulus 1, they are all equal. This is the standard mechanism for turning an extremal modulus into a rigidity statement, and it is how aperiodicity is proved in every finite Markov chain argument. See Book 1, field: Complex numbers, topic: equality cases.

Markov chains, stationarity and the spectral gap. A doubly stochastic transition matrix has the uniform distribution as stationary; irreducibility follows from the steps generating the group, aperiodicity from a self loop. The convergence theorem then gives $P_m \to U$, and the rate is governed by the second largest eigenvalue modulus b, with mixing time of order $\log(n)/(1-b)$. See Book 1, field: Probability, topic: Markov chains and mixing.

The generalised recursion (this is the load bearing generalisation). The problem contains the recursion $P_m = P_{m-1} * P$, that is, $v_m = Tv_{m-1}$ with T linear on a finite dimensional space. The general solution: if T is diagonalisable with eigenpairs (μ_j, w_j) and $v_0 = \sum_j c_j w_j$, then $v_m = \sum_j c_j \mu_j^m w_j$. If $\mu_0 = 1$ is the unique eigenvalue of maximal modulus, then $v_m \to c_0 w_0$ and, with b the next largest modulus and J the set of indices attaining it,

$$\lim_{m\to\infty} \frac{\|v_m - c_0 w_0\|^2}{b^{2m}} = \sum_{j\in J} |c_j|^2 \|w_j\|^2$$

whenever the eigenvectors attaining b are pairwise orthogonal and the μ_j with $|\mu_j| = b$ are equal in modulus but the cross terms vanish, which holds here because distinct characters are orthogonal and the sum was expanded in an orthogonal basis. The same template solves every linear recurrence $a_m = c_1 a_{m-1} + \cdots + c_d a_{m-d}$ through its companion matrix, where the dominant root controls growth and ties among roots of equal modulus produce oscillating or period doubling corrections. See Book 1, field: Sequences and recurrences, topic: linear recursions by diagonalisation.

Circuit Bank

- **WHEN** a probability is described as the product of m independent group valued choices **DO** write the m fold convolution and take the Fourier transform on the group **BECAUSE** convolution becomes multiplication, so the m th step becomes an m th power, and powers have visible asymptotics while convolutions do not
- **WHEN** the quantity to evaluate is $\sum(\cdot)^2$ over a finite index set **DO** apply Parseval in the basis that diagonalises the relevant operator, never compute entries **BECAUSE** a squared norm is basis independent, so you may choose the basis in which the vector has explicit coordinates
- **WHEN** a hypothesis looks decorative, such as "the identity is among the generators" or a strict subset symbol **DO** find the exact inequality it produces before writing anything, and count unused hypotheses against unproved claims **BECAUSE** Putnam hypotheses are never decoration, and the pairing between spare hypotheses and missing inequalities tells you the shape of the proof in advance
- **WHEN** a sum of complex numbers of modulus one attains the maximal possible modulus **DO** conclude that all of them are equal **BECAUSE** equality in the triangle inequality forces a common argument, and equal modulus then forces equality; this is the standard aperiodicity mechanism
- **WHEN** you must produce an exact exponential rate rather than bounds **DO** expand in eigenvectors, take b to be the largest subdominant eigenvalue modulus, and divide **BECAUSE** terms below the maximum vanish geometrically and tied terms contribute exactly one each, so the limit exists and counts the maximisers

Backtesting

1. First useful cue: the product of m independent uniform picks is a convolution power, and the requested quantity is a squared L^2 distance to uniform, so the problem lives in the character basis.
2. Method the expression suggested: Fourier transform on G, convolution theorem to get λ_χ^m, Parseval to get $D_m = \frac{1}{n}\sum_{\chi\neq\hat{e}}|\lambda_\chi|^{2m}$, then b as the maximum.
3. Where you would hesitate, and the thought to reinforce: at proving $0 < b < 1$, which looks like the technical part but is the part the hypotheses were designed for. Reinforce the audit habit: two unused hypotheses, two strict inequalities, match them before you look for techniques.
4. The trap the question sets: computing $\text{Prob}(g = x)$ for individual x, or working with a transition matrix without checking whether it produces the distribution of g or of g^{-1}. The first burns the clock, the second is a real correctness issue that a careful grader can penalise.
5. What makes you recognise it faster next time: the word abelian in a probability problem is never about probability, it is naming the diagonalising basis; and any request for an exact exponential rate is a request for a subdominant eigenvalue.
6. The reusable decision rule: convolution plus abelian group equals characters; sum of squares equals Parseval; exact rate equals second eigenvalue.

Mirror drills

1. Let $G = \mathbb{Z}/n$ with $n \geq 3$ and $S = \{0, 1\}$. Compute the eigenvalues λ_t, the value of b, and the number of maximisers. *Answer:* $\lambda_t = (1 + \omega^t)/2$ with $\omega = e^{2\pi i/n}$, so $|\lambda_t| = |\cos(\pi t/n)|$; the maximum over $t \neq 0$ is $\cos(\pi/n)$, attained at $t = 1$ and $t = n - 1$, so $b = \cos(\pi/n)$ and $N = 2$.

2. Show that a character χ of a finite abelian group that is trivial on a generating set is trivial. *Answer:* the set $\{x : \chi(x) = 1\}$ is the kernel of χ, hence a subgroup; it contains a generating set, so it is the whole group.

3. Show that $|\lambda_\chi| = 1$ for some nontrivial χ if and only if the step set S is contained in a single coset of a proper subgroup of G. *Answer:* if $|\lambda_\chi| = 1$ then all $\chi(g_i)$ share a value z, so $S \subseteq \chi^{-1}(z)$, a coset of $\ker\chi \subsetneq G$; conversely if $S \subseteq cH$ with H proper, lift a nontrivial character of G/H to χ, and then χ is constant on S, so $|\lambda_\chi| = 1$. This is exactly aperiodicity, and $e \in S$ rules it out.

15.7 B1. squeezing a scaled root difference into a window

Let h and k be positive integers. Prove that for every $\epsilon > 0$, there are positive integers m and n such that

$$\epsilon < |h\sqrt{m} - k\sqrt{n}| < 2\epsilon.$$

Read it out loud

This is a request to hit a moving target. You are not asked to solve an equation, you are asked to land a specific real quantity, $h\sqrt{m} - k\sqrt{n}$, inside a window of width exactly ϵ, for every window you are handed. The variables you control are m and n, both positive integers; h, k, ϵ are fixed before you choose. So the fields wired into this are elementary number theory (density of the rationals, existence of integer solutions) and real analysis (an approximation argument), dressed up as an algebra problem about square roots.

The first cue: two objects of the same shape, $h\sqrt{m}$ and $k\sqrt{n}$, subtracted. Whenever you see a difference of two square roots, or scaled square roots, the reaction circuit is to rationalise: multiply and divide by the conjugate sum, because $\sqrt{X} - \sqrt{Y} = \frac{X-Y}{\sqrt{X}+\sqrt{Y}}$ converts an uncontrolled difference of two irrational, wildly varying quantities into a controlled quotient, where the numerator is an integer you choose directly. That is the guiding light: this problem is not really about square roots, it is about engineering a quotient to land in an interval, and the factor of exactly 2 in "ϵ to 2ϵ" is the examiners' signal that some slack is available, you do not have to hit ϵ on the nose.

The second cue, "for every $\epsilon > 0$", is the density-of-the-rationals cue: whenever a problem asks you to get arbitrarily close to a target using only integers, and the target can be phrased as a ratio, density of $\mathbb{Q}$ in $\mathbb{R}$ is the tool, once the problem has been reduced to choosing that ratio.

Within thirty seconds you should have written down "difference of scaled roots, rationalise", and be hunting for a way to force $h\sqrt{m}$ and $k\sqrt{n}$ to both be a fixed multiple of a square root, so that h and k cancel and you are left with a bare, one-parameter-family difference of roots.

Approaches, ranked worst to best

1. **Guess and check small cases.** *Cue:* a specific small ϵ, an existence claim. *Circuit:* unstructured pattern matching. (why it ranks here: it might locate a working pair (m, n) for one numerical ϵ, but it proves nothing about "every $\epsilon > 0$" and gives no method to run in the arena when ϵ is handed to you as a free variable; it costs unbounded ink and never terminates into a proof.)

2. **Fix n, sweep m, and use a vanishing step size.** *Cue:* an unbounded increasing sequence must eventually cross any fixed window. *Circuit:* a discrete intermediate value argument. (why it ranks here: fix any n and look at $x_m = h\sqrt{m} - k\sqrt{n}$ for $m = 1, 2, 3, \ldots$. This is strictly increasing to infinity, and consecutive gaps $x_{m+1} - x_m = h/(\sqrt{m+1} + \sqrt{m})$ shrink to 0, so eventually the sequence cannot jump over an interval of length ϵ without landing inside it. This works, but it forces you to separately guarantee that the gap is already below ϵ before the sequence reaches the window, which means choosing n large first, purely to buy room; that is a layer of bookkeeping the algebraic route below does not need, and it hands you an existence claim with no explicit formula for m, n.)

3. **Rationalise, force a common scale, then invoke density of the rationals.** *Cue:* difference of two scaled square roots, "for every ϵ". *Circuit:* conjugate rationalisation plus a scaling trick to patch a side condition. (the ideal solution: fully explicit formulas for m and n in terms of two auxiliary positive integers, no asymptotic bookkeeping, minimal casework.)

The ideal solution

Fix positive integers h, k and $\epsilon > 0$, and write $N = hk$.

Choose positive integers a, b with

$$\frac{3\epsilon}{N} < \frac{b}{a} < \frac{4\epsilon}{N}.$$

Such a, b exist because $\left(\frac{3\epsilon}{N}, \frac{4\epsilon}{N}\right)$ is a nonempty open interval of positive reals, of length $\epsilon/N > 0$, and the rationals are dense in the reals, so some rational lies in it; write that rational as b/a with a, b positive integers.

If $3a^2 \leq b$, replace the pair (a, b) by (ta, tb) for a positive integer t large enough that $3(ta)^2 > tb$, that is, $t > b/(3a^2)$. This replacement leaves the ratio b/a unchanged, so the displayed inequality above still holds, and now $3a^2 > b$. Relabel so a, b satisfy both the ratio bound and $3a^2 > b$.

Set

$$m = k^2(a^2 + b), \qquad n = h^2a^2.$$

Both are positive integers, and

$$h\sqrt{m} = hk\sqrt{a^2 + b}, \qquad k\sqrt{n} = hka = Na,$$

so

$$h\sqrt{m} - k\sqrt{n} = N\left(\sqrt{a^2 + b} - a\right).$$

Since $b > 0$, $\sqrt{a^2 + b} > a$, so this quantity is positive and equals its own absolute value. It remains to show

$$\frac{\epsilon}{N} < \sqrt{a^2 + b} - a < \frac{2\epsilon}{N}.$$

Rationalise:

$$\sqrt{a^2 + b} - a = \frac{b}{\sqrt{a^2 + b} + a}.$$

Bound the denominator on both sides using the two facts already in hand. Since $b > 0$, $\sqrt{a^2 + b} > a$, so $\sqrt{a^2 + b} + a > 2a$. Since $3a^2 > b$, $a^2 + b < 4a^2$, so $\sqrt{a^2 + b} < 2a$, giving $\sqrt{a^2 + b} + a < 3a$. Hence

$$\frac{b}{3a} < \sqrt{a^2 + b} - a < \frac{b}{2a}.$$

Substitute the ratio bound $\frac{3\epsilon}{N} < \frac{b}{a} < \frac{4\epsilon}{N}$:

$$\sqrt{a^2 + b} - a > \frac{b}{3a} > \frac{1}{3} \cdot \frac{3\epsilon}{N} = \frac{\epsilon}{N}, \qquad \sqrt{a^2 + b} - a < \frac{b}{2a} < \frac{1}{2} \cdot \frac{4\epsilon}{N} = \frac{2\epsilon}{N}.$$

This is exactly the sandwich required, so

$$\epsilon < N(\sqrt{a^2 + b} - a) = h\sqrt{m} - k\sqrt{n} = |h\sqrt{m} - k\sqrt{n}| < 2\epsilon,$$

with $m = k^2(a^2 + b)$ and $n = h^2a^2$ positive integers, as required.

Layer 1: WHAT

Block 1: see a difference of two scaled square roots and reach for the rationalising identity before touching anything else. Block 2: force $h\sqrt{m}$ and $k\sqrt{n}$ to both carry the factor $N = hk$, by choosing m, n as k^2 and h^2 times other squares, so the coefficients cancel and only a bare $\sqrt{a^2 + b} - a$ survives. Block 3: rationalise that bare difference into $b/(\sqrt{a^2 + b} + a)$, converting a two-variable geometric statement into a one-variable ratio statement. Block 4: sandwich the denominator using $\sqrt{a^2 + b} > a$ (always true) and $\sqrt{a^2 + b} < 2a$ (true once $3a^2 > b$), turning the quotient into the range $b/(3a)$ to $b/(2a)$. Block 5: choose a, b by density of the rationals so b/a lands in the interval $(3\epsilon/N, 4\epsilon/N)$, an interval reverse engineered from Block 4 to land exactly on $(\epsilon/N, 2\epsilon/N)$. Block 6: patch the side condition $3a^2 > b$ by scaling $(a, b) \mapsto (ta, tb)$, which preserves the ratio.

Juxtapose the nominal route against this one. The nominal route (Approach 2) never leaves the two-variable world: it tracks an increasing sequence x_m and argues by vanishing step size that it cannot leap over a window, which then needs a separate argument for why the sequence is already fine grained by the time it reaches the window. The bifurcation point is Block 2: the ideal route immediately asks whether the coefficients h, k can be forced to cancel by a clever choice of m, n, collapsing the problem to one free ratio b/a; the nominal route leaves h, k inside the sequence and pays for it later in bookkeeping about how large n must be chosen first.

Layer 2: HOW

Block 1. **Cue.** A difference of two scaled square roots, $h\sqrt{m} - k\sqrt{n}$. **Why natural.** Whenever an expression is a difference of square roots, its size is not controlled directly, since $\sqrt{}$ is not linear; the standard reroute is to multiply by the conjugate sum, which turns the difference into a quotient whose numerator is a plain integer difference and is therefore fully under your control. **Link to the next block.** Before rationalising anything, first ask whether the coefficients h, k can be absorbed so the two radicands share a common structure.

Block 2. **Cue.** The presence of two independent coefficients h, k sitting outside two independent radicands m, n. **Why natural.** Carrying four independent symbols through an inequality argument costs more ink than carrying two. Setting $n = h^2a^2$ makes $k\sqrt{n} = kha$ a bare product with no leftover root, and setting $m = k^2(a^2 + b)$ makes $h\sqrt{m} = hk\sqrt{a^2 + b}$; both choices are forced by wanting the coefficient in front of the remaining square root to be the same combined constant $N = hk$ in both terms. **Link to the next block.** With h, k cancelled, the entire remaining problem is a statement about the single expression $\sqrt{a^2 + b} - a$, which is exactly the shape rationalising was built for.

Block 3. **Cue.** The now-bare expression $\sqrt{a^2 + b} - a$. **Why natural.** This is precisely $\sqrt{X} - \sqrt{Y}$ with $X = a^2 + b$, $Y = a^2$, so the identity $\sqrt{X} - \sqrt{Y} = (X - Y)/(\sqrt{X} + \sqrt{Y})$ applies directly, and $X - Y = b$, an integer you chose yourself. **Link to the next block.** A quotient is easy to bound once its denominator is sandwiched, so the next task is pinning $\sqrt{a^2 + b} + a$ between two explicit multiples of a.

Block 4. **Cue.** The denominator $\sqrt{a^2 + b} + a$, needing bounds on both sides. **Why natural.** The lower bound $\sqrt{a^2 + b} > a$ is automatic since $b > 0$; the upper bound $\sqrt{a^2 + b} < 2a$ is not automatic, it needs $a^2 + b < 4a^2$, that is $3a^2 > b$, an inequality you have not yet arranged. Naming this missing inequality explicitly, rather than assuming it, is what lets you fix it cleanly one step later. **Link to the next block.** Once the denominator is trapped between $2a$ and $3a$, the whole quotient $b/(\sqrt{a^2 + b} + a)$ is trapped between $b/(3a)$ and $b/(2a)$, so the target sandwich on $\sqrt{a^2 + b} - a$ has become a target sandwich on the single ratio b/a.

Block 5. **Cue.** A target interval for the ratio b/a, and the freedom to choose positive integers a, b. **Why natural.** Density of the rationals in the reals says every nonempty open interval of reals contains a rational; reading the target sandwich backwards through the factors of 3 and 2 from Block 4 pins down exactly which interval, $(3\epsilon/N, 4\epsilon/N)$, the ratio b/a must land in. **Link to the next block.** The only loose end is the side condition $3a^2 > b$ assumed in Block 4, which the chosen a, b may not yet satisfy, and which scaling both by the same integer t repairs without disturbing the ratio.

Layer 3: WHY

The truth underneath is that density of $\mathbb{Q}$ in $\mathbb{R}$ is the only tool that turns "for every $\epsilon > 0$" into "there exist integers"; everything else in the solution exists to reduce the original two-variable geometric statement down to a bare statement about a ratio of two free integers, because only a ratio can be placed anywhere by density. Rationalising is the reroute that makes this reduction possible: a raw difference of roots is not proportional to anything simple, but a quotient of the form $b/(\text{something near } 2a)$ is a bounded multiple of b/a, and bounded multiples of a freely placeable ratio are themselves freely placeable, up to the known bound.

The discernment mechanism: whenever a problem says "for every ϵ, find integers with an expression trapped in a window", check first whether the expression can be rewritten as a bounded multiple of a ratio of two free integer parameters. If it can, density of the rationals finishes the problem in two lines; if it cannot, you are in a genuinely harder approximation problem and may need the fuller machinery of Diophantine approximation. Train this discernment by practising the rationalising reroute on sight, every time a difference of roots appears, rather than reaching for it only after other routes stall.

The examiners nudged you toward this exact construction by choosing the window as ϵ to 2ϵ, a clean factor of two, not ϵ to $\epsilon + \delta$ for some fussy separate δ. That factor of two is exactly the slack a $2a$-to-$3a$ denominator sandwich produces on its own, which is a strong hint, once you notice it, that the intended route runs through exactly this kind of rationalise-then-sandwich construction rather than through a finer analytic estimate.

Revolving concepts

Density of $\mathbb{Q}$ in $\mathbb{R}$: between any two reals $x < y$ there is a rational, provable via the Archimedean property by choosing a denominator q with $1/q < y - x$ and rounding qx up to the nearest integer. See Book 1, field: Real analysis, topic: density and the Archimedean property.

Rationalising conjugates: $\sqrt{X} - \sqrt{Y} = (X - Y)/(\sqrt{X} + \sqrt{Y})$, the standard device for converting an additive difference of roots into a quotient; the same identity is the reason $\sqrt{n+1} - \sqrt{n} \to 0$ and underlies estimates like the one this year's A3 needs for x^r against x^{r+1} type ratios. See Book 1, field: Sequences and recurrences, topic: rationalising estimates.

Scaling a pair of integers defined only through their ratio, to force a side inequality: whenever a, b are only constrained by their ratio b/a, you may replace (a, b) by (ta, tb) for any positive integer t without disturbing the ratio; this is a free extra degree of freedom, useful whenever one side of a needed inequality grows faster in t than the other (here $3a^2$, quadratic in t, eventually beats b, linear in t). See Book 1, field: Number theory, topic: scaling arguments in Diophantine constructions.

Diophantine approximation, as context beyond what this problem needs: the general theory of approximating reals by rationals, including Dirichlet's approximation theorem, that for any real α and positive integer N there exist integers p, q with $1 \le q \le N$ and $|\alpha - p/q| < 1/(qN)$. This problem is a miniature instance of the same theme, trapping a constructed real inside a window using integer choices, though it needs only bare density, not the sharper Dirichlet bound.

Circuit Bank

- **WHEN** you see a difference of two scaled or shifted square roots **DO** multiply and divide by the conjugate sum immediately, before attempting any other manipulation **BECAUSE** it converts an unruly additive difference of irrationals into a quotient whose numerator is an integer you can choose directly
- **WHEN** a problem hands you free integer parameters that only interact through their ratio **DO** look for a target interval for that ratio and invoke density of the rationals to place it there

BECAUSE density of $\mathbb{Q}$ in $\mathbb{R}$ is the tool that turns "arbitrarily close" into "there exist integers", at no cost

- **WHEN** a construction needs a side inequality between two auxiliary integers that were only defined by a ratio **DO** scale both by a large positive integer t **BECAUSE** scaling preserves the ratio exactly while a term linear in t is eventually beaten by a term quadratic in t, in whichever direction the side inequality needs

Backtesting

1. First useful cue: a difference of two scaled square roots, $h\sqrt{m} - k\sqrt{n}$, reading as "rationalise me".
2. Method the expression suggested: force the coefficients h, k to cancel by choosing m, n as perfect-square multiples, then rationalise the remaining bare difference of square roots into a quotient.
3. Where you would hesitate, and the thought to reinforce: after rationalising you have $b/(\sqrt{a^2+b}+a)$, and it is tempting to approximate the denominator as roughly $2a$ without proving a clean two-sided bound; the thought to reinforce is that "roughly" is not a proof, so pin the denominator explicitly between $2a$ and $3a$ using a side condition you can always arrange by scaling.
4. The trap the question sets: the window is exactly ϵ to 2ϵ, a factor of two, which is precisely the slack the $2a$-to-$3a$ sandwich produces; a tighter window would force a finer sandwich, so read the given factor of two as a gift rather than an arbitrary choice of constants.
5. What makes you recognise it faster next time: any "for every ϵ, trap this integer-built expression in a window" problem is a density-of-the-rationals problem in disguise, the moment the expression can be rewritten as a bounded multiple of a free ratio.
6. The reusable decision rule: difference of roots, rationalise first; a free ratio of integer parameters, invoke density; a side inequality on auxiliary integers, fix it by scaling.

Mirror drills

1. Prove that for every $\epsilon > 0$ there are positive integers m, n with $0 < \sqrt{m} - \sqrt{n} < \epsilon$. *Answer:* take $n = a^2$, $m = a^2 + 1$ for a large enough that $1/(2a) < \epsilon$, then rationalise exactly as above.
2. Prove that $\{\sqrt{m} - \sqrt{n} : m, n \in \mathbb{Z}^+\}$ is dense in $[0, \infty)$. *Answer:* the same rationalise-and-scale construction, run against a target interval $(\epsilon, 2\epsilon)$ centred anywhere, not only near 0.
3. For fixed positive integers h, k, show there are infinitely many pairs (m, n) with $0 < h\sqrt{m} - k\sqrt{n} < 1$. *Answer:* run this problem's construction with $\epsilon = 1/2^j$ for $j = 1, 2, 3, \ldots$, producing infinitely many distinct pairs since the trapped value shrinks each time.

15.8 B2. why two and five dominate this set

Let S be the set of all ordered triples (p, q, r) of prime numbers for which at least one rational number x satisfies $px^2 + qx + r = 0$. Which primes appear in seven or more elements of S?

Read it out loud

This is a counting question wearing a quadratic-equation costume. The surface object is "a quadratic with prime coefficients has a rational root"; the real question, once that is stripped away, is "how many ordered triples of primes can a single prime sit inside". The phrase "at least one rational number x satisfies" is the command term: for a quadratic with integer coefficients, a rational root exists exactly when the discriminant is a perfect square, since an integer discriminant has a rational square root only when it has an integer one. That translation is the first thing you write down, inside thirty seconds: $(p, q, r) \in S \iff q^2 - 4pr = a^2$ for some integer $a \geq 0$.

The fields wired in are elementary number theory, parity and divisibility arguments, residues modulo a small number, a difference-of-squares factorisation, dressed as algebra. The word "prime" attached to all three of p, q, r, rather than "integer", is a second guiding light: it means every divisor-pair argument you run terminates in at most two or three cases, because a prime has almost no divisors beyond 1 and itself. Whenever a Putnam problem hands you primes as the objects being counted or factored, the reaction circuit is to force a small, explicit, finite structure, a factor pair or a residue class, out of that primality, rather than treating p, q, r as generic integers and hoping an inequality closes the argument.

The third cue is the number "seven": the question is not asking for the maximum, it is asking you to find a threshold and show only certain primes clear it. "Seven or more" signals a two-part proof: an explicit construction reaching the threshold for the primes that do, and a uniform upper bound ruling out every other prime, with the argument built so the bound is tight, not generous.

Approaches, ranked worst to best

1. **Numerically search small primes.** *Cue:* "which primes appear", a finite-looking search. *Circuit:* unstructured trial. (why it ranks here: you can stumble onto the fact that $(2, 5, 2)$ and similar triples work, but primes are unbounded, so a search alone cannot prove that no other prime ever reaches seven appearances; it produces examples, never a bound, and the problem needs both.)

2. **Treat p, q, r as generic integers and search the discriminant condition directly.** *Cue:* $q^2 - 4pr = a^2$. *Circuit:* brute algebraic manipulation that ignores primality. (why it ranks here: without forcing the primality of p, q, r into a small divisor structure early, you re-solve a two-variable Diophantine condition from scratch for every candidate prime, at high cost in ink, and you will not notice the forced appearance of 2 without the residue argument that primality of q and oddness of the discriminant actually supplies.)

3. **Force primality into a factor pair via a modulus-8 parity argument and a difference-of-squares factorisation, then pigeonhole modulo 3 to cap large primes.** *Cue:* primes, discriminant a perfect square, "seven or more". *Circuit:* parity forcing, a finite divisor-pair count, and a residue argument to bound every other candidate. (the ideal solution: converts an apparently unbounded counting problem into checking the primality of four explicit small numbers per candidate prime.)

The ideal solution

Reformulating membership in S. For primes p, q, r, the quadratic $px^2 + qx + r = 0$ has a rational root exactly when its discriminant $q^2 - 4pr$ is the square of a rational number. Since p, q, r are

integers, $q^2 - 4pr$ is an integer, and an integer is the square of a rational number exactly when it is the square of an integer. So

$$(p,q,r) \in S \iff q^2 - 4pr = a^2 \text{ for some integer } a \geq 0.$$

Forcing $q \geq 5$ and a 2 into every triple. Since $p, r \geq 2$, $4pr \geq 16$, so $q^2 = a^2 + 4pr \geq 16$, giving $q \geq 4$; as q is prime, $q \geq 5$, so q is odd. Then $a^2 = q^2 - 4pr$ is odd, so a is odd too. Odd squares are 1 modulo 8, so

$$4pr = q^2 - a^2 \equiv 1 - 1 = 0 \pmod 8,$$

hence $pr \equiv 0 \pmod 2$, so $2 \in \{p, r\}$.

Solving for q when $r = 2$. Suppose $r = 2$. Then $8p = q^2 - a^2 = (q-a)(q+a)$. Both factors are positive, since $a < q$ (as $a^2 = q^2 - 4pr < q^2$), and both are even, since q, a are both odd. Write $q - a = 2s$, $q + a = 2t$ with $0 < s < t$ integers, strict since $a \geq 1$; then $st = 2p$ and $s + t = q$. Since p is prime, the factor pairs of $2p$ with $s < t$ are $(1, 2p)$ and, when $p > 2$, $(2, p)$, giving

$$q = 1 + 2p = 2p + 1 \quad \text{or} \quad q = 2 + p = p + 2.$$

(When $p = 2$, only $(1, 4)$ has $s < t$, giving $q = 5$, consistent with $q = 2p + 1$.)

By the identical argument with the roles of p, r exchanged, since $q^2 - 4pr$ is symmetric in p, r, if instead $p = 2$, then

$$q = 2r + 1 \quad \text{or} \quad q = r + 2.$$

Counting appearances of a fixed prime $\ell \neq 2$. Every triple in S has $2 \in \{p, r\}$. Fix a prime $\ell \neq 2$ and count triples in which ℓ appears as p, q, or r.

If $r = 2$: ℓ can appear as p, giving $(\ell, q, 2)$ with $q \in \{2\ell + 1, \ell + 2\}$, contributing one triple for each of $2\ell + 1, \ell + 2$ that is prime; or ℓ can appear as q, giving $q = \ell \in \{2p + 1, p + 2\}$, so $p = (\ell - 1)/2$ or $p = \ell - 2$, contributing one triple for each of $(\ell - 1)/2, \ell - 2$ that is prime, since $q = \ell$ is automatically prime. So the branch $r = 2$ contributes at most one triple for each prime appearing in the list

$$2\ell + 1, \quad \ell + 2, \quad \frac{\ell - 1}{2}, \quad \ell - 2.$$

By the mirrored argument, the branch $p = 2$ contributes at most one further triple for each prime in this same list. So ℓ appears in at most twice as many elements of S as there are primes in this four-number list, hence at most 8, and strictly fewer whenever one of the four fails to be prime.

Ruling out every prime $\ell \geq 7$. The three numbers $\ell - 2, \ell, \ell + 2$ form an arithmetic progression with common difference 2, and $\gcd(2, 3) = 1$, so they occupy all three residues modulo 3 between them; exactly one is divisible by 3. Since $\ell \geq 7$ is prime, ℓ itself is not divisible by 3, so the multiple of 3 among the three is $\ell - 2$ or $\ell + 2$; both exceed 3 (as $\ell \geq 7$), so that one is composite. Hence at least one of the four list entries above, $\ell - 2$ or $\ell + 2$, is not prime, so at most three of the four are prime, and ℓ appears in at most $2 \times 3 = 6 < 7$ elements of S.

Ruling out $\ell = 3$. The list becomes $2(3) + 1 = 7$ (prime), $3 + 2 = 5$ (prime), $(3 - 1)/2 = 1$ (not prime), $3 - 2 = 1$ (not prime). Only two of the four are prime, so 3 appears in at most $2 \times 2 = 4 < 7$ elements of S.

The prime 2. The bound just proved assumed $\ell \neq 2$; it does not apply to $\ell = 2$, since 2 is the distinguished prime that appears in every branch of the case split, $r = 2$ or $p = 2$, not merely as an occasional coincidence produced by the four-number list. So 2 is not restricted by this counting argument at all, and its appearances, like 5's, must be confirmed directly by example.

Explicit examples reaching seven. The seven triples

$$(2,5,2),\ (2,5,3),\ (2,7,5),\ (2,11,5),\ (3,5,2),\ (5,7,2),\ (5,11,2)$$

each lie in S: their discriminants $q^2 - 4pr$ are $25 - 16 = 9$, $25 - 24 = 1$, $49 - 40 = 9$, $121 - 40 = 81$, $25 - 24 = 1$, $49 - 40 = 9$, $121 - 40 = 81$ respectively, all perfect squares $(3^2, 1^2, 3^2, 9^2, 1^2, 3^2, 9^2)$.

Every one of these seven triples contains a 2, so 2 appears in at least seven elements of S; every one of these seven triples also contains a 5, as p, q, or r, so 5 appears in at least seven elements of S too.

Answer. The primes appearing in seven or more elements of S are exactly 2 and 5.

Layer 1: WHAT

Block 1: translate "has a rational root" into "discriminant is a perfect square", the standard quadratic-formula cue. Block 2: use $p, r \geq 2$ to force $q \geq 5$, hence q odd, hence, via odd squares modulo 8, force a factor of 2 into $\{p, r\}$. Block 3: turn $8p = (q-a)(q+a)$, or its mirror $8r = (q-a)(q+a)$, into an explicit finite list of possible q, using the divisor pairs of $2p$ and that p is prime to limit those pairs to at most two. Block 4: reframe "how many triples contain ℓ" as "how many of four explicit numbers built from ℓ are prime", collapsing an unbounded search into a four-item checklist. Block 5: use a pigeonhole on residues modulo 3 over $\ell-2, \ell, \ell+2$ to show every prime $\ell \geq 7$ fails at least one item on the checklist, capping its count at six. Block 6: check $\ell = 3$ directly, which fails two of the four items, and exhibit seven explicit triples confirming both $\ell = 2$ and $\ell = 5$ reach seven.

Juxtapose the nominal route against this one. Approach 2 treats p, q, r as generic integers and tries to bound $q^2 - 4pr = a^2$ by raw size or search; it never notices that primality of p (or r) collapses an infinite divisor search into at most two cases, because it never runs the difference-of-squares factorisation with a prime specifically in view. The bifurcation point is Block 3: the moment you factor $8p = (q-a)(q+a)$ and ask how many ways a prime can split as a product of two positive integers, the whole problem becomes finite and explicit; skip that step, and you are searching an unbounded two-variable lattice by hand.

Layer 2: HOW

Block 1. **Cue.** "At least one rational number x satisfies $px^2 + qx + r = 0$." **Why natural.** A rational root of an integer quadratic exists exactly when the quadratic formula's square root term is rational, and the square root of an integer is rational only when that integer is a perfect square; this is a fixed reaction, not a case-by-case check. **Link to the next block.** With S rewritten as a perfect-square condition on $q^2 - 4pr$, the next move is to exploit that p, q, r are specifically primes, not arbitrary integers.

Block 2. **Cue.** Three prime variables p, q, r, and the size bound $4pr \geq 16$ forced by $p, r \geq 2$. **Why natural.** A crude size bound on q is the cheapest way to extract a first piece of structure before any casework; it costs one line and immediately restricts q to being odd, since the only even prime, 2, is now excluded. **Link to the next block.** Oddness of q, and hence of a, invites a residue argument, since odd squares have a single fixed residue modulo 8.

Block 3. **Cue.** Two odd squares q^2, a^2, both congruent to 1 modulo 8. **Why natural.** Subtracting forces $4pr \equiv 0 \pmod 8$, that is pr even, and since p, r are primes this can only mean one of them literally equals 2; a residue argument on a difference of two odd squares is the standard route to planting a factor of 2 into a product of primes. **Link to the next block.** With $2 \in \{p, r\}$ established, the discriminant equation for the case $r = 2$ becomes $8p = q^2 - a^2$, a genuine difference-of-squares factorisation with the prime p isolated on one side.

Block 4. **Cue.** $8p = (q-a)(q+a)$, with p prime. **Why natural.** A prime has only two positive factor pairs, $1 \times p$ and (when $p \neq 2$) $2 \times (p/1)$ scaled appropriately; running that through $st = 2p$ with $s < t$ produces exactly two candidate values of q, no more, because there is nothing else $2p$ can factor as. **Link to the next block.** Because the same relation holds with p, r exchanged by symmetry, every triple in S has its q pinned down by one of two linear formulas in whichever of p, r equals the non-2 prime, and this is the moment to ask how a fixed prime ℓ can appear across all such triples.

Block 5. **Cue.** A fixed prime ℓ, appearing either as the non-2 prime or as q itself, across two mirrored branches. **Why natural.** Each role ℓ could play corresponds to one of the four numbers $2\ell+1, \ell+2, (\ell-1)/2, \ell-2$ being prime, and the two branches ($p=2$ versus $r=2$) mirror each other exactly, so the count of triples containing ℓ is bounded by twice the count of primes in this fixed, explicit list. **Link to the next block.** Turning an unbounded question about appearances of ℓ into a bounded question about primality of four fixed numbers is what makes a pigeonhole argument on ℓ itself possible.

Block 6. **Cue.** Three numbers $\ell-2, \ell, \ell+2$ in arithmetic progression with common difference 2. **Why natural.** Since $\gcd(2,3)=1$, these three numbers hit every residue class modulo 3 exactly once, so one of them is always a multiple of 3; once $\ell \geq 7$, that multiple cannot be ℓ itself (which is prime), so it must be $\ell-2$ or $\ell+2$, and being a multiple of 3 exceeding 3, it is composite. **Link to the next block.** This composite entry knocks the four-item checklist down to at most three primes for every $\ell \geq 7$, capping appearances at six and leaving only $\ell=2$ and $\ell=5$ as candidates once $\ell=3$ is checked by hand and $\ell=2$ is set aside as exempt from the bound.

Layer 3: WHY

The mathematical truth underneath is that a prime has exactly the divisor pairs $1\times p$ and (for $p\neq 2$) its own analogue, nothing else; every restriction in this solution that looks engineered is really this one fact, applied three times over, once to bound q by raw size, once to force a 2 by parity, once to force the finite q-list by the divisor pairs of $2p$.

The discernment mechanism: whenever a Putnam problem asks you to count or classify objects built from primes, check first whether a size bound, a parity or residue bound, or a divisor-pair count can shrink an infinite search to a finite, explicit one, before you touch any inequality chasing. Train that discernment by asking, every time "prime" appears as a hypothesis rather than merely "integer", exactly what divisor structure that hypothesis is silently handing you.

The examiners nudged you toward the residue step by setting the threshold at "seven", a number just above the maximum any prime other than 2 and 5 can reach, namely six, which only becomes visible once you have built the four-item checklist. That is the signature of a bound meant to be tight rather than generous, and tight bounds of this kind are almost always proved by a residue or parity argument, not by a size estimate; a size estimate alone would leave you unable to explain why the threshold is exactly seven rather than, say, ten.

Revolving concepts

Rational root of an integer quadratic if and only if its discriminant is a perfect square: a direct reading of the quadratic formula, combined with the fact that the square root of an integer is rational only when it is already an integer. See Book 1, field: Polynomials, topic: discriminants and rational roots.

Quadratic residues modulo 8: every odd square is congruent to 1 modulo 8; a standard, load-bearing fact whenever a difference or sum of two odd squares appears. See Book 1, field: Number theory, topic: quadratic residues modulo small moduli.

Difference-of-squares factorisation combined with divisor-pair counting against a known, largely prime, factorisation: the standard route from "a number is a difference of two squares" to an explicit finite list of representations. See Book 1, field: Number theory, topic: difference of squares and divisor pairs.

Pigeonhole on residues modulo a small prime, applied to an arithmetic progression whose common difference is coprime to that modulus: guarantees exactly one term of any full residue cycle is divisible by it. See Book 1, field: Number theory, topic: pigeonhole on residue classes.

Circuit Bank

- **WHEN** a quadratic with integer coefficients is said to have a rational root **DO** rewrite the condition immediately as "the discriminant is a perfect square" **BECAUSE** the quadratic formula makes the root rational exactly when the square root term is rational, and an integer's square root is rational only when it is already an integer
- **WHEN** a Diophantine condition involves primes specifically, not generic integers **DO** look for a size bound, a parity or residue bound, or a divisor-pair count that the primality forces **BECAUSE** a prime's only factor pairs are 1 and itself, which collapses an unbounded search the instant you factor something as a product involving that prime
- **WHEN** you must bound how often a parameter ℓ can appear across a family of constructions built from small linear translates of ℓ **DO** reduce to checking primality of a short explicit list of numbers derived from ℓ, then use a residue pigeonhole on a small modulus to show large ℓ cannot pass every check **BECAUSE** an arithmetic progression with common difference coprime to a small modulus always hits every residue class, forcing one entry to become composite once ℓ is large enough

Backtesting

1. First useful cue: "at least one rational number x satisfies", translating directly to a perfect-square discriminant.
2. Method the expression suggested: force primality of p, q, r into a small explicit structure, first via a size bound on q, then via a parity argument planting a 2 into every triple.
3. Where you would hesitate, and the thought to reinforce: after the modulus-8 step gives $2 \in \{p, r\}$, it is tempting to handle $p = 2$ and $r = 2$ as one case by symmetry without saying so; the thought to reinforce is to name the symmetry explicitly, since $q^2 - 4pr$ is unchanged under swapping p, r, so the grader sees both branches were actually handled rather than assumed.
4. The trap the question sets: the threshold "seven" looks arbitrary until you have derived that every prime other than 2 and 5 tops out at six; do not hunt for the threshold's significance before finishing the general bound, or you will chase a pattern that only appears at the very end.
5. What makes you recognise it faster next time: any Putnam question counting or bounding "how many configurations of primes satisfy an algebraic condition" very likely routes through a perfect-square-discriminant translation plus a small-modulus parity or pigeonhole argument, because primes carry almost no divisor structure beyond size and residues.
6. The reusable decision rule: a quadratic with a rational root, translate to a perfect-square discriminant; primes doing the structural work, hunt for a forced parity or divisor-pair collapse; a numeric threshold in the question, prove the general bound first and let the threshold's significance fall out at the end.

Mirror drills

1. For which primes p does $x^2 + px + 1 = 0$ have a rational root? *Answer:* never; the discriminant $p^2 - 4$ would need to equal a^2 with $(p - a)(p + a) = 4$, forcing $p \leq 3$, and direct checking rules out $p = 2, 3$.
2. How many ordered pairs of primes (p, q) satisfy $q^2 - 4p$ a perfect square and $q < 20$? *Answer:* run the same $8p = (q - a)(q + a)$-style factorisation and list the finitely many candidates by hand for $q < 20$.

3. Fix a prime $\ell \geq 7$; show directly, without reference to S, that $\ell - 2, \ell, \ell + 2$ cannot all be prime. *Answer:* the same modulus-3 pigeonhole: one of the three is always a multiple of 3 exceeding 3.

15.9 B3. recovering differentiability from a product and quotient

Let f and g be real valued functions defined on an open interval containing 0, with g nonzero and continuous at 0. If fg and f/g are differentiable at 0, must f be differentiable at 0?

Read it out loud

This is a "must it follow" question, which folds two questions into one sentence: does the implication hold, and why does it need both hypotheses, fg differentiable and f/g differentiable, rather than either alone. Notice immediately that g carries the weakest hypothesis on the list, merely continuous and nonzero at 0, not differentiable; that is the guiding light. If g were assumed differentiable, this would be a non-problem: the product rule and quotient rule would hand you $f = (fg)/g$ differentiable instantly. The entire content of the problem is squeezed into the gap between "continuous" and "differentiable" for g.

The second cue is structural: you are handed a product fg and a quotient f/g of the same two functions. Whenever two given quantities are a product and a quotient of the same underlying objects, the reaction circuit is to multiply them, because the "other" factor cancels: $(fg) \cdot (f/g) = f^2$. That single line eliminates g entirely and produces a new differentiable function, f^2, built only from the two hypotheses you were actually given.

The third thing to notice, before writing a single further line, is that recovering f from f^2 is not free. $f = \pm\sqrt{f^2}$, and the square root function is differentiable at a value only when that value is positive, not at 0. So the moment you write $f^2 = (fg)(f/g)$, you have located the fault line of the whole problem: what happens when $f(0) = 0$, exactly where the square root loses differentiability. A full-marks solution announces this fault line before working through the cases, rather than discovering it midway and patching around it.

A caveat worth clarifying up front: g nonzero on the interval, together with continuity at 0, is what lets f/g even be defined near 0 in the first place; that housekeeping fact is used silently everywhere below and is worth stating once, at the start, rather than re-justifying each time.

Approaches, ranked worst to best

1. **Formally differentiate $f = \sqrt{(fg)(f/g)}$ without checking $f(0)$.** *Cue:* f looks like the square root of a differentiable product. *Circuit:* blind chain-rule differentiation of a composite. (why it ranks here: the resulting formula $f'(0) = \dfrac{(fg)'(0)(f/g)(0) + (fg)(0)(f/g)'(0)}{2f(0)}$ divides by $2f(0)$, silently assuming $f(0) \neq 0$; it produces a correct-looking answer that is simply undefined exactly in the case the problem is really testing, and a grader withholds full marks for the unhandled case even when the rest of the algebra is right.)

2. **Chase the definitions of $(fg)'(0)$ and $(f/g)'(0)$ directly, with no algebraic reduction first.** *Cue:* differentiability is ultimately a limit statement. *Circuit:* unstructured limit manipulation. (why it ranks here: it can be made to work, since it re-derives essentially the same combination of difference quotients as the ideal route, but without first isolating $f^2 = (fg)(f/g)$ or an equivalent identity, you are juggling three unknown limits at once with no organising principle, at real risk of an unjustified step or a missed case.)

3. **Multiply to get $f^2 = (fg)(f/g)$, split on whether $f(0)$ is zero, and handle each case on its own terms.** *Cue:* a product and a quotient of the same two functions. *Circuit:* cancellation, followed by a case split forced exactly where the square root loses differentiability. (the ideal solution: motivated at every step, and the case split is not a defect, it is the precise location the problem is testing.)

The ideal solution

Let I be the open interval containing 0 on which f, g are defined. Since g is continuous and nonzero at 0, there is a subinterval around 0 on which $g \neq 0$, so f/g is defined there; shrink I to that subinterval.

Step 1: f is continuous at 0. Since f/g is differentiable at 0, it is continuous at 0; since g is continuous at 0 by hypothesis, the product

$$f = (f/g) \cdot g$$

is continuous at 0, being a product of two functions continuous at 0.

Step 2: eliminate g. Since fg and f/g are both differentiable at 0, and a product of two functions differentiable at 0 is differentiable at 0,

$$(fg) \cdot (f/g) = f^2$$

is differentiable at 0.

Step 3: the case $f(0) \neq 0$. By Step 1, f is continuous at 0, so f has constant sign on some neighbourhood of 0, matching the sign of $f(0)$. Let $\delta = 1$ if $f(0) > 0$ and $\delta = -1$ if $f(0) < 0$; then $\delta f > 0$ on that neighbourhood, and there

$$\delta f = \sqrt{f^2},$$

since δf is the positive square root of $(\delta f)^2 = f^2$ whenever $\delta f > 0$. The function f^2 is differentiable at 0 (Step 2) and takes the positive value $f(0)^2$ there, and $\sqrt{\ }$ is differentiable at every positive real. By the chain rule, $\sqrt{f^2}$ is differentiable at 0, hence so is δf, hence so is $f = \delta \cdot (\delta f)$.

Step 4: the case $f(0) = 0$. Then $(f/g)(0) = f(0)/g(0) = 0$, so

$$(f/g)'(0) = \lim_{x \to 0} \frac{(f/g)(x) - (f/g)(0)}{x} = \lim_{x \to 0} \frac{f(x)}{xg(x)}.$$

This limit exists and is finite, since f/g is differentiable at 0. Since g is continuous at 0 with $g(0) \neq 0$, $g(x) \to g(0) \neq 0$ as $x \to 0$, so

$$\frac{f(x)}{x} = \frac{f(x)}{xg(x)} \cdot g(x) \longrightarrow (f/g)'(0) \cdot g(0)$$

as $x \to 0$, a finite limit, being a product of two convergent limits. Since $f(0) = 0$,

$$f'(0) = \lim_{x \to 0} \frac{f(x) - f(0)}{x} = \lim_{x \to 0} \frac{f(x)}{x}$$

exists, so f is differentiable at 0.

Assembling the two cases. In both cases f is differentiable at 0, so yes, f must be differentiable at 0.

Remark, a route avoiding the case split. The split in Steps 3 and 4 can be avoided by eliminating $g(x) - g(0)$ directly, rather than eliminating g multiplicatively. Write $u = fg$, $v = f/g$, and expand

$$u(x) - u(0) = (f(x) - f(0))g(x) + f(0)(g(x) - g(0)),$$

$$g(0)g(x)\big(v(x) - v(0)\big) = (f(x) - f(0))g(0) - f(0)(g(x) - g(0)).$$

Adding cancels the two $f(0)(g(x) - g(0))$ terms, since they enter with opposite sign, leaving

$$(f(x) - f(0))\big(g(x) + g(0)\big) = \big(u(x) - u(0)\big) + g(0)g(x)\big(v(x) - v(0)\big).$$

Since $g(x) + g(0) \to 2g(0) \neq 0$, dividing by $x\big(g(x) + g(0)\big)$ and letting $x \to 0$ shows $\lim_{x\to 0} \frac{f(x)-f(0)}{x}$ exists directly, in one line, with no reference to the sign of $f(0)$, because every term on the right converges: u, v are differentiable at 0, and g is continuous at 0. This is the same fact, proved uniformly instead of by cases. It is worth keeping as a second circuit, because eliminating an uncontrolled quantity by an additive combination, rather than working around it case by case, is a reroute worth having whenever one hypothesis in a problem is deliberately weaker than the others.

Layer 1: WHAT

Block 1: notice the product-and-quotient-of-the-same-two-functions structure, and multiply them to cancel g, producing $f^2 = (fg)(f/g)$, differentiable at 0 since it is a product of two functions differentiable at 0. Block 2: recognise that recovering f from f^2 needs the square root, which is differentiable only away from 0; this locates the fault line, $f(0) = 0$ against $f(0) \neq 0$, before doing any further work. Block 3: handle $f(0) \neq 0$ via the chain rule on $\sqrt{f^2}$ composed with the sign of $f(0)$. Block 4: handle $f(0) = 0$ separately by returning to f/g's difference quotient directly, dividing by $g(x)$ and then multiplying back by $g(x)$, which tends to the nonzero $g(0)$, to recover the difference quotient of f itself.

Juxtapose the nominal route against this one. Approach 1 writes down exactly the same identity, $f = \sqrt{(fg)(f/g)}$, but differentiates it with a ready-made composite-function formula, dividing by $2f(0)$ without asking whether that division is legal. The bifurcation point is Block 2: the ideal route stops the instant f^2 is known differentiable and asks whether the square root is safe to apply here, before writing any derivative formula; the nominal route writes the formula first and never asks.

Layer 2: HOW

Block 1. **Cue.** A product fg and a quotient f/g of the same two functions, both differentiable at 0. **Why natural.** Whenever a product and a quotient of the same pair of objects are both available, multiplying them cancels the shared factor; here $(fg)(f/g) = f^2$ removes g, the one function whose regularity is deliberately weak, and leaves a function built entirely from the two strong hypotheses. **Link to the next block.** f^2 being differentiable at 0 is not the same statement as f being differentiable at 0; recovering f from f^2 is a further, separate step, with its own restrictions.

Block 2. **Cue.** The recovery step $f = \pm\sqrt{f^2}$. **Why natural.** The square root function is differentiable at every positive real but not at 0, where its difference quotient diverges; since $f^2(0) = f(0)^2$, whether this recovery step is safe depends entirely on whether $f(0)$ itself is zero, which is a fact about f, not about f^2. **Link to the next block.** This is the exact fault line to split on, so the two remaining blocks are simply the two sides of that line, handled by whichever tool fits each side.

Block 3. **Cue.** $f(0) \neq 0$, so f is continuous (Step 1) and hence of constant sign near 0. **Why natural.** Once $\delta f > 0$ near 0 for the correct sign δ, δf literally equals $\sqrt{f^2}$ there, a genuine composition of the differentiable function f^2 with the square root, evaluated at the positive point $f(0)^2$; the chain rule applies without qualification. **Link to the next block.** Nothing here helps when $f(0) = 0$, since then $f^2(0) = 0$ sits exactly at the square root's point of non-differentiability, so a different tool is needed for that case, not a limiting version of this one.

Block 4. **Cue.** $f(0) = 0$, so f^2 vanishes at 0 and the square-root route is unavailable. **Why natural.** Returning to the raw definition of $(f/g)'(0)$ and multiplying its difference quotient back by $g(x)$, which is bounded away from 0 near 0 by continuity, reconstructs $f(x)/x$ as a product of two convergent quantities; this sidesteps the square root entirely rather than trying to rescue it.

Link to the next block. Both cases now closed, the two halves reassemble into one statement, f is differentiable at 0 regardless of the value of $f(0)$, closing the "must" in the question.

Layer 3: WHY

The truth underneath is that differentiability is a local, pointwise property, and the square root's derivative is unbounded at 0; any argument that recovers f from f^2 by taking a square root is only as strong as the square root is differentiable at the specific value $f(0)^2$ actually takes, which depends entirely on whether $f(0)$ is zero. The case split is not an artefact of a clumsy proof, it is a direct restatement of exactly where $\sqrt{}$ fails to be differentiable.

The discernment mechanism: whenever a solution manufactures a new function via a product, a quotient, or a composition of given data, check the domain on which the recovery step, a square root, a reciprocal, a logarithm, whatever undoes the manufacturing, is actually smooth, before trusting the manufactured function to hand back the original. That check is exactly the case split, or the reason there is none. Train this by asking, every time you multiply or compose two hypotheses together to build a new object, "what operation would I need to undo this, and where does that operation stop being differentiable".

The examiners chose "g nonzero and continuous, not differentiable" as the one deliberately weak hypothesis; the whole problem is an exercise in noticing that a weak hypothesis on one function, combined with strong hypotheses on two functions built from it and another, can still force a strong conclusion on the first, provided you find the algebraic combination, the product here, or the additive elimination in the remark, that never needs the weak hypothesis upgraded to anything stronger than it already is.

Revolving concepts

Differentiability implies continuity at the same point: used twice, once directly for f/g giving f continuous at 0 in Step 1, once implicitly wherever a differentiable function is treated as continuous. See Book 1, field: Real analysis, topic: differentiability implies continuity.

The chain rule, together with the domain of differentiability of the outer function: a composition $k(h(x))$ is differentiable at c once h is differentiable at c and k is differentiable at $h(c)$ specifically, not merely defined there; the square root is the standing example of a function differentiable everywhere on its domain except at one boundary point, 0. See Book 1, field: Calculus and integrals, topic: chain rule and domain restrictions on standard functions.

Algebra of limits: sums and products of functions with existing finite limits at a point have limits equal to the sum and product of those limits; used repeatedly to combine separately known limits of difference quotients into the limit defining $f'(0)$. See Book 1, field: Real analysis, topic: algebra of limits.

Eliminating an uncontrolled quantity between two expanded identities by an additive combination chosen so its coefficients cancel: a linear-elimination move, here applied to difference quotients rather than to a literal system of linear equations, useful whenever one function in a problem is assumed only continuous while others built from it are assumed differentiable. See Book 1, field: Real analysis, topic: elimination as a proof technique.

Circuit Bank

- **WHEN** you are given a product and a quotient of the same two functions, each with known but unequal regularity **DO** multiply them to cancel the shared, weaker factor, immediately **BECAUSE** $(fg)(f/g) = f^2$ eliminates the less regular function entirely and produces a new object built only from what was actually given

- **WHEN** you recover a function from its square, or from its image under any function that is not smooth everywhere **DO** check first whether the recovery step is smooth exactly where you need it, and split into cases at the boundary of where it fails **BECAUSE** the square root is differentiable only at positive values, and silently applying a derivative formula across that boundary produces an undefined or wrong answer disguised as a finished proof
- **WHEN** one hypothesis in a problem is visibly weaker than the others, continuous rather than differentiable **DO** look for an algebraic combination of the given data, a product, or an additive elimination of the weak function's difference quotient, that never requires upgrading the weak hypothesis **BECAUSE** the problem is testing exactly how far the weak hypothesis can be leveraged, not whether a stronger one can be smuggled in

Backtesting

1. First useful cue: fg and f/g given differentiable, g only continuous, a product and a quotient of the same pair of functions.
2. Method the expression suggested: multiply the product and the quotient to cancel g and produce f^2, differentiable at 0.
3. Where you would hesitate, and the thought to reinforce: right after writing $f = \pm\sqrt{f^2}$, the thought to reinforce is "is the square root differentiable at the value f^2 actually takes at 0", not "is f^2 differentiable", since those are different questions and only the first can fail.
4. The trap the question sets: applying the composite-derivative formula for $\sqrt{f^2}$ without checking $f(0) \neq 0$ first, dividing by $2f(0)$ when it may be 0.
5. What makes you recognise it faster next time: whenever you are asked to recover a function from a product or combination of two other functions, name the "undoing" operation explicitly, a square root, a division, and ask where it stops being smooth before applying it.
6. The reusable decision rule: a product and a quotient of the same functions, multiply to cancel; recovering the original via an operation that is not smooth everywhere, split exactly at its failure point; a hypothesis visibly weaker than the rest, hunt for a combination that never needs it upgraded.

Mirror drills

1. Let f, g be differentiable at 0 with $g(0) \neq 0$. Show, without quoting the quotient rule, that f/g is differentiable at 0. *Answer:* this is the base case of the same technique: write out the difference quotient of f/g, multiply and divide by $g(x)g(0)$, and use that $g(x) \to g(0) \neq 0$.
2. If f^2 and f^3 are both differentiable at 0, must f be differentiable at 0? *Answer:* yes; $f^3/f^2 = f$ wherever $f \neq 0$, and where $f(0) = 0$ a limit argument analogous to Step 4 applies, mirroring the product and quotient circuit with f^2, f^3 in place of $fg, f/g$.
3. Suppose only fg is known differentiable at 0, not f/g, but g itself is differentiable and nonzero at 0. Is f necessarily differentiable at 0? *Answer:* yes, trivially, since $f = (fg)/g$ with g differentiable and nonzero lets the ordinary quotient rule finish it in one line; contrast this against the original problem to see exactly why weakening g from differentiable to merely continuous is what creates the real difficulty.

15.10 B4. Tournament standings as a Gaussian Gram matrix

In a tournament, 2011 players meet 2011 times to play a multiplayer game. Every game is played by all 2011 players together and ends with each of the players either winning or losing. The standings are kept in two 2011×2011 *matrices,* $T = (T_{hk})$ *and* $W = (W_{hk})$*. Initially,* $T = W = 0$*. After every game, for every* (h, k) *(including for* $h = k$*), if players* h *and* k *tied (that is, both won or both lost), the entry* T_{hk} *is increased by 1, while if player* h *won and player* k *lost, the entry* W_{hk} *is increased by 1 and* W_{kh} *is decreased by 1.*

Prove that at the end of the tournament, $\det(T + iW)$ *is a non-negative integer divisible by* 2^{2010}*.*

Read it out loud

Say the structure to yourself before you touch a single entry. There are 2011 objects (the players). There is a table whose (h, k) entry is built only out of a comparison between object h and object k, accumulated over 2011 independent trials. You are asked for the determinant of that table. That is the whole shape of the question, and it is the shape of an inner product table. A matrix whose (h, k) entry is a pairwise comparison is a Gram matrix until proven otherwise; your first move is not to compute anything, it is to hunt for the vectors.

The second reading is about symmetry type. T is symmetric, because tying is a symmetric relation. W is antisymmetric with $W_{hh} = 0$, because the update rule explicitly writes $+1$ into W_{hk} and -1 into W_{kh}. Therefore $(T + iW)^* = T^{\mathsf{T}} - iW^{\mathsf{T}} = T + iW$: the matrix is Hermitian. The question chose the letter i for you, and it chose it precisely so that the symmetric part and the antisymmetric part could be carried in one Hermitian object. A Hermitian matrix has real determinant, so the word "integer" in the conclusion is already half explained. The word "non-negative" is the loud one. Over $\mathbb{C}$ there is essentially one structural reason a determinant is non-negative: the matrix is A^*A for some A. So you should have written $T + iW = A^*A$ on your paper inside thirty seconds, with A unknown, and then spent your effort finding the alphabet that A is written in.

The third reading is the exponent. Not 2^{2011}, not 2^{1005}, but 2^{2010}, and $2010 = 2011 - 1$, one less than the size of the matrix. Whenever a divisor of an $n \times n$ determinant carries the exponent $n - 1$, the mechanism is almost always the same: every entry of the matrix lies in a single residue class modulo something, so you may subtract one row from the other $n - 1$ rows and pull a common factor out of each of them. The exponent counts the rows you can clear. So the problem has told you, in the exponent, that the matrix you should be reducing has 2011 rows all congruent to each other, and told you, in the word non-negative, that this matrix is not $T + iW$ itself but its square root A.

The fields wired into this problem are linear algebra (Gram matrices, Hermitian forms, multiplicativity of the determinant), complex numbers used as an alphabet rather than as numbers, and a thin slice of the arithmetic of the Gaussian integers $\mathbb{Z}[i]$. That last slice is where the problem hides its real content, and it is where the candidates who get 2^{1005} instead of 2^{2010} lose four points.

Approaches, ranked worst to best

1. **Leibniz expansion.** *Cue:* "prove det of this explicit integer matrix is divisible by ...". *Circuit:* brute expansion of a determinant. You have 2011! signed products and no control over any of them. There is no parity bookkeeping that survives. This is zombie maths: it costs infinite ink and never terminates.

2. **Peel off** W **as a low rank perturbation.** *Cue:* W_{hk} counts wins against losses, which looks like a difference of two one-player statistics. *Circuit:* rank one and rank two determinant updates. This one is worth doing in your head because it produces a true and pretty fact. Write $\varepsilon_{jk} = +1$ if player k won game j and -1 if he lost. Then in game j the quantity $(\varepsilon_{jh} - \varepsilon_{jk})/2$ is $+1$ when h won and k lost, -1 when h lost and k won, and 0 on a tie, which is exactly the update to

W_{hk}. Summing over games, $W_{hk} = (s_h - s_k)/2$ where s_h is player h's wins minus losses. So $W = \frac{1}{2}(s\mathbf{1}^\mathsf{T} - \mathbf{1}s^\mathsf{T})$ has rank at most 2. Now you are tempted to compute $\det(T + iW)$ as a rank two update of $\det T$. It stalls: the update formula drags in T^{-1}, which you have no reason to believe exists, and the factors of $\frac{1}{2}$ generate a 2^{-2011} that you then have to fight. You have learnt something structural and gained nothing computational.

3. **Reduce $T + iW$ itself modulo the Gaussian prime $1 + i$.** *Cue:* the exponent $2010 = 2011 - 1$ shouts "congruent rows". *Circuit:* if all entries of an $n \times n$ matrix are congruent modulo π then π^{n-1} divides the determinant. This is the right circuit fired at the wrong matrix, and it is instructive to see exactly how much it gives. For $h \neq k$, each game either has the pair tying or splitting, so $T_{hk} + (\text{number of splits}) = 2011$, and W_{hk} is a signed count of those splits, hence $W_{hk} \equiv 2011 - T_{hk} \equiv 1 + T_{hk} \pmod 2$. Therefore $T_{hk} + iW_{hk} \equiv T_{hk}(1 + i) + i \equiv i \pmod{1 + i}$, while on the diagonal $T_{hh} + iW_{hh} = 2011 \equiv 1 \pmod{1 + i}$; and $1 \equiv i$ modulo $1 + i$ since $i - 1 = i(1 + i)$. So every entry of $T + iW$ is congruent to every other modulo $1 + i$, and $(1 + i)^{2010}$ divides $\det(T + iW)$ in $\mathbb{Z}[i]$. But $2 = -i(1 + i)^2$, so the prime 2 ramifies, and $(1 + i)^{2010}$ dividing a rational integer only gives 2^{1005}. You are exactly a square root short. That deficiency is the signal to go looking for a square root of the matrix.

4. **Encode results as ± 1 and use the real correlation matrix.** *Cue:* results are binary, so use signs. *Circuit:* Gram matrix over $\mathbb{R}$. With $E = (\varepsilon_{jk})$ you get $(E^\mathsf{T}E)_{hk} = T_{hk} - (2011 - T_{hk})$, so $E^\mathsf{T}E = 2T - 2011J$ where J is all ones. Clean, but fatal: $E^\mathsf{T}E$ is symmetric and therefore cannot see W at all. Real correlations are blind to the order of a pair. That failure is not a dead end, it is a specification: you need an alphabet whose Hermitian products are non-real.

5. **Gram factorisation over $\mathbb{Z}[i]$ with alphabet $\{1, i\}$, then congruent rows on A.** *Cue:* "non-negative" plus "2^{n-1}". *Circuit:* $\det(A^*A) = |\det A|^2$, combined with row clearing modulo $1 - i$. Everything the problem says is used, nothing is computed, and the norm at the end doubles the $(1 - i)$ valuation into exactly the required power of 2. This is the ideal route.

The ideal solution

Write $n = 2011$ throughout, and index games by j and players by h, k.

Choosing the alphabet. Suppose we look for complex numbers u (recording a win) and v (recording a loss) and set $a_{jk} = u$ if player k won game j and $a_{jk} = v$ if he lost. Consider the Hermitian product $\overline{a_{jh}}\, a_{jk}$ contributed by game j to the (h, k) position. We need it to equal 1 when h and k tied, $+i$ when h won and k lost, and $-i$ in the reverse case, because those are precisely the increments to $T_{hk} + iW_{hk}$. The tie conditions force $|u| = |v| = 1$; the split condition forces $\bar{u}v = i$, that is $v = iu$. Taking $u = 1$ gives $v = i$, and every other admissible choice is this one multiplied by a fixed number of modulus one, which changes nothing. The alphabet is not invented, it is solved for.

The factorisation. Let $A = (a_{jk})$ be the $n \times n$ matrix over $\mathbb{Z}[i]$ with $a_{jk} = 1$ if player k won game j and $a_{jk} = i$ if player k lost game j, and let $A^* = \overline{A}^\mathsf{T}$.

Claim 15.10.1. *$T + iW = A^*A$ at the end of the tournament.*

Proof. $(A^*A)_{hk} = \sum_{j=1}^{n} \overline{a_{jh}}\, a_{jk}$. Fix a game j and a pair (h, k), allowing $h = k$. If both players won, the term is $\bar{1} \cdot 1 = 1$; if both lost, it is $\bar{i} \cdot i = |i|^2 = 1$; in both cases the pair tied and game j added exactly 1 to T_{hk} and 0 to W_{hk}. If h won and k lost, the term is $\bar{1} \cdot i = i$, and game j added 1 to W_{hk}, contributing $i \cdot 1$. If h lost and k won, the term is $\bar{i} \cdot 1 = -i$, and game j added -1 to W_{hk}, contributing $i \cdot (-1) = -i$. The case $h = k$ is covered by the first two lines, since a player always ties with himself and the term is $|a_{jh}|^2 = 1$. So in every game and every position the term of A^*A equals the increment of $T + iW$. Both matrices start at 0 and both accumulate these increments over $j = 1, \ldots, n$, so they are equal at the end. □

Lemma 15.10.2 (congruent rows)**.** *Let R be a commutative ring, $\pi \in R$, and M an $n \times n$ matrix over R all of whose entries are congruent to one another modulo π. Then π^{n-1} divides* $\det M$ *in R.*

Proof. Subtract row 1 of M from each of rows $2, \dots, n$. This is a determinant preserving operation. Every entry of every new row is a difference of two entries of M, hence divisible by π; write each such row as π times a row over R. Multilinearity of the determinant in the rows lets us extract one factor of π from each of those $n-1$ rows, so $\det M = \pi^{n-1} \det M'$ for a matrix M' over R. □

Applying the lemma to A. Every entry of A lies in $\{1, i\}$, and $i - 1 = -(1 - i)$, so all entries of A are congruent modulo $\pi = 1 - i$ in $R = \mathbb{Z}[i]$. By the lemma there is $z \in \mathbb{Z}[i]$, say $z = a + bi$ with $a, b \in \mathbb{Z}$, such that

$$\det A = (1-i)^{n-1} z = (1-i)^{2010}(a + bi).$$

Taking the norm. The determinant is multiplicative, and $\det(A^*) = \det(\overline{A}^{\mathsf{T}}) = \det(\overline{A}) = \overline{\det A}$, since transposing preserves the determinant and conjugation commutes with the polynomial expression defining it. Hence

$$\det(T + iW) = \det(A^* A) = \overline{\det A}\, \det A = |\det A|^2 = |1-i|^{2 \cdot 2010}\, |z|^2.$$

Now $|1 - i|^2 = 2$, so $|1 - i|^{2 \cdot 2010} = 2^{2010}$, and $|z|^2 = a^2 + b^2$. Therefore

$$\boxed{\det(T + iW) = 2^{2010}\,(a^2 + b^2)}$$

for some integers a, b. Since $a^2 + b^2$ is a non-negative integer, $\det(T + iW)$ is a non-negative integer divisible by 2^{2010}, as required.

Remark on the hypothesis 2011 games. The equality of the number of games and the number of players is used only to make A square. It is not needed for the conclusion. If there are g games and n players, A is $g \times n$, and the Cauchy and Binet formula gives $\det(A^* A) = \sum_S |\det A_S|^2$, the sum over all n-element subsets S of the games, where A_S is the corresponding $n \times n$ submatrix. Each $\det A_S$ is divisible by $(1 - i)^{n-1}$ by the same lemma, so each $|\det A_S|^2$ is divisible by 2^{n-1}, and the conclusion holds for any number of games (vacuously with determinant 0 when $g < n$).

Layer 1: WHAT

Block 1. Read the (h, k) entry as a pairwise comparison and hypothesise $T + iW = A^* A$.

Block 2. Confirm the hypothesis is legal: T symmetric, W antisymmetric, so $T + iW$ is Hermitian, which is a necessary condition for being $A^* A$.

Block 3. Solve for the alphabet: unimodular u, v with $\bar{u} v = i$, giving $u = 1$, $v = i$.

Block 4. Verify $T + iW = A^* A$ by checking the four outcome cases of one game in one position, including $h = k$.

Block 5. Convert the conclusion: $\det(A^* A) = |\det A|^2$ delivers "real" and "non-negative" at once, and reduces the problem to a divisibility statement about $\det A$.

Block 6. Read 2010 as $n - 1$; all entries of A are congruent modulo $1 - i$; clear $n - 1$ rows and extract $(1 - i)^{2010}$.

Block 7. Take absolute squares. The norm doubles the valuation, turning $(1 - i)^{2010}$ into 2^{2010}, and $|z|^2 = a^2 + b^2$ is a non-negative integer.

Juxtaposition. The nominal route works on $T + iW$ directly: compute its entries in terms of win counts, notice they are all congruent modulo $1 + i$, apply the congruent rows lemma, and land on 2^{1005} with no idea why the problem asked for twice as much. The ideal route never computes an entry of T or W at all; it factorises first and applies the same lemma one level down, to A.

Bifurcation point. The split is at the word *non-negative*. If you treat it as decoration, you work on $T + iW$ and lose half the exponent. If you treat it as a command term meaning "this matrix is $A^* A$, go and find A", every later step is forced. There is no second decision in this problem.

Layer 2: HOW

Block 1. **Cue.** The phrase "for every (h, k)" together with an update rule that depends only on the results of players h and k. Nothing in the rule mentions any third player. **Why natural.** A table indexed by pairs of objects, whose entry depends only on those two objects and accumulates over independent trials, is by definition a sum over trials of a two-object function. If that function factorises as $\overline{\phi(h)}\phi(k)$ for each trial, the table is a Gram matrix. Since determinants of general matrices are unmanageable and determinants of Gram matrices are trivial, you always test this factorisation first. **Link to the next block.** Before hunting for ϕ, check that the target has the symmetry a Gram matrix must have.

Block 2. **Cue.** W_{kh} is decreased by exactly the amount W_{hk} is increased; T treats h and k alike. **Why natural.** A^*A is always Hermitian, so if $T + iW$ were not Hermitian the search would be over. It is: $T^\mathsf{T} = T$ and $W^\mathsf{T} = -W$ give $(T + iW)^* = T^\mathsf{T} - i\,W^\mathsf{T} = T + iW$. The problem manufactured a Hermitian matrix on purpose, which is why i appears in the statement at all. **Link to the next block.** A Hermitian target tells you the products $\overline{a_{jh}}a_{jk}$ must reproduce the increments. Write down what those increments are and solve.

Block 3. **Cue.** The increment is 1 on a tie and $\pm i$ on a split, with the sign flipping when the pair is swapped. **Why natural.** $\overline{a_{jh}}a_{jk}$ swaps to its conjugate when h and k swap. So a symmetric increment needs a real product and an antisymmetric increment needs a purely imaginary one. Setting u, v for win and loss, the tie conditions $\bar{u}u = \bar{v}v = 1$ force modulus one and the split condition $\bar{u}v = i$ forces $v = iu$. This is a two line calculation with a unique answer up to an irrelevant global phase, so nothing here is invention. It also explains, retroactively, why the ± 1 encoding of results cannot work: with real entries the product is symmetric and W is invisible. **Link to the next block.** You now have a candidate A; verify it exhaustively, because a Gram claim is only worth what its case check is worth.

Block 4. **Cue.** "for every (h, k) (including for $h = k$)". The examiners inserted that parenthesis; treat it as an instruction to check the diagonal separately. **Why natural.** There are exactly four outcomes for a pair in a game and the verification is four one line computations. The diagonal case is the one candidates drop, and it is the one that makes $T_{hh} = 2011$ match $\sum_j |a_{jh}|^2 = 2011$. **Link to the next block.** With the factorisation proved, restate the goal in terms of $\det A$.

Block 5. **Cue.** det is multiplicative and $\det(A^*) = \overline{\det A}$. **Why natural.** $\det(A^*A) = |\det A|^2$ converts a statement about a complicated Hermitian matrix into a statement about one Gaussian integer. Reality and non-negativity are now automatic rather than things to prove, which is the whole payoff of factorising. **Link to the next block.** The surviving problem is: why is $|\det A|^2$ divisible by 2^{2010}? Equivalently, why is $\det A$ divisible by something of modulus squared 2, raised to the power 2010?

Block 6. **Cue.** $2010 = 2011 - 1 = n - 1$, and A has only two distinct entries. **Why natural.** The exponent $n - 1$ is the fingerprint of row clearing: you can always make $n - 1$ rows divisible by π if all entries are congruent modulo π, and no more than that, because the first row survives. Here the two entries are 1 and i, whose difference is $-(1 - i)$, so $\pi = 1 - i$ is not chosen, it is read off. The element $1 - i$ has $|1 - i|^2 = 2$, which is exactly the modulus squared you needed in Block 5. **Link to the next block.** Extract $(1 - i)^{2010}$ and take the norm.

Block 7. **Cue.** A Gaussian integer written as $a + bi$, and $|z|^2 = a^2 + b^2$. **Why natural.** Taking $|\cdot|^2$ of $\det A = (1 - i)^{2010}z$ multiplies valuations by two: $|1 - i|^2 = 2$ gives 2^{2010}, and $|z|^2$ is a non-negative

rational integer with no further structure needed. This is where the ramification of 2 in $\mathbb{Z}[i]$ pays you back the factor the nominal route lost. **Link to the next block.** Nothing remains; state the boxed identity and read the conclusion off it.

Layer 3: WHY

Three mathematical truths carry this problem, and each is worth installing on its own.

First, the Gram principle. An $n \times n$ complex matrix M is of the form A^*A if and only if M is Hermitian positive semidefinite, and in that case $\det M \geq 0$ because the determinant is the product of the (real, non-negative) eigenvalues. So "prove this determinant is a non-negative integer" is never a computational instruction; it is a request for a factorisation. In the arena, the reflex must be: non-negative determinant, find the vectors. Here the vectors are the columns of A, one per player, living in $\mathbb{C}^{2011}$ with one coordinate per game, and the entry $T_{hk} + iW_{hk}$ is literally the Hermitian inner product of player h's history with player k's history.

Second, the arithmetic of $\mathbb{Z}[i]$, which is the part of the problem that is not linear algebra at all. In $\mathbb{Z}[i]$ the rational prime 2 is not prime: $2 = -i(1+i)^2$, and $1+i$ (equivalently $1-i$, its associate) is the unique ramified prime, of norm 2. The consequence you must feel in your fingers is that the $(1+i)$ valuation of a rational integer is twice its 2 valuation. That single fact explains the entire design of the problem. The naive route obtains $(1+i)^{2010} \mid \det(T+iW)$ and therefore only 2^{1005}; the ideal route obtains $(1-i)^{2010} \mid \det A$ and then squares the norm, gaining a factor of two in the exponent and reaching 2^{2010}. The examiners chose the exponent 2010 rather than 1005 exactly to detect which of the two you did. The discernment mechanism is therefore quantitative: compute what the lazy route gives, compare it with what is demanded, and if you are short by a factor of two in an exponent over $\mathbb{Z}[i]$, you are being asked for a square root of the matrix.

Third, the congruent rows lemma, which is the general reason exponents of the form $n-1$ appear in divisibility statements about determinants. It holds over any commutative ring and its proof is one row operation. Learn it as a rule about *alphabets*: if the entries of a matrix are drawn from a set that lies in a single residue class modulo π, you get π^{n-1} free. Sets like $\{1,-1\}$ modulo 2, $\{0,1\}$ modulo 1 (useless), $\{1,i,-1,-i\}$ modulo $1-i$, and $\{1,\omega,\omega^2\}$ modulo $1-\omega$ for a primitive cube root of unity, are all worth knowing by sight.

How to train this. Take every past problem in which the answer is a determinant and ask, before computing, which of the three standard structures it has: Gram (A^*A), circulant or group-invariant (diagonalised by characters), or combinatorial incidence (Cauchy and Binet or matrix tree). Then ask what the entries are made of. Two of those three questions solve this problem, and neither of them is a calculation.

Revolving concepts

Gram matrix. For vectors $v_1, \ldots, v_n$ in $\mathbb{C}^m$ the Gram matrix is $G_{hk} = \langle v_h, v_k \rangle = v_h^* v_k$, and $G = A^*A$ where A has the v_k as columns. Orbiting facts: G is Hermitian positive semidefinite; $\operatorname{rank} G = \operatorname{rank} A$; $\det G \geq 0$ with equality if and only if the vectors are linearly dependent; over $\mathbb{R}$, $\det G$ is the square of the volume of the parallelotope they span. Conversely every Hermitian positive semidefinite matrix is a Gram matrix, via its positive semidefinite square root. See Book 1, field: Linear algebra, topic: Gram matrices and positive semidefinite forms.

Hermitian matrices. $M^* = M$; eigenvalues real; $\det M$ and $\operatorname{tr} M$ real; the decomposition of a real matrix pair into $T + iW$ with T symmetric and W antisymmetric is the standard way to package a symmetric and an antisymmetric statistic into one object. See Book 1, field: Linear algebra, topic: Hermitian and unitary matrices.

Cauchy and Binet. For A of size $g \times n$ with $g \geq n$, $\det(A^*A) = \sum_{|S|=n} |\det A_S|^2$, the sum over n-subsets of rows. This is the tool that removes the artificial coincidence between the number of

games and the number of players, and it is the correct generalisation of $\det(A^*A) = |\det A|^2$. See Book 1, field: Matrices and determinants, topic: Cauchy and Binet formula.

Gaussian integers. $\mathbb{Z}[i]$ is a Euclidean domain with norm $N(a+bi) = a^2+b^2$, units $\{\pm 1, \pm i\}$. A rational prime q splits if $q \equiv 1 \pmod 4$, stays prime if $q \equiv 3 \pmod 4$, and ramifies for $q = 2$, where $2 = -i(1+i)^2$. Hence $v_{1+i}(m) = 2v_2(m)$ for $m \in \mathbb{Z}$. Sums of two squares, Fermat's theorem on $q \equiv 1 \pmod 4$, and the classification of Gaussian primes all orbit this. See Book 1, field: Number theory, topic: Gaussian integers and sums of two squares.

The congruent rows lemma. Stated and proved above. Generalise it to: if the rows of M fall into r classes modulo π then π^{n-r} divides $\det M$, by clearing all but one row in each class. The version with $r = 1$ is the one you will use ninety per cent of the time.

The recursion in the problem, generalised. The tournament is a recursion: if M_g denotes $T + iW$ after g games and $v_g \in \mathbb{C}^n$ is the row of game g (entry 1 for a winner, i for a loser), then the update rule says exactly

$$M_g = M_{g-1} + v_g^* v_g, \qquad M_0 = 0.$$

That is the general rank one accumulation recursion, and its general solution is $M_g = \sum_{j \le g} v_j^* v_j = A^*A$ with A the matrix of rows $v_1, \dots, v_g$. Two standard consequences travel with it. The matrix determinant lemma, $\det(M + uu^*) = \det(M)\,(1 + u^* M^{-1} u)$ for invertible M, is the step by step evaluation and is usually the wrong tool. The closed form via Cauchy and Binet is the right one. Whenever a problem describes a process that adds a rank one Hermitian correction at each step, do not iterate: recognise the sum as a Gram matrix and jump straight to the closed form. See Book 1, field: Matrices and determinants, topic: rank one updates and accumulation.

Roots of unity as an alphabet. Encoding an m-valued outcome by m-th roots of unity so that $\overline{u}v$ records the difference of two outcomes is the same device that underlies Gauss sums, characters of finite abelian groups, and the discrete Fourier transform. The specialisation here is the smallest interesting case: two outcomes, ratio i, so that $\overline{u}v$ is purely imaginary and can carry an antisymmetric statistic. See Book 1, field: Complex numbers, topic: roots of unity as encodings.

Circuit Bank

- **WHEN** a matrix whose (h,k) entry is a comparison between object h and object k **DO** look for vectors v_h with entry $= v_h^* v_k$ and write $M = A^*A$ **BECAUSE** a pairwise table is an inner product table until proven otherwise, and factorising hands you reality, non-negativity, rank and multiplicativity of the determinant in one line

- **WHEN** the words "prove that this determinant is non-negative" **DO** stop computing and find the Gram factorisation **BECAUSE** over $\mathbb{C}$ the only structural source of a non-negative determinant is A^*A, so the phrase is a command term, not decoration

- **WHEN** a claim that π^{n-1} divides an $n \times n$ determinant **DO** check whether all entries lie in one residue class modulo π, then subtract row 1 from the other rows **BECAUSE** the exponent $n-1$ counts exactly the rows you can clear by one determinant preserving operation

- **WHEN** a two valued outcome that must be recorded antisymmetrically **DO** encode the outcomes as unimodular numbers whose ratio is i, never as ± 1 **BECAUSE** $\overline{u}v$ is symmetric under swapping the pair precisely when u/v is real, so real alphabets are blind to orientation

- **WHEN** a process defined by "after every step, add one to these entries" **DO** write the step as $M_g = M_{g-1} + v_g^* v_g$ and pass to the closed form A^*A **BECAUSE** rank one accumulation always has a Gram closed form, and iterating the determinant instead is strictly more expensive

Backtesting

1. First useful cue: the pair of words "non-negative integer" attached to a determinant, reinforced by the exponent $2010 = 2011 - 1$.
2. Method the expression suggested: factorise $T + iW$ as A^*A where A records each player's history in an alphabet of two unimodular symbols, then apply the congruent rows lemma to A over $\mathbb{Z}[i]$ and take norms.
3. Where you would hesitate, and the thought to reinforce: choosing i for a loss rather than -1. Reinforce by solving rather than guessing: write u, v unimodular, demand $\bar{u}v = i$, conclude $v = iu$. Any encoding question of this type is a two line linear demand, never a flash of insight.
4. The trap the question sets: applying the congruent rows lemma to $T + iW$ itself. It is a legal argument, it is quick, and it yields only 2^{1005} because 2 ramifies in $\mathbb{Z}[i]$. A candidate who does this and writes "hence divisible by 2^{2010}" has made a valuation error worth the whole problem.
5. What makes you recognise it faster next time: the exponent audit. Compute the exponent the cheap route produces, compare it with the exponent demanded, and let the ratio tell you what structure you are missing. A shortfall by a factor of exactly two in an exponent over a quadratic ring means a norm is waiting to be taken.
6. The reusable decision rule: pairwise table plus non-negativity equals Gram factorisation; exponent $n - 1$ equals congruent rows; and when both appear, apply the second to the factor, not to the product.

Mirror drills

1. Let M be an $n \times n$ integer matrix all of whose entries are odd. Show $2^{n-1} \mid \det M$. *Answer:* all entries are congruent modulo 2; subtract row 1 from the other $n - 1$ rows and pull out a factor of 2 from each.
2. Let M be an $n \times n$ matrix each of whose entries is a fourth root of unity. Show that 2^{n-1} divides $|\det M|^2$. *Answer:* all of $1, i, -1, -i$ are congruent modulo $1 - i$ (their pairwise differences are $1 - i$ times a Gaussian integer), so $(1 - i)^{n-1} \mid \det M$; now take $|\cdot|^2$ and use $|1 - i|^2 = 2$.
3. Same tournament, but with g games instead of 2011, where g may be less than or greater than the number n of players. Show $\det(T + iW)$ is still a non-negative integer divisible by 2^{n-1}. *Answer:* $T + iW = A^*A$ with A of size $g \times n$; apply the Cauchy and Binet formula and the congruent rows lemma to each $n \times n$ minor, noting that the determinant is 0 when $g < n$.

15.11 B5. Overlap integrals of Lorentzians against reciprocal sums

Let $a_1, a_2, \ldots$ be real numbers. Suppose that there is a constant A such that for all n,

$$\int_{-\infty}^{\infty} \left(\sum_{i=1}^{n} \frac{1}{1+(x-a_i)^2} \right)^2 dx \le An.$$

Prove there is a constant $B > 0$ such that for all n,

$$\sum_{i,j=1}^{n} (1+(a_i-a_j)^2) \ge Bn^3.$$

Read it out loud

The hypothesis is the L^2 norm squared of a sum of n identical bumps, each bump a Lorentzian $1/(1+x^2)$ translated to sit over a_i. The conclusion is a double sum over the same index pairs of $1+(a_i-a_j)^2$. Say that out loud and the shape of the problem is already fixed: the hypothesis is a quadratic form in the pairs (i,j), and the conclusion is a quadratic form in the same pairs. The only work is to make the hypothesis look like the conclusion.

The mechanism that turns an L^2 norm of a sum of translates into a pairwise quadratic form is expansion. Never bound a squared sum before you expand it: the cross terms are the entire content, and any pointwise estimate on the sum destroys them. Expanding gives $\sum_{i,j} \int \phi(x-a_i)\phi(x-a_j)\,dx$ with $\phi(x) = 1/(1+x^2)$, and the inner integral is translation invariant, so it depends only on $a_i - a_j$. Call it $f(a_i-a_j)$. Within thirty seconds you should have written

$$\sum_{i,j=1}^{n} f(a_i-a_j) \le An, \qquad f(y) = \int_{-\infty}^{\infty} \frac{dx}{(1+x^2)\big(1+(x+y)^2\big)}.$$

Now look at the two sums side by side. The hypothesis, once you know the size of f, controls $\sum_{i,j} 1/(1+(a_i-a_j)^2)$ from above. The conclusion asks for $\sum_{i,j}(1+(a_i-a_j)^2)$ from below. Those two summands are exact reciprocals. There is no pointwise inequality connecting a positive number to its reciprocal in the direction you need, so the bridge has to be a global one, and the global statement about a family and its reciprocals is the Cauchy and Schwarz inequality: $\big(\sum 1\big)^2 \le \big(\sum u\big)\big(\sum 1/u\big)$. That is not a choice, it is the only mechanism available.

Check the exponent before you commit. There are n^2 index pairs, so $\sum_{i,j} 1 = n^2$, and Cauchy and Schwarz will deliver $\sum u \ge (n^2)^2 / \sum(1/u) \ge n^4/(\text{constant}\cdot n) = \text{constant}\cdot n^3$. The exponent 3 in the problem is the fingerprint of exactly this manoeuvre. The fields here are real analysis (convergence and term by term integration), the calculus of the Cauchy kernel, and inequalities. Note also the phrase "there is a constant $B > 0$": that licenses you to throw away every fixed numerical factor from the first line onward, so you must never compute f exactly.

Approaches, ranked worst to best

1. **Bound the integrand pointwise before expanding.** *Cue:* a squared sum inside an integral looks like something to estimate. *Circuit:* crude majorisation. Any bound of the form $\sum_i \phi(x-a_i) \le$ something, or an application of the Cauchy and Schwarz inequality inside the integral, collapses the pairwise structure into a single number. The conclusion is a statement about pairs (i,j), so information about pairs is exactly what you must not throw away. This is the pure zombie route: it produces true inequalities that are useless.

2. **Contrapositive by clustering.** *Cue:* "prove there is a constant $B > 0$" invites a proof by contradiction. *Circuit:* if the pairwise distances are small then the bumps pile up and the L^2

norm is large. Assume $\sum_{i,j}(1+(a_i-a_j)^2)$ is small, deduce that the a_i crowd into few unit intervals, deduce that $\int \Phi_n^2$ is large. This works, and pushed properly it gives the stronger bound Bn^4: count q_z points in $[z, z+1)$, note $\sum_z q_z^2 \lesssim An$, apply Jensen to see the points occupy at least cn distinct unit intervals, then sum $(|i-j|-1)^2$ over those. It ranks low here because it is strictly more machinery than the question asks for, and because it still requires the expansion step first.

3. **Plancherel.** *Cue:* an L^2 norm of a sum of translates. *Circuit:* energy in frequency space. Since $\widehat{\phi}(\xi) = \pi e^{-|\xi|}$ for $\phi(x) = 1/(1+x^2)$, Plancherel turns the hypothesis into $\frac{\pi}{2}\int e^{-2|\xi|}\left|\sum_j e^{i\xi a_j}\right|^2 d\xi \le An$. This is the conceptual explanation of why the hypothesis is a positive definite quadratic form in the differences, and it is worth knowing. As a write-up it is longer, it needs the Fourier transform of the Cauchy kernel as a quoted fact, and it lands you back at the same pairwise sum.

4. **Evaluate f exactly.** *Cue:* a convolution of two Lorentzians. *Circuit:* partial fractions, contour integration, or the Poisson kernel semigroup. You can compute $f(y) = 2\pi/(4+y^2)$, most cheaply by noting that $P_t(x) = \frac{t}{\pi(t^2+x^2)}$ is the Poisson kernel with $P_s * P_t = P_{s+t}$, so $f = \pi^2(P_1 * P_1) = \pi^2 P_2$. Correct, and the exact constant is pleasant, but the problem only ever needs the order of magnitude of f, and a contour integral with two double poles in the arena is ink you do not have to spend.

5. **Expand, bound f below on one fixed interval, then Cauchy and Schwarz.** *Cue:* reciprocal summands on the two sides, and the exponent $n^3 = (n^2)^2/n$. *Circuit:* a lower bound for an integral of a positive function is obtained by shrinking the domain, and reciprocal families are compared by Cauchy and Schwarz. Three moves, no computation, every constant deliberately crude. This is the ideal route.

The ideal solution

Write $\phi(x) = 1/(1+x^2)$ and $\Phi_n(x) = \sum_{i=1}^n \phi(x-a_i)$, and put

$$f(y) = \int_{-\infty}^{\infty} \frac{dx}{(1+x^2)\big(1+(x+y)^2\big)}.$$

Step 0: the constant A is positive. Apply the hypothesis with $n=1$: $\int_{-\infty}^{\infty} dx/(1+(x-a_1)^2)^2 \le A$. The left side equals $\int_{-\infty}^{\infty} dx/(1+x^2)^2 = \pi/2$, so $A \ge \pi/2 > 0$. This is needed only so that the constant B produced below is positive.

Step 1: expand the hypothesis into a pairwise sum. For each pair (i,j) the integrand $\phi(x-a_i)\phi(x-a_j)$ is continuous and non-negative, and

$$\int_{-\infty}^{\infty} \phi(x-a_i)\phi(x-a_j)\,dx \le \int_{-\infty}^{\infty} \phi(x-a_i)\,dx = \pi < \infty,$$

because $\phi \le 1$ everywhere. So each of the n^2 integrals converges, and since the sum is finite we may expand the square and integrate term by term:

$$\int_{-\infty}^{\infty} \Phi_n(x)^2\,dx = \sum_{i,j=1}^{n} \int_{-\infty}^{\infty} \phi(x-a_i)\phi(x-a_j)\,dx.$$

Substituting $x = t + a_i$ in the (i,j) term turns it into $\int \phi(t)\phi(t+a_i-a_j)\,dt = f(a_i-a_j)$. Hence the hypothesis reads

$$\sum_{i,j=1}^{n} f(a_i-a_j) \le An \qquad \text{for all } n. \tag{1}$$

Step 2: a crude lower bound for f. First, f is even: replacing x by $-x$ in the defining integral sends $f(-y)$ to $f(y)$. So it suffices to bound $f(y)$ for $y \geq 0$.

Let $y \geq 0$ and restrict the integral to $x \in [-1, 0]$, which is legitimate as a lower bound because the integrand is positive everywhere. On that interval $0 \leq x^2 \leq 1$, so $1 + x^2 \leq 2$; and $x + y$ lies between $y - 1$ and y, so $(x+y)^2 \leq (1+y)^2$ and $1 + (x+y)^2 \leq 1 + (1+y)^2 = y^2 + 2y + 2$. Using $2y \leq y^2 + 1$,

$$(1 + x^2)\big(1 + (x+y)^2\big) \leq 2\,(y^2 + 2y + 2) \leq 2\,(2y^2 + 3) \leq 6(1 + y^2).$$

The interval $[-1, 0]$ has length 1, so

$$f(y) \geq \frac{1}{6(1+y^2)} \qquad \text{for all } y \in \mathbb{R}. \tag{2}$$

Step 3: convert the hypothesis into an algebraic statement. Combining (1) and (2),

$$\sum_{i,j=1}^{n} \frac{1}{1 + (a_i - a_j)^2} \;\leq\; 6 \sum_{i,j=1}^{n} f(a_i - a_j) \;\leq\; 6An. \tag{3}$$

Step 4: Cauchy and Schwarz against the reciprocals. Put $u_{ij} = 1 + (a_i - a_j)^2 > 0$. Applying the Cauchy and Schwarz inequality to the n^2 pairs of numbers $\sqrt{u_{ij}}$ and $1/\sqrt{u_{ij}}$,

$$n^4 = \Big(\sum_{i,j=1}^{n} 1\Big)^2 = \Big(\sum_{i,j=1}^{n} \sqrt{u_{ij}} \cdot \frac{1}{\sqrt{u_{ij}}}\Big)^2 \leq \Big(\sum_{i,j=1}^{n} u_{ij}\Big)\Big(\sum_{i,j=1}^{n} \frac{1}{u_{ij}}\Big).$$

By (3) the second factor is at most $6An$, and it is strictly positive, so

$$\sum_{i,j=1}^{n} \big(1 + (a_i - a_j)^2\big) \;\geq\; \frac{n^4}{6An} \;=\; \frac{n^3}{6A}.$$

Therefore the conclusion holds with

$$\boxed{B = \frac{1}{6A}}$$

which is positive by Step 0, and the proof is complete.

Layer 1: WHAT

Block 1. Expand the squared sum inside the integral into n^2 cross terms, and check that each converges.

Block 2. Use translation invariance: the (i, j) cross term depends only on $a_i - a_j$. Name it $f(a_i - a_j)$; the hypothesis becomes a pairwise sum bounded by An.

Block 3. Compare the two sides. The conclusion sums $1 + (a_i - a_j)^2$; so what you want from f is a lower bound of size $1/(1 + y^2)$, and nothing more. Decide not to evaluate f.

Block 4. Get that lower bound by shrinking the domain of integration to a fixed interval of length one, and bounding the denominator crudely there.

Block 5. You now hold $\sum 1/u_{ij} \leq 6An$ and want $\sum u_{ij} \geq Bn^3$. Reciprocal families with n^2 members: apply the Cauchy and Schwarz inequality.

Block 6. Read off $B = 1/(6A)$, and check $A > 0$ from the case $n = 1$ so that $B > 0$.

Juxtaposition. The nominal route treats the hypothesis as an analysis problem to be solved exactly: compute f by partial fractions or residues, obtain $2\pi/(4 + y^2)$, then do Steps 3 to 5 anyway. It reaches the same place after an extra page. The genuinely zombie route never expands at all, and instead tries to bound Φ_n pointwise, or tries to argue directly that the points a_i must be spread out; both lose the pairwise information the conclusion is made of.

Bifurcation point. The first bifurcation is the very first line: expand the square, or estimate it. Expanding is correct because the conclusion is indexed by pairs. The second bifurcation is Step 3: compute f, or bound f. Bounding is correct because the problem said "there is a constant", and that phrase forbids you from caring about any fixed factor.

Layer 2: HOW

Block 1. **Cue.** A square of a finite sum sitting inside an integral, with the conclusion indexed by pairs (i, j). **Why natural.** $\left(\sum_i c_i\right)^2 = \sum_{i,j} c_i c_j$ is the only identity that converts a sum of n objects into data about n^2 pairs, and pairs are what the conclusion is about. The check that each cross term converges is one line, using $\phi \le 1$ and $\int \phi = \pi$, and it is what makes term by term integration legal rather than hopeful. **Link to the next block.** Once you have n^2 integrals, ask what each one depends on.

Block 2. **Cue.** The integrand $\phi(x - a_i)\phi(x - a_j)$ and an integral over the whole line. **Why natural.** Integration over $\mathbb{R}$ is translation invariant, so a shift $x = t + a_i$ costs nothing and reveals that the cross term is a function of $a_i - a_j$ alone. Structurally this says: the L^2 energy of a sum of translates of a fixed profile is a quadratic form in the pairwise displacements, with kernel equal to the autocorrelation of the profile. Recognise that and the analytic hypothesis has become an algebraic one. **Link to the next block.** Name the kernel f and put the hypothesis and the conclusion side by side.

Block 3. **Cue.** The conclusion's summand $1 + (a_i - a_j)^2$ is the reciprocal of $\phi(a_i - a_j)$, and the problem promises only the existence of a constant. **Why natural.** A Lorentzian has tails of order $1/y^2$, and the overlap of two Lorentzians separated by y is of order $1/y^2$ as well, so $f(y) \asymp 1/(1 + y^2)$ is what you expect before computing anything. Since only the order matters, the exact value of f is dead weight. Deciding what not to compute is the single most valuable habit in this problem. **Link to the next block.** You need the lower half of that estimate; get it in the cheapest way available.

Block 4. **Cue.** "Bound an integral of a positive function from below." **Why natural.** For a positive integrand there is exactly one cheap lower bound: throw away part of the domain and estimate the rest crudely. The choice of $[-1, 0]$ rather than $[0, 1]$ is not aesthetic. With $y \ge 0$ fixed, on $[-1, 0]$ the shifted argument $x + y$ stays in $[y - 1, y]$, so $|x + y| \le 1 + y$ with no case analysis, while both factors of the denominator remain controlled. A fixed length interval also guarantees the length factor is 1, so no length bookkeeping is needed. **Link to the next block.** The hypothesis is now an inequality between two explicit finite sums.

Block 5. **Cue.** Two sums over the same n^2 index pairs whose summands are reciprocals, one bounded above, the other to be bounded below. **Why natural.** The Cauchy and Schwarz inequality in the form $\left(\sum 1\right)^2 \le \left(\sum u\right)\left(\sum 1/u\right)$ is precisely the statement that a family and its reciprocals cannot both be small. Equivalently it is the arithmetic mean and harmonic mean inequality. Nothing else can turn an upper bound for $\sum 1/u$ into a lower bound for $\sum u$, because no pointwise inequality does so. **Link to the next block.** Substitute the numbers and read off the constant.

Block 6. **Cue.** The problem asks for the existence of $B > 0$, not for its value. **Why natural.** The arithmetic is $n^4/(6An) = n^3/(6A)$, so $B = 1/(6A)$. The only thing left to verify is that $A > 0$, which the case $n = 1$ gives for free since the left side of the hypothesis is then $\pi/2$. Checking that your constant is genuinely positive is the sort of edge case a grader looks for. **Link to the next block.** Nothing follows; the chain closes.

Layer 3: WHY

The truth beneath this problem is a single identity. For any $\phi \in L^2(\mathbb{R})$ and any reals $a_1, \dots, a_n$,

$$\int_{-\infty}^{\infty} \Big(\sum_{i=1}^{n} \phi(x - a_i) \Big)^2 dx \;=\; \sum_{i,j=1}^{n} K(a_i - a_j), \qquad K(y) = \int_{-\infty}^{\infty} \phi(t)\phi(t + y)\, dt.$$

The energy of a superposition equals a quadratic form in the pairwise displacements, and its kernel is the autocorrelation of the profile. That form is positive semidefinite for every choice of points, since the left side is an integral of a square; equivalently, K is a positive definite function in the sense of Bochner, and its Fourier transform $|\widehat{\phi}|^2$ is non-negative. So the hypothesis of this problem is not an arbitrary analytic condition: it says that a specific positive semidefinite quadratic form in the configuration $(a_1, \dots, a_n)$ grows at most linearly in n, which is a precise way of saying the points do not clump.

The second truth is the reciprocal duality. The hypothesis kernel behaves like $1/(1+y^2)$ and the conclusion kernel is exactly $1+y^2$. Reciprocal quantities are compared only by the Cauchy and Schwarz inequality (or its special case, the arithmetic mean and harmonic mean inequality), which is sharp when all u_{ij} are equal. That sharpness is worth internalising: the bound Bn^3 is what you get when all pairwise distances are comparable, that is, when the points sit on an arithmetic progression of spacing of order $\sqrt{n}$ scaled correctly, and in fact the truth is n^4 for the extremal configurations, which is why the remark that this can be improved is available. The problem deliberately asks for the weaker n^3 because n^3 is exactly what the one line Cauchy and Schwarz gives.

The discernment mechanism is exponent arithmetic, and you should perform it before writing any mathematics. There are n^2 pairs. The hypothesis is of size n. Cauchy and Schwarz over N terms with an upper bound M on the reciprocal sum gives N^2/M. Here $N^2/M = n^4/n = n^3$. If the problem had asked for n^4 you would know immediately that Cauchy and Schwarz alone cannot do it and that a counting argument over unit intervals is required. Reading the exponent tells you which tool is intended, every time.

To train this: for each analysis problem you meet, before starting, write down the number of terms, the size of the hypothesis, and the size of the conclusion, and check whether the conclusion is the Cauchy and Schwarz consequence of the hypothesis. If it is, the entire problem is the translation step from analysis into algebra, and all your effort should go there. Second, train the habit of asking "what am I allowed not to compute": every appearance of the phrase "there is a constant" deletes a page of work if you let it.

Revolving concepts

The Cauchy kernel and the Poisson kernel. $\phi(x) = 1/(1+x^2)$ has $\int \phi = \pi$ and $\int \phi^2 = \pi/2$. Normalised, $P_t(x) = \frac{t}{\pi(t^2+x^2)}$ is the Poisson kernel for the upper half plane; it is a probability density (the Cauchy distribution with scale t) and it forms a semigroup under convolution, $P_s * P_t = P_{s+t}$. Hence the exact value $f(y) = \pi^2(P_1 * P_1)(y) = \pi^2 P_2(y) = 2\pi/(4+y^2)$, obtained without a single residue. See Book 1, field: Calculus and integrals, topic: Poisson and Cauchy kernels.

Fourier transform and Plancherel. With $\widehat{\phi}(\xi) = \int \phi(x) e^{-i\xi x} dx$ one has $\widehat{\phi}(\xi) = \pi e^{-|\xi|}$ for the Cauchy kernel, and Plancherel gives $\int |\Phi_n|^2 = \frac{1}{2\pi} \int |\widehat{\phi}|^2 \left|\sum_j e^{-i\xi a_j}\right|^2 d\xi$. This is the frequency space reading of the same identity, and it is the reason the pairwise form is positive semidefinite. See Book 1, field: Real analysis, topic: Fourier transform, Plancherel, positive definite functions.

Autocorrelation. $K = \phi \star \phi$ with $K(y) = \int \phi(t)\phi(t+y)dt$; K is even when ϕ is even, $K(0) = \|\phi\|_2^2$ is the maximum, and $\widehat{K} = |\widehat{\phi}|^2 \geq 0$. Every problem about the energy of a superposition of translates reduces to K. See Book 1, field: Real analysis, topic: convolution and autocorrelation.

The Cauchy and Schwarz inequality in reciprocal form. For positive $u_1, \dots, u_N$, $\left(\sum u_k\right)\left(\sum 1/u_k\right) \geq N^2$, with equality if and only if all u_k are equal. Equivalent formulations: the arithmetic mean and harmonic mean inequality; the Engel form $\sum c_k^2/u_k \geq (\sum c_k)^2/\sum u_k$. Learn the Engel form as the default, since it specialises to both. See Book 1, field: Inequalities, topic: Cauchy and Schwarz, Engel form, arithmetic and harmonic means.

Bounding integrals from below. For a non-negative integrand, restricting to any subdomain gives a valid lower bound; choose a subdomain of fixed measure on which the integrand is uniformly comparable to its scale. This is the standard replacement for exact evaluation and it is nearly always

enough when the target is an order of magnitude. See Book 1, field: Real analysis, topic: crude estimates and domain restriction.

On recursion. There is no recursion in this problem, and you should not manufacture one. The structure that plays the role a recursion usually plays, namely the thing to generalise, is the pairwise quadratic form. Its generalisation is stated in Layer 3 for an arbitrary profile $\phi \in L^2$, and the same identity with m factors gives $\int \left(\sum_i \phi(x - a_i)\right)^m dx = \sum_{i_1,\ldots,i_m} K_m(a_{i_1}, \ldots, a_{i_m})$ with K_m an m point correlation depending only on differences. The counting refinement used for the n^4 improvement does contain an implicit recursion, namely the partition of $\mathbb{R}$ into unit intervals with occupancy numbers q_z satisfying $\sum_z q_z = n$, and there the standard tool is Jensen's inequality in the form $\sum_z q_z^2 \geq n^2/k$ when exactly k of the q_z are nonzero.

Circuit Bank

- **WHEN** a square of a sum inside an integral, with a conclusion indexed by pairs **DO** expand into cross terms before doing anything else, and verify each converges **BECAUSE** the cross terms are the only place the pairwise information lives, and any pointwise estimate on the sum destroys it
- **WHEN** an integral of a product of translates of one fixed profile **DO** substitute to make it depend only on the difference of the translations, and name that kernel **BECAUSE** integration over the line is translation invariant, so the energy of a superposition is always a quadratic form in the pairwise displacements
- **WHEN** the phrase "there is a constant $B > 0$" in the conclusion **DO** throw away every fixed numerical factor and refuse to evaluate any integral exactly **BECAUSE** the statement is about orders of magnitude only, so exact constants are ink spent on nothing
- **WHEN** an upper bound on $\sum 1/u_k$ and a required lower bound on $\sum u_k$ **DO** apply Cauchy and Schwarz in the form $(\sum u)(\sum 1/u) \geq N^2$ **BECAUSE** no pointwise inequality relates a positive number to its reciprocal in that direction, so only a global comparison can work
- **WHEN** a required lower bound for an integral of a positive function **DO** restrict to a fixed interval and bound the integrand crudely there **BECAUSE** positivity makes domain restriction free, and a fixed length interval removes all length bookkeeping

Backtesting

1. First useful cue: a squared sum inside an L^2 integral, with a conclusion summed over ordered pairs (i, j). That mismatch of index sets orders the expansion immediately.
2. Method the expression suggested: expand into pairwise overlap integrals, recognise them as a translation invariant kernel $f(a_i - a_j)$, bound f below by $1/(6(1 + y^2))$, then apply Cauchy and Schwarz against the reciprocal family.
3. Where you would hesitate, and the thought to reinforce: at the temptation to compute f exactly. Reinforce with the phrase "there is a constant $B > 0$", which is a licence to be crude, and with the observation that a Lorentzian overlap must be of order $1/y^2$ because Lorentzian tails are.
4. The trap the question sets: bounding the integrand before expanding, or applying Cauchy and Schwarz to the integral rather than to the pair sums. Both are legal and both lose the problem.
5. What makes you recognise it faster next time: count the index pairs, note the hypothesis has size n, and observe that $(n^2)^2/n = n^3$ is exactly the exponent demanded. When the exponent matches the Cauchy and Schwarz output, the intended solution is Cauchy and Schwarz and the rest of the problem is translation.

6. The reusable decision rule: convert every analytic hypothesis about a superposition into a pairwise algebraic sum first, then compare the two index sums and let the exponent choose the inequality.

Mirror drills

1. Evaluate $\int_{-\infty}^{\infty} \frac{dx}{(1+x^2)(1+(x+y)^2)}$ exactly. *Answer:* $2\pi/(4+y^2)$; write the integrand as $\pi^2 P_1(x)P_1(-(x+y))$ with P_t the Cauchy density of scale t and use $P_1 * P_1 = P_2$.
2. Let $u_1, \dots, u_N$ be positive with $\sum_k 1/u_k \le M$. Show $\sum_k u_k \ge N^2/M$. *Answer:* Cauchy and Schwarz on $\sqrt{u_k}$ against $1/\sqrt{u_k}$; equality when all u_k agree.
3. Suppose $\int_{-\infty}^{\infty} \left(\sum_{i=1}^{n} e^{-(x-a_i)^2}\right)^2 dx \le An$ for all n. Prove $\sum_{i,j=1}^{n} e^{(a_i-a_j)^2/2} \ge Bn^3$ for some $B > 0$. *Answer:* the cross term is $\sqrt{\pi/2}\, e^{-(a_i-a_j)^2/2}$ by completing the square, so the hypothesis bounds $\sum_{i,j} e^{-(a_i-a_j)^2/2}$ above by a multiple of n; now apply the same reciprocal Cauchy and Schwarz.

15.12 B6. Wilson reflection and double roots of a truncated exponential

Let p be an odd prime. Show that for at least $(p+1)/2$ values of n in $\{0, 1, 2, \ldots, p-1\}$,

$$\sum_{k=0}^{p-1} k!\, n^k \qquad \textit{is not divisible by } p.$$

Read it out loud

Strip the costume off. The expression $\sum_{k=0}^{p-1} k!\, n^k$ is the value at $x = n$ of the polynomial $f(x) = \sum_{k=0}^{p-1} k!\, x^k$ over the field $\mathbb{F}_p$, since every $k!$ with $k \leq p-1$ is a residue and every n is an element of $\mathbb{F}_p$. The statement "for at least $(p+1)/2$ values of n the value is nonzero" is the complement of "for at most $p - (p+1)/2 = (p-1)/2$ values of n the value is zero". So the entire problem is:

f has at most $(p-1)/2$ roots in $\mathbb{F}_p$.

Now audit the numbers. The polynomial f has degree $p-1$, so Lagrange's bound already gives at most $p-1$ roots. You are asked for at most $(p-1)/2$, which is exactly half of the trivial bound. That factor of two is the whole problem, and there is exactly one mechanism in the theory of polynomials over a field that halves a root count: multiplicity. If you can produce a polynomial in which every root of f appears at least twice, and whose degree is at most p, then $2N \leq p$ forces $N \leq (p-1)/2$ because p is odd. Everything after this observation is the search for that auxiliary polynomial.

Multiplicity means derivatives, so ask what happens when you differentiate. $f'(x) = \sum_{k \geq 1} k \cdot k!\, x^{k-1}$, whose coefficients are worse than the ones you started with. Differentiation likes factorials in the denominator, not the numerator. The only tool in existence that says anything about $k!$ modulo p is Wilson's theorem, and the only symmetry the coefficient list $0!, 1!, \ldots, (p-1)!$ possesses is the reflection $k \mapsto p-1-k$, under which Wilson's theorem gives $k!\,(p-1-k)! \equiv (-1)^{k+1}$. Applying that reflection replaces $k!$ by $1/k!$ and reverses the polynomial. The reversed object is $g(x) = \sum_{k=0}^{p-1} x^k/k!$, the truncated exponential, whose derivative is itself up to one term. That is the object you can differentiate. So the route is forced by the requirements of the endgame, not discovered by luck.

The fields wired in are number theory (Wilson, Fermat), polynomial algebra over a finite field (root counting with multiplicity, formal derivatives), and the structure of $\mathbb{F}_p[x]$ as a ring of functions. Within thirty seconds you should have on paper: "at most $(p-1)/2$ roots", "half of deg f, so double roots", and "differentiate: I need $1/k!$, so use Wilson to reverse".

One more reading, and it is the one that tells you the problem cannot be attacked head on. You are asked for at least $(p+1)/2$ good values of n but you are never asked to name one. There is a reason. Taking $n = 1$ gives $\sum_{k=0}^{p-1} k!$, and the assertion that this is never divisible by an odd prime p is Kurepa's conjecture, a long standing open problem. So no argument that identifies specific good residues can exist at the present state of knowledge. The problem must be, and is, a counting argument that never inspects a single value.

Approaches, ranked worst to best

1. **Tabulate and look for a pattern.** *Cue:* small modulus, finite check. *Circuit:* experimentation. Compute $f(n)$ for $p = 3, 5, 7, 11$ and hope the good n are describable. They are not: the set of roots of f has no known description, and as noted above even the single value $n = 1$ is an open problem. Experimentation here produces nothing but consumed time.

2. **Find a closed form for $\sum k! n^k$.** *Cue:* a sum with a clean summand. *Circuit:* generating functions. The generating function does satisfy a differential equation: over $\mathbb{F}_p$ one checks directly that

$x^2f'(x) + (x-1)f(x) + 1 = 0$, because $p! \equiv 0$ kills the truncation error. But this is a formal relation, not an evaluation, and sums of factorials have no closed form in any useful sense. Ranks second worst because it looks productive and is not, although the differential relation itself is worth keeping and reappears below.

3. **Force double roots directly on f using $x^p - x$.** *Cue:* multiplicity is needed, and $x^p - x$ vanishes on all of $\mathbb{F}_p$. *Circuit:* modify a polynomial's derivative without changing its values. This is the right idea applied to the wrong polynomial, and understanding why it fails is what makes the ideal route inevitable. From $x^2f' + (x-1)f + 1 = 0$, at any root z of f we get $z^2f'(z) = -1$, and $z \neq 0$ since $f(0) = 1$, so $f'(z) = -z^{-2} = -z^{p-3}$. To make the roots of f into double roots of $h = f + c(x)(x^p - x)$ we need $h'(z) = f'(z) - c(z) = 0$ at every root, so c must agree with $-x^{p-3}$ on the root set. Since the roots are unknown, you must take $c(x) = -x^{p-3}$, and then $\deg h = 2p - 3$, so the count $2N \leq 2p - 3$ yields only $N \leq p - 2$. The bound is useless. The obstruction is precise: f' takes a different value at each root, so no single cheap corrector exists.

4. **Padé approximation and a Hankel determinant of factorials.** *Cue:* "at most t roots", so assume more and derive a linear dependence. *Circuit:* a rational function with small numerator and denominator forces a Hankel matrix to be singular. This is Elkies' solution. Suppose f vanishes at all but $m < t = (p-1)/2$ nonzero residues, build $Q(x)$ of degree m vanishing at the surviving points, deduce that the coefficients of $x^t, \ldots, x^{2t-1}$ in $f(x)Q(x)$ vanish, and conclude that the Hankel matrix $A = ((i+j+1)!)_{i,j=0}^{t-1}$ kills a nonzero vector. Then invoke $\det\big((i+j+n)!\big)_{i,j=0}^{m} = \prod_{k=0}^{m} k!\,(k+n)!$, which is nonzero modulo p because every factorial involved is a factorial of an integer less than p. Complete, beautiful, and far more expensive: it needs Padé style reasoning and a binomial matrix row reduction to evaluate the Hankel determinant. Rank it second because it is a real solution, not a sketch, but it costs three times the ink.

5. **Wilson reflection to the truncated exponential, then double roots via $x^p - x$.** *Cue:* coefficients $k!$ plus a target of exactly half the degree. *Circuit:* Wilson's reflection reverses factorials into reciprocal factorials; the truncated exponential is its own derivative up to the top term; $x^p - x$ tunes derivatives for free. Four short steps, one standard theorem, no machinery beyond the formal derivative. This is the ideal route.

The ideal solution

Convention. Read the sum as the value at $x = n$ of a polynomial: the $k = 0$ term is the constant $0! \cdot x^0 = 1$ for every n, including $n = 0$. This is the ordinary convention for the constant term of a polynomial and it is the only reading under which the expression is a polynomial function of n. (If one instead insists on $0^0 = 0$, then $n = 0$ is deleted from the count and the argument below delivers $(p-1)/2$ good values rather than $(p+1)/2$.)

Work in $\mathbb{F}_p$ throughout. Define

$$f(x) = \sum_{k=0}^{p-1} k!\,x^k, \qquad g(x) = \sum_{k=0}^{p-1} \frac{x^k}{k!},$$

both polynomials over $\mathbb{F}_p$; every $k!$ with $0 \leq k \leq p-1$ is a product of nonzero residues and is therefore invertible modulo p, so g is well defined. The claim to be proved is that f has at most $(p-1)/2$ roots in $\mathbb{F}_p$.

Lemma 15.12.1 (Wilson reflection)**.** *For $0 \leq k \leq p-1$ we have $k!\,(p-1-k)! \equiv (-1)^{k+1} \pmod p$.*

Proof. Write $(p-1)! = k! \prod_{m=k+1}^{p-1} m$. As m runs over $k+1, \ldots, p-1$, the residue $p-m$ runs over $1, \ldots, p-1-k$, and $m \equiv -(p-m)$, so $\prod_{m=k+1}^{p-1} m \equiv (-1)^{p-1-k}(p-1-k)!$. Since p is odd,

$(-1)^{p-1-k} = (-1)^k$. By Wilson's theorem $(p-1)! \equiv -1$, so $-1 \equiv (-1)^k k!\,(p-1-k)!$, which rearranges to the stated congruence. □

Lemma 15.12.2 (reversal)**.** *For every nonzero $z \in \mathbb{F}_p$ we have $f(z) = -\,g(-1/z)$. Consequently f and g have exactly the same number of roots in $\mathbb{F}_p$.*

Proof. By the previous lemma, $k! = (-1)^{k+1}/(p-1-k)!$ in $\mathbb{F}_p$. Hence for any $z \neq 0$,

$$f(z) = \sum_{k=0}^{p-1} \frac{(-1)^{k+1} z^k}{(p-1-k)!} = \sum_{j=0}^{p-1} \frac{(-1)^{p-j}\, z^{\,p-1-j}}{j!},$$

where $j = p-1-k$ and $(-1)^{k+1} = (-1)^{p-j}$. Since p is odd, $(-1)^{p-j} = -(-1)^j$, so

$$f(z) = -\,z^{p-1} \sum_{j=0}^{p-1} \frac{(-1)^j z^{-j}}{j!} = -\,z^{p-1}\, g(-1/z) = -\,g(-1/z),$$

using $z^{p-1} = 1$ by Fermat's little theorem. For the count: $f(0) = 1 \neq 0$ and $g(0) = 1 \neq 0$, so all roots of both polynomials are nonzero, and $z \mapsto -1/z$ is a bijection of $\mathbb{F}_p^\times$ onto itself. Hence $f(z) = 0$ if and only if $g(-1/z) = 0$, and the two root sets are in bijection. □

Lemma 15.12.3 (the truncated exponential is almost its own derivative)**.** $g'(x) = g(x) + x^{p-1}$ *in* $\mathbb{F}_p[x]$. *In particular, if $g(z) = 0$ for some $z \in \mathbb{F}_p$ then $z \neq 0$ and $g'(z) = 1$.*

Proof. Differentiating termwise,

$$g'(x) = \sum_{k=1}^{p-1} \frac{k\, x^{k-1}}{k!} = \sum_{k=1}^{p-1} \frac{x^{k-1}}{(k-1)!} = \sum_{j=0}^{p-2} \frac{x^j}{j!} = g(x) - \frac{x^{p-1}}{(p-1)!}.$$

By Wilson's theorem $(p-1)! = -1$ in $\mathbb{F}_p$, so $-x^{p-1}/(p-1)! = x^{p-1}$, giving $g' = g + x^{p-1}$. If $g(z) = 0$ then $z \neq 0$ because $g(0) = 1$, so $z^{p-1} = 1$ and $g'(z) = 0 + 1 = 1$. □

Proof of the required bound. Set

$$h(x) = x^p - x + g(x) \in \mathbb{F}_p[x].$$

Since $\deg g = p-1$ (its leading coefficient is $1/(p-1)! = -1 \neq 0$), h has degree exactly p with leading coefficient 1; in particular h is not the zero polynomial. Its formal derivative is

$$h'(x) = p\, x^{p-1} - 1 + g'(x) = -1 + g(x) + x^{p-1},$$

because $p = 0$ in $\mathbb{F}_p$.

Let $z \in \mathbb{F}_p$ satisfy $g(z) = 0$. By Fermat's little theorem $z^p = z$ for every element of $\mathbb{F}_p$, so $h(z) = z - z + g(z) = 0$. By the previous lemma $z \neq 0$ and $z^{p-1} = 1$, so $h'(z) = -1 + 0 + 1 = 0$. A common root of h and h' is a root of h of multiplicity at least two: writing $h = (x-z)q$ gives $h' = q + (x-z)q'$, so $h'(z) = q(z) = 0$ and hence $(x-z)^2$ divides h.

Let N be the number of roots of g in $\mathbb{F}_p$. The roots are distinct elements, so $\prod_z (x-z)^2$ divides the nonzero polynomial h, whence $2N \leq \deg h = p$. As p is odd, $N \leq (p-1)/2$.

By the reversal lemma, f also has exactly $N \leq (p-1)/2$ roots in $\mathbb{F}_p$. Therefore the number of $n \in \{0, 1, \ldots, p-1\}$ with $f(n) \neq 0$ in $\mathbb{F}_p$ is at least

$$p - \frac{p-1}{2} = \boxed{\frac{p+1}{2}},$$

which is exactly the assertion of the problem. □

Layer 1: WHAT

Block 1. Restate: the sum is a polynomial f of degree $p-1$ over $\mathbb{F}_p$, and the claim is that f has at most $(p-1)/2$ roots.

Block 2. Audit: $(p-1)/2$ is half the trivial Lagrange bound, so the mechanism must be multiplicity. You need an auxiliary polynomial of degree at most p in which every root of f is at least double.

Block 3. Multiplicity needs derivatives; f' has coefficients $k \cdot k!$, which are worse. Reverse the coefficient list using Wilson's reflection, turning $k!$ into $1/k!$ and f into the truncated exponential g.

Block 4. Verify the reversal is a genuine bijection on root sets: $f(z) = -g(-1/z)$ for $z \neq 0$, and neither polynomial vanishes at 0.

Block 5. Differentiate g: $g' = g + x^{p-1}$, so at any root, $g' = 1$. The roots of g are simple, which is the opposite of what you want, but the derivative there is the same constant at every root, which is what makes the repair cheap.

Block 6. Repair with $x^p - x$: adding it changes no value on $\mathbb{F}_p$ and shifts the derivative by exactly -1, converting $g' = 1$ into $h' = 0$. The degree rises only to p. Count: $2N \leq p$, so $N \leq (p-1)/2$.

Juxtaposition. The nominal route attacks f where it stands. It either tries to evaluate the sum (impossible, and in the single case $n = 1$ an open problem) or tries the multiplicity argument on f itself. The latter is the instructive failure: because $f'(z) = -z^{p-3}$ varies over the root set, the corrector must be the polynomial $-x^{p-3}$ rather than a constant, the auxiliary polynomial has degree $2p-3$, and the count collapses to the vacuous $N \leq p-2$.

Bifurcation point. The split is the line "I need a polynomial whose derivative at every one of its roots is the same constant". Once that requirement is written down, the reflection to $1/k!$ is not an idea, it is the only way to satisfy the requirement, because the truncated exponential is the unique polynomial family that reproduces itself under differentiation. A candidate who never writes that requirement will apply the correct circuit to the wrong polynomial and lose the problem while feeling that the method worked.

Layer 2: HOW

Block 1. **Cue.** "for at least $(p+1)/2$ values of n in $\{0, 1, \ldots, p-1\}$" combined with a summand that is a polynomial in n with integer coefficients. **Why natural.** Counting residues at which an expression is nonzero is never done by inspecting residues; it is done by counting the roots of the corresponding polynomial over $\mathbb{F}_p$, because Lagrange's theorem is the only quantitative statement in the subject. Passing to the complement converts "at least $(p+1)/2$ nonzero" into "at most $(p-1)/2$ zero", which is a bound of the shape that root counting produces. **Link to the next block.** Compare the required bound with the degree.

Block 2. **Cue.** $\deg f = p-1$ and the required bound is $(p-1)/2$, exactly one half. **Why natural.** Over a field, the sum of the multiplicities of the roots of a nonzero polynomial is at most its degree. Therefore the only way to beat the naive bound by a factor of two is to make each root count twice. This is not one option among several; there is no other source of a factor of two in polynomial root counting. **Link to the next block.** Multiplicity is detected by the derivative, so ask whether you can differentiate the polynomial you have.

Block 3. **Cue.** The coefficients are $k!$, and differentiation multiplies the coefficient of x^k by k. **Why natural.** Factorials in the numerator get worse under differentiation and factorials in the denominator get better: $\frac{d}{dx}\frac{x^k}{k!} = \frac{x^{k-1}}{(k-1)!}$. So you want the reciprocal coefficients. The only theorem about factorials modulo p is Wilson's, and the only symmetry available on the index set $\{0, \ldots, p-1\}$ is $k \mapsto p-1-k$; putting the two together gives $k! = (-1)^{k+1}/(p-1-k)!$, which reverses the polynomial into the truncated exponential. Nothing here is invention: you specify what you need

and Wilson is the unique supplier. **Link to the next block.** Reversing a polynomial changes the variable, so you must check the change of variable respects the root count.

Block 4. **Cue.** The reversal produces z^{p-1} and z^{-j}, both meaningful only for $z \neq 0$. **Why natural.** $z^{p-1} = 1$ on $\mathbb{F}_p^\times$ by Fermat, which collapses the prefactor and leaves the identity $f(z) = -g(-1/z)$. The map $z \mapsto -1/z$ is a bijection of $\mathbb{F}_p^\times$, and both f and g have constant term 1, so neither vanishes at 0 and no root is created or destroyed. Checking that the substitution is a bijection on the set you are counting over is the step a careless write-up skips, and it is exactly where marks are lost. **Link to the next block.** You now hold a polynomial designed to be differentiated. Differentiate it.

Block 5. **Cue.** g is the truncated exponential, and $\exp' = \exp$. **Why natural.** Termwise differentiation gives $g' = g - x^{p-1}/(p-1)!$, and Wilson converts the correction into $+x^{p-1}$. On the root set of g this reads $g'(z) = z^{p-1} = 1$. Read that carefully: it says the roots of g are all simple, which appears to be a defeat, but it also says the derivative takes the *same* value at every root. That constancy is the asset. A correction that is constant costs no degree. **Link to the next block.** You need to subtract 1 from the derivative without disturbing any value on $\mathbb{F}_p$. Ask which polynomials are invisible as functions.

Block 6. **Cue.** $x^p - x$ vanishes at every element of $\mathbb{F}_p$ but is not the zero polynomial. **Why natural.** The evaluation map $\mathbb{F}_p[x] \to \{\text{functions } \mathbb{F}_p \to \mathbb{F}_p\}$ has kernel exactly the ideal generated by $x^p - x$. That ideal is your free parameter: adding a multiple of $x^p - x$ changes nothing about values and everything about derivatives, since $(x^p - x)' = -1$. Adding it once shifts every derivative by -1, which is precisely what turns $g'(z) = 1$ into $h'(z) = 0$, and it raises the degree only from $p-1$ to p. The degree budget is the reason this works and the reason the same manoeuvre on f does not: there the required corrector is $-x^{p-3}$, not a constant, and the degree balloons to $2p-3$. **Link to the next block.** With h of degree p and every root of g doubled, the count $2N \leq p$ closes the problem.

Layer 3: WHY

Three truths carry this problem and each one generalises.

The first is Lagrange's theorem with multiplicity: over any field, a nonzero polynomial of degree d has at most d roots counted with multiplicity. It is the only counting device available, so every problem of the form "the number of residues with property P is at most M" must be arranged into a polynomial whose degree is M, or into one of degree $2M$ with double roots, or $3M$ with triple roots. Reading the ratio between the degree you have and the bound you want tells you which multiplicity you are being asked to produce. Here the ratio is two, so you look for double roots, and the derivative is what detects them: z is a multiple root of h if and only if $h(z) = h'(z) = 0$, a fact that holds over any field, with the standard proof by writing $h = (x-z)q$.

The second is that over $\mathbb{F}_p$ polynomials and functions are different things, and the difference is exactly the ideal $(x^p - x)$. Every function $\mathbb{F}_p \to \mathbb{F}_p$ is a polynomial function, and two polynomials induce the same function if and only if they differ by a multiple of $x^p - x$. This means you have a free parameter of degree p available at every moment. You spend it to adjust derivative behaviour without touching values. The cost is degree, and since your entire argument is a degree budget, the question is always: how cheap is the corrector? The design decision in this problem is the choice of a polynomial whose derivative is a single constant on its own root set, because that makes the corrector a constant and the cost exactly p. The failed attempt on f is not a different idea, it is the same idea with a corrector of degree $p-3$, and it fails on budget alone. That comparison is the sharpest thing in the problem and you should be able to say it in one sentence in the arena.

The third is Wilson's theorem, which exists in your toolkit for exactly one purpose: it is the multiplicative structure of $\mathbb{F}_p^\times$ compressed into a statement about $(p-1)!$. Proof in one line:

pairing each element with its inverse in $\mathbb{F}_p^\times$ leaves only the self inverse elements ± 1 unpaired, so $(p-1)! \equiv -1$. Its most useful corollary is the reflection $k!\,(p-1-k)! \equiv (-1)^{k+1}$, which is the statement that the sequence of factorials is, up to signs, its own reversal in the reciprocal sense. Whenever a problem hands you factorials as coefficients modulo p, the reflection is the first thing you write, because there is nothing else to write.

The discernment mechanism, stated for reuse: compare the bound demanded with the degree you have; the ratio names the multiplicity you must manufacture; the manufacture requires a polynomial you can differentiate cleanly; if the one you are given cannot be differentiated cleanly, apply the unique available symmetry of its coefficients to convert it into one that can. To train it, take any problem asserting "at most half the residues satisfy ..." and force yourself to name, before doing anything, the auxiliary polynomial of degree at most p whose double roots you will count.

A final honest word on the shape of the result. The bound $(p-1)/2$ on the number of roots of the truncated exponential over $\mathbb{F}_p$ is far from what is believed to be true; heuristically the number of roots should be around 1 on average. The problem asks for a bound that a single degree count can prove, not for the truth. Recognising the gap between "provable in ten lines" and "true" is part of reading a Putnam B6 correctly: you are being asked for the cheapest rigorous statement, and you should stop the moment you have it.

Revolving concepts

Wilson's theorem. $(p-1)! \equiv -1 \pmod{p}$ for prime p, proved by pairing each element of $\mathbb{F}_p^\times$ with its multiplicative inverse and noting that only 1 and -1 are self inverse. The converse also holds: if $(n-1)! \equiv -1 \pmod{n}$ then n is prime. Corollary used here: $k!\,(p-1-k)! \equiv (-1)^{k+1}$, and in particular $\binom{p-1}{k} \equiv (-1)^k$. See Book 1, field: Number theory, topic: Wilson's theorem and factorial reflection.

Fermat's little theorem and the polynomial $x^p - x$. $z^p = z$ for all $z \in \mathbb{F}_p$, hence $x^p - x = \prod_{a \in \mathbb{F}_p} (x - a)$. The evaluation map from $\mathbb{F}_p[x]$ to the p^p functions $\mathbb{F}_p \to \mathbb{F}_p$ is surjective with kernel $(x^p - x)$, so $\mathbb{F}_p[x]/(x^p - x)$ is the ring of all functions. Its derivative is -1, which makes it the standard device for adjusting derivatives at prescribed points without changing values. See Book 1, field: Number theory, topic: polynomial functions over a finite field.

Formal derivative and multiplicity. Over any commutative ring the formal derivative is defined coefficientwise; over a field, z is a root of h of multiplicity at least two if and only if $h(z) = h'(z) = 0$, and more generally of multiplicity at least m if and only if the first $m-1$ Hasse derivatives vanish (over characteristic p you must use Hasse derivatives, not iterated ordinary derivatives, once m reaches p). The separability criterion $\gcd(h, h') = 1$ is the same fact in different clothes. See Book 1, field: Polynomials, topic: formal derivatives, multiplicity, separability.

Truncated exponential and the recursion to generalise. The coefficient sequence $c_k = 1/k!$ satisfies the first order recursion $c_k = c_{k-1}/k$, and the polynomial family $e_m(x) = \sum_{k=0}^{m} x^k/k!$ satisfies

$$e_m'(x) = e_m(x) - \frac{x^m}{m!},$$

the general statement of which the lemma above is the case $m = p-1$ over $\mathbb{F}_p$. This is the general principle: a first order recursion $c_k = c_{k-1}\lambda(k)$ on coefficients becomes a first order differential relation on the generating polynomial, with an error term supplied by the truncation. The mirror statement for the reversed sequence $c_k = k!$, satisfying $c_k = k\,c_{k-1}$, is $x^2 f'(x) + (x-1)f(x) + 1 = 0$, which over $\mathbb{F}_p$ holds exactly for the truncation because $p! \equiv 0$. Whenever coefficients obey a first order recursion, write down the corresponding differential relation before doing anything else: it is where all information about derivatives at roots comes from. See Book 1, field: Polynomials, topic: generating polynomials of first order recursions.

Reversal of a polynomial. For $\deg q = d$, the reversal is $x^d q(1/x)$, which reverses the coefficient list; combined with a scalar substitution $x \mapsto \lambda/x$ it is a bijection of $\mathbb{F}_p^\times$ onto itself and therefore

preserves root counts away from 0. Always confirm that the constant term and leading coefficient are nonzero before transporting a count across a reversal. See Book 1, field: Polynomials, topic: reciprocal and reversed polynomials.

Hankel determinants of factorials. $\det\big((i+j+n)!\big)_{i,j=0}^{m} = \prod_{k=0}^{m} k!\,(k+n)!$, proved by turning the matrix into $\big(\binom{i+j+n}{i}\big)$ and observing that decreasing n by one is a sequence of elementary row operations, so the determinant of the binomial version is independent of n and equals 1. Needed only for Elkies' alternative solution. See Book 1, field: Matrices and determinants, topic: Hankel and binomial determinants.

Knowledge gaps, named without disguise. To attempt this problem at all you must have installed: $\mathbb{F}_p$ as a field and Lagrange's root bound; the formal derivative and the multiple root criterion; Wilson's theorem with its reflection corollary; Fermat's little theorem in the polynomial form $x^p - x = \prod_a (x-a)$; and the fact that the kernel of the evaluation map is $(x^p - x)$. None of these appear in A-level or Further Mathematics. Two further items are optional context rather than requirements: Hasse derivatives, which are what you need if you ever want multiplicity three or higher in characteristic p; and the Artin and Hasse exponential together with the arithmetic of truncated exponentials modulo p, which is the natural home of the polynomial g and explains why its root structure is hard. Finally, be clear that Kurepa's conjecture, the assertion that $\sum_{k=0}^{p-1} k! \not\equiv 0 \pmod{p}$ for every odd prime, is open; the problem is soluble only because it never asks about a specific n.

Circuit Bank

- **WHEN** "for at least N of the residues modulo p, this expression is nonzero" **DO** pass to the complement and count the roots of the corresponding polynomial over $\mathbb{F}_p$ **BECAUSE** Lagrange's bound is the only quantitative tool for counting residues, and it counts roots, not non-roots
- **WHEN** a required root bound that is exactly half the degree **DO** manufacture an auxiliary polynomial of degree at most twice the bound in which every root is at least double **BECAUSE** multiplicity is the only mechanism in polynomial algebra that improves a root count by a fixed factor
- **WHEN** a need to change a polynomial's derivative at points of $\mathbb{F}_p$ without changing any of its values **DO** add a multiple of $x^p - x$, and count the degree that costs **BECAUSE** the kernel of the evaluation map is exactly $(x^p - x)$, whose derivative is -1, so it is a free parameter for derivative data and a priced one for degree
- **WHEN** factorials appearing as coefficients modulo p **DO** apply Wilson's reflection $k!(p-1-k)! = (-1)^{k+1}$ and consider the reversed polynomial **BECAUSE** Wilson is the only theorem about factorials modulo p, and $k \mapsto p-1-k$ is the only symmetry the coefficient list has
- **WHEN** a substitution used to transport a count from one polynomial to another **DO** prove it is a bijection of the set being counted, and check the excluded point separately **BECAUSE** a count transported across a non-bijection is not a count, and the point $x = 0$ is where reversals always break

Backtesting

1. First useful cue: the target $(p+1)/2$ out of p, which complements to "at most $(p-1)/2$ roots", read against $\deg f = p-1$. The ratio of exactly two is the cue.
2. Method the expression suggested: produce double roots. Since f cannot be differentiated cleanly, use Wilson's reflection to reverse f into the truncated exponential g, differentiate that, and repair the derivative with the free polynomial $x^p - x$.

3. Where you would hesitate, and the thought to reinforce: at the appearance of $x^p - x$, which looks unmotivated. Reinforce it as the kernel of the evaluation map: it is the unique way to change derivatives while fixing all values, and its own derivative is -1, which is exactly the amount you need to subtract.
4. The trap the question sets: applying the multiplicity circuit to f itself. It is the right circuit, the algebra is valid, and the degree budget silently destroys the bound because f' is not constant on its root set. The trap punishes candidates who fire circuits without auditing degrees.
5. What makes you recognise it faster next time: the requirement audit. Before choosing a polynomial, write the property you need from it, here "the derivative must take one and the same nonzero constant value at every root", and only then ask which available transformation supplies it.
6. The reusable decision rule: a root bound equal to half the degree means double roots; double roots mean a derivative you control; if the given polynomial's derivative is uncontrolled, reverse the coefficients using the only available theorem about them and try again.

Mirror drills

1. Show that $\sum_{k=0}^{p-1} k!\, x^k$ and $\sum_{k=0}^{p-1} x^k/k!$ have the same number of roots in $\mathbb{F}_p$. *Answer:* Wilson's reflection turns one coefficient list into the other, giving $f(z) = -g(-1/z)$ for $z \neq 0$; both have constant term 1, and $z \mapsto -1/z$ is a bijection of $\mathbb{F}_p^\times$.
2. Prove that every root of $g(x) = \sum_{k=0}^{p-1} x^k/k!$ in $\mathbb{F}_p$ is a simple root. *Answer:* termwise differentiation and Wilson give $g' = g + x^{p-1}$; a root z is nonzero since $g(0) = 1$, so $g'(z) = z^{p-1} = 1 \neq 0$.
3. Let $q \in \mathbb{F}_p[x]$ have degree less than p, and suppose there is a single nonzero constant c with $q'(z) = c$ for every root z of q in $\mathbb{F}_p$. Show that q has at most $p/2$ roots in $\mathbb{F}_p$. *Answer:* put $h = q + c\,(x^p - x)$, so h has degree p, every root of q satisfies $h(z) = q(z) = 0$ and $h'(z) = c - c = 0$, hence is a double root of h; now count multiplicities against $\deg h = p$.

Chapter 16

Putnam 2010

16.1 A1. splitting 1 through n into equal sums

Given a positive integer n, what is the largest k such that the numbers $1, 2, \ldots, n$ can be put into k boxes so that the sum of the numbers in each box is the same? (When $n = 8$, the example $\{1, 2, 3, 6\}, \{4, 8\}, \{5, 7\}$ shows that the largest k is at least 3.)

Read it out loud

This is a partition question wearing an optimisation costume. "Largest k" tells you the answer is one closed formula in n, not a case description, because a Putnam optimisation answer is always exact. Strip the costume off and the whole content is: distribute $1, \ldots, n$ into k nonempty disjoint groups sharing one invariant, the sum.

The field wired into this is elementary combinatorics, the arithmetic series and a pigeonhole style counting bound, nothing more exotic. What is really being tested is whether you reach, inside thirty seconds, for the two things every equal-invariant partition problem needs: an upper bound on k, and a construction proving that bound is tight. The bracketed $n = 8$ example is a gift and a trap at once. It proves $k \geq 3$ for one specific n, but it is not shaped like the general construction, so do not try to reverse engineer the formula from it.

The first useful cue is that n itself is one of the numbers being distributed, and it is the largest of them. Within thirty seconds you should have written: whichever box holds n already has sum at least n. That one sentence is the entire upper bound.

Approaches, ranked worst to best

1. **trial and error on small n.** *Cue:* the bracketed hint for $n = 8$. *Circuit:* pattern spotting. (you can find the pattern by hand for $n = 1, \ldots, 8$, but a guess is not a proof of either half, the bound or the construction, so this only orients you.)
2. **pigeonhole on box sizes.** *Cue:* k boxes, n numbers, no box empty. *Circuit:* counting argument. (let j be the number of singleton boxes; every other box holds at least 2 numbers, so $n \geq j + 2(k - j) = 2k - j$, giving $j \geq 2k - n$. Once $k > (n+1)/2$ this forces $j \geq 2$, and two singleton boxes hold two different numbers, hence two different sums, a contradiction. Correct, but the variable j and the case split cost more ink than the problem needs.)
3. **the box containing n.** *Cue:* n is the largest number being distributed. *Circuit:* extremal element bound. (the box holding n already has sum at least n with no further argument; combined with the fixed total this delivers the bound in two lines and points straight at the construction, pairing numbers to a constant sum.)

The ideal solution

Write $S = 1 + 2 + \cdots + n = \dfrac{n(n+1)}{2}$. Suppose $1, \ldots, n$ are placed in k boxes, each with common sum s. No box is empty, since an empty box has sum 0, which would force every box to sum to 0, impossible once $n \geq 1$. Summing the k equal box sums recovers the total: $ks = S$.

The number n lies in some box, and every number in a box is a positive integer, so that box's sum is at least n: $s \geq n$. Then

$$k = \frac{S}{s} \leq \frac{S}{n} = \frac{n+1}{2},$$

and since k is an integer, $k \leq \left\lfloor \dfrac{n+1}{2} \right\rfloor$.

This bound is attained. If $n = 2m$, form the m pairs $\{1, 2m\}, \{2, 2m-1\}, \ldots, \{m, m+1\}$, each summing to $2m + 1$. If $n = 2m + 1$, form the singleton $\{n\}$ together with the m pairs

$\{1, n-1\}, \{2, n-2\}, \ldots, \{m, m+1\}$, each summing to n. Both constructions use $\lfloor (n+1)/2 \rfloor$ boxes, matching the bound, so

$$\boxed{k_{\max} = \left\lfloor \frac{n+1}{2} \right\rfloor = \left\lceil \frac{n}{2} \right\rceil .}$$

Layer 1: WHAT

Block 1: the box containing n has sum at least n. Block 2: multiply the common sum s by k to recover the fixed total S, combine with block 1 to bound $k \leq (n+1)/2$. Block 3: construct a partition attaining the bound, split by the parity of n. Block 4: state and box the closed form.

Against the nominal route, guessing from the $n = 8$ example or running the heavier pigeonhole on singleton boxes, the ideal route reaches the bound in two lines because it uses the single most informative fact available: n is already sitting in some box. The bifurcation point is exactly there. The zombie response to "largest k" is to start counting boxes and sizes in the abstract; the trained response is to ask what the single largest object already forces.

Layer 2: HOW

Block 1. **Cue.** The numbers being distributed are $1, \ldots, n$, and n is manifestly the largest. **Why natural.** Every number sharing a box with n is a positive integer, so it can only add to the sum; a box containing n has sum at least n with no further work. **Link to the next block.** This lower bound on the common sum s is exactly the quantity that controls k, since k and s are reciprocally tied through the fixed total.

Block 2. **Cue.** The sum of the numbers in each box is the same. **Why natural.** A partition sends every number into exactly one box, so the k equal box sums must add to the grand total S; this is counting the same numbers twice, once by box and once as a whole. **Link to the next block.** Substituting $s \geq n$ into $ks = S$ turns a statement about sums into a statement about the count k, the object the question actually maximises.

Block 3. **Cue.** A bound with no matching example proves nothing about what is achievable. **Why natural.** Whenever $1, \ldots, n$ needs a constant sum split, the reflex is Gauss's pairing, i with $n+1-i$, since these pairs are engineered to sum to $n+1$ regardless of i; the odd case leaves the unpaired middle term n sitting alone. **Link to the next block.** This construction meets the block 2 bound with equality, so the two halves of the proof now agree.

Block 4. **Cue.** Bound and construction coincide at $\lfloor (n+1)/2 \rfloor$. **Why natural.** A Putnam optimisation answer is complete only once both halves match exactly. **Link to the next block.** State the closed form.

Layer 3: WHY

The mechanism underneath is a general principle about partitioning a totally ordered set under an equal invariant constraint: the extremal element is already forced into some part, and its own magnitude is a ready made bound on that part's invariant, with no combinatorial search required. This converts a question about the number of parts, which you would otherwise have to search for, into a question about the size of one specific part, readable directly off the ordering of the set.

Train the discernment by asking, first, whenever a problem partitions $1, \ldots, n$ into groups sharing a common invariant: which group must the extreme element occupy, and what does that force. Pigeonhole is not wrong, the second ranked approach proves the same bound, but it answers a more general question, how many singleton boxes must exist, than the one asked, how large

can the common sum be, and answering the more general question costs more ink for the same conclusion. The examiners hand you n itself as manifestly the largest object being partitioned; recognising that the set is already ordered, and the largest element is non negotiable, is the entire skill.

Revolving concepts

Arithmetic series. $1 + 2 + \cdots + n = n(n+1)/2$ is the fixed total every equal sum partition must divide exactly. See Book 1, field: Sequences and recurrences, topic: arithmetic series.

Gauss pairing. Pairing i with $n + 1 - i$ splits $1, \ldots, n$ into pairs of constant sum $n + 1$; it resurfaces whenever a problem wants a constant sum or constant product decomposition of consecutive integers. See Book 1, field: Combinatorics, topic: pairing arguments.

Pigeonhole principle. If n objects sit in k nonempty boxes and $n < 2k$, some structural constraint is forced, here at least two singleton boxes. Keep this as a second method precisely because it generalises to partition problems where no single element dominates the invariant. See Book 1, field: Combinatorics, topic: pigeonhole principle.

Circuit Bank

- **WHEN** $1, \ldots, n$ is partitioned into groups sharing a common additive invariant, and you are asked for the largest or smallest number of groups **DO** find which group the largest, or smallest, element must occupy, and read off the bound it forces before any general counting **BECAUSE** the extremal element is already committed to some group, and its magnitude is the cheapest possible constraint on that group's invariant
- **WHEN** an upper bound on a count k falls out of a fixed total against a per group minimum **DO** immediately look for the matching construction that attains equality, splitting by parity if needed **BECAUSE** a largest k such that answer is a closed form, and a bound alone never proves a formula exact
- **WHEN** you need $1, \ldots, n$ split into pairs, or a near pairing, of constant sum **DO** pair i with $n + 1 - i$, leaving n or nothing unpaired according to parity **BECAUSE** this pairing is engineered so every pair sums to exactly $n + 1$, independent of i

Backtesting

1. First useful cue: n, the largest number being partitioned, must sit in some box.
2. Method the expression suggested: bound the common sum below by n, then use the fixed total to bound k.
3. Where you would hesitate, and the thought to reinforce: whether boxes can be empty; reinforce that an empty box forces every box to sum to zero, impossible once $n \geq 1$.
4. The trap the question sets: the bracketed $n = 8$ example looks like the general construction; pattern matching off it directly, without deriving the parity split, produces an unproven guess.
5. What makes you recognise it faster next time: any phrase of the form "distributed among groups with a shared sum" is your cue to check what the largest single object already forces.
6. The reusable decision rule: extremal element bounds its group's invariant; combine with the fixed total for an upper bound on the group count; construct a matching partition, typically by Gauss pairing, to prove the bound tight.

Mirror drills

1. State the largest k for splitting $1, \ldots, 15$ into equal sum boxes. *Answer:* $n = 15$ odd, $m = 7$, so $k = 8$: the singleton $\{15\}$ plus the pairs $\{1, 14\}, \ldots, \{7, 8\}$, each summing to 15.
2. Split $1, \ldots, n$ into boxes of equal sum where every box must hold exactly two elements. Why does the extremal element argument become trivial here? *Answer:* $k = n/2$ automatically; the size constraint removes all freedom, so there is nothing left to optimise.
3. Ask the same question for equal *product* rather than equal sum. Does the extremal bound still work cleanly? *Answer:* the box containing n still has product at least n, but the total product $n!$ does not distribute as evenly across a fixed per box minimum as $n(n+1)/2$ does; this is genuinely harder, not a free restatement.

16.2 A2. differentiability forces f to be linear

Find all differentiable functions $f : \mathbb{R} \to \mathbb{R}$ such that

$$f'(x) = \frac{f(x+n) - f(x)}{n}$$

for all real numbers x and all positive integers n.

Read it out loud

Say the equation back to yourself before touching it: the instantaneous rate of change of f at x equals the average rate of change of f over the window $[x, x+n]$, for every integer window length n, and this holds identically, not at some unspecified intermediate point. That last clause is the whole problem. The Mean Value Theorem already guarantees SOME point in $(x, x+n)$ where the instantaneous rate matches the average rate; this equation demands it happen at the left endpoint itself, for every positive integer n at once. A statement that rigid about a merely differentiable function should smell like it forces a very narrow family of solutions.

The field wired in is real analysis, the derivative as a limit of difference quotients, and functional equations, an unknown function constrained by an identity rather than by an initial value problem. What is really being tested is whether you notice the equation is not one condition but an infinite family indexed by n, and whether you have the discipline to ask which members of that family actually carry information, rather than trying to use "for all n" all at once.

The first useful cue, inside thirty seconds you should have written the $n = 1$ instance,

$$f'(x) = f(x+1) - f(x),$$

because it is the simplest member of the family and it converts the right side into the most standard object in analysis, a forward difference. Everything else in the solution is what you do with this one line and its $n = 2$ neighbour.

Approaches, ranked worst to best

1. **Taylor expansion in n.** *Cue:* $f(x+n)$ looks like it wants a series expansion. *Circuit:* formal power series matching. (assuming f is smooth enough to expand $f(x+n) = \sum_k f^{(k)}(x) n^k / k!$ and matching coefficients is an unjustified leap: the problem only grants f differentiable once, and even granting the expansion, matching a formal series against an exact identity does not by itself prove convergence or validity. Costs ink to patch and is never fully sound on the hypotheses given.)

2. **guess $f = cx + d$ from $n = 1$ and verify.** *Cue:* the $n = 1$ relation looks linear-shaped. *Circuit:* pattern matching plus sufficiency check. (spotting and verifying the answer is necessary but not sufficient, the problem says find all, and worse, the $n = 1$ relation alone genuinely does not pin f down, see Layer 3, so a write up that only ever invokes $n = 1$ cannot be a complete proof no matter how it is phrased.)

3. **combine $n = 1$ and $n = 2$, telescope, differentiate.** *Cue:* two consecutive integer witnesses of the same family. *Circuit:* minimal witness extraction. (telescoping the $n = 2$ relation into two $n = 1$ gaps forces periodicity of f' in two lines, and a further differentiation of the $n = 1$ relation itself collapses that periodicity to a constant. Uses only that f is once differentiable, and only two of the infinitely many hypotheses on offer.)

The ideal solution

Sufficiency. If $f(x) = cx + d$ for constants $c, d \in \mathbb{R}$, then $f'(x) = c$, and $(f(x+n) - f(x))/n = (c(x+n) + d - cx - d)/n = c$ for every positive integer n and every real x. So every such f works.

Necessity. Suppose f has the stated property. Write the $n = 1$ instance, valid for every real t,

$$f'(t) = f(t+1) - f(t). \tag{1}$$

and the $n = 2$ instance,

$$2f'(t) = f(t+2) - f(t). \tag{2}$$

Telescope the right side of (2) through (1) applied at t and again at $t+1$:

$$f(t+2) - f(t) = \big(f(t+2) - f(t+1)\big) + \big(f(t+1) - f(t)\big) = f'(t+1) + f'(t).$$

Comparing with (2), $2f'(t) = f'(t+1) + f'(t)$, so

$$f'(t+1) = f'(t) \qquad \text{for every } t \in \mathbb{R}. \tag{3}$$

This is a value level identity, established by pure algebra on (1) and (2); it does not require differentiating f'.

Now define $g : \mathbb{R} \to \mathbb{R}$ by $g(x) = f(x+1) - f(x)$. Since f is differentiable everywhere, so are the two shifted functions $x \mapsto f(x+1)$ and $x \mapsto f(x)$, hence so is their difference g, and by the chain rule applied to f itself, not to f',

$$g'(x) = f'(x+1) - f'(x).$$

By (3) this is 0 for every x, so g is constant on $\mathbb{R}$; write $g(x) = c$ for all x, where $c = g(0)$. But by (1), $g(x) = f'(x)$ identically, so $f'(x) = c$ for every x. A function with derivative c everywhere on $\mathbb{R}$ differs from cx by a constant, so

$$\boxed{f(x) = cx + d \text{ for some real constants } c, d.}$$

Layer 1: WHAT

Block 1: verify sufficiency of the guessed form, to know exactly what shape the proof must arrive at. Block 2: write the $n = 1$ relation as an identity in t. Block 3: write the $n = 2$ relation and telescope it through two copies of the $n = 1$ relation, forcing $f'(t+1) = f'(t)$. Block 4: rename the $n = 1$ relation's right side as $g(x) = f(x+1) - f(x)$, differentiate g directly from its definition, using block 3 to conclude $g' \equiv 0$, hence f' constant. Block 5: integrate to the final closed form.

Against the nominal route, expanding formally in powers of n or stopping once a plausible answer is verified, the ideal route uses only the two smallest witnesses of the hypothesis and never assumes more regularity than the problem grants. The bifurcation point sits exactly at block 3 to block 4: the zombie instinct is to try to differentiate the periodicity relation $f'(t+1) = f'(t)$ as though it were a statement about a differentiable function f'; the trained instinct is to notice that relation is a fact about function *values*, and to instead differentiate a different, provably differentiable object, g, whose derivative happens to equal exactly that difference of values.

Layer 2: HOW

Block 1. **Cue.** The right side of the equation, $(f(x+n) - f(x))/n$, is a difference quotient over an integer step. **Why natural.** A difference quotient is one thing above all others: cheap to instantiate at the smallest available step. Setting $n = 1$ costs nothing and immediately turns the abstract family into the single cleanest member. **Link to the next block.** The $n = 1$ relation becomes the definition you will keep returning to throughout the proof, both as an equation in its own right and, later, as the definition of the auxiliary function g.

Block 2. **Cue.** Two members of the same family, $n = 1$ and $n = 2$, both hold simultaneously for the same f. **Why natural.** Whenever a family of relations shares a variable, the value of combining two members is that their difference, or in this case their telescoped relationship, can eliminate the unknown function entirely and leave a statement purely about f'. **Link to the next block.** Telescoping $f(t+2) - f(t)$ through the $n = 1$ relation at t and at $t+1$ expresses the $n = 2$ right side using nothing but f', so the $n = 2$ equation collapses to a bare relation between $f'(t)$ and $f'(t+1)$.

Block 3. **Cue.** $f'(t+1) = f'(t)$ looks like a statement crying out to be differentiated. **Why natural.** It cannot be differentiated directly, since f' is only known to exist, not to be itself differentiable; the honest move is to notice that $f'(x)$ already equals $f(x+1) - f(x)$ by the $n = 1$ relation, so the object worth differentiating is the right side, $g(x) = f(x+1) - f(x)$, which is manifestly differentiable because f is. **Link to the next block.** Differentiating g by the ordinary chain rule on f produces $g'(x) = f'(x+1) - f'(x)$, and block 2's periodicity says this is zero, so g, and therefore f', is constant.

Block 4. **Cue.** f' is now known to be a constant c. **Why natural.** A function with everywhere derivative c is cx plus a constant, this is the single variable integration you have used since school. **Link to the next block.** Box the final family and match it against the sufficiency check from the start, closing the loop.

Layer 3: WHY

The deep question this problem hides is why exactly two witnesses, $n = 1$ and $n = 2$, suffice, when the hypothesis is stated for every positive integer n. The honest answer, beyond A level, comes from treating the $n = 1$ relation on its own as a linear delay differential equation and asking for its exponential modes $f(x) = e^{\lambda x}$. Substituting gives $\lambda e^{\lambda x} = e^{\lambda x}(e^{\lambda} - 1)$, so $\lambda = e^{\lambda} - 1$. Among real λ this forces $\lambda = 0$ (the function $e^{\lambda} - 1 - \lambda$ has derivative $e^{\lambda} - 1$, negative for $\lambda < 0$ and positive for $\lambda > 0$, so it is strictly minimised, at value 0, exactly at $\lambda = 0$), but a transcendental equation of this shape is known to admit infinitely many further roots off the real axis, in the complex plane. Each such root would contribute a genuine extra solution to the $n = 1$ relation alone, so $n = 1$ by itself does not logically force linearity, only real exponential rigidity, which is why the second ranked approach above is marked incomplete rather than merely inelegant.

Now bring in $n = 2$: the same substitution gives $2\lambda = e^{2\lambda} - 1$. Since $e^{\lambda} = \lambda + 1$ from the first equation, squaring gives $e^{2\lambda} = (\lambda + 1)^2 = \lambda^2 + 2\lambda + 1$, so the second equation becomes $2\lambda = \lambda^2 + 2\lambda$, that is $\lambda^2 = 0$, so $\lambda = 0$ is now the *only* root common to both equations, real or complex. This is the reason two witnesses, not one, are load bearing: $n = 1$ alone leaves room for oscillatory or growing complex modes, and it is specifically the second relation, $n = 2$, that annihilates every one of them simultaneously. The discernment mechanism to train: when a functional equation is imposed "for all n" but your proof only ever seems to need finitely many instances, do not treat that as a coincidence of the write up, ask what the extra instances are ruling out, since the answer usually reveals the true rigidity of the equation and tells you, in advance, the minimum witness set to reach for.

Revolving concepts

Mean Value Theorem. For f differentiable on $[a, b]$, some $c \in (a, b)$ has $f'(c) = (f(b) - f(a))/(b - a)$. The given equation is a far stronger demand, equality at the left endpoint itself, for every integer window, which is why it pins f down completely rather than merely constraining it. See Book 1, field: Real analysis, topic: Mean Value Theorem.

Method of differences and telescoping. Any statement about $f(x+n) - f(x)$ can be rewritten as a telescoping sum of n consecutive forward differences, $f(x+n) - f(x) = \sum_{i=0}^{n-1} \big(f(x+i+1) -$

$f(x+i)\big)$. This is the general device whenever a step n relation and a step 1 relation on the same function must be reconciled, and it generalises beyond $n = 2$: for any n, the same telescoping combined with the $n = 1$ relation forces $\sum_{i=0}^{n-1} f'(x+i) = nf'(x)$, a genuinely different looking constraint for each n worth checking against the periodicity already established. See Book 1, field: Sequences and recurrences, topic: method of differences.

Zero derivative implies constant. A function differentiable on all of $\mathbb{R}$ with $g' \equiv 0$ is constant, itself a corollary of the Mean Value Theorem applied to any two points. It is the final joint that closes the argument, turning a value level periodicity into an outright constant. See Book 1, field: Real analysis, topic: consequences of the Mean Value Theorem.

Circuit Bank

- **WHEN** a functional equation is imposed for all positive integers n, but you suspect it is over determined **DO** test whether the smallest one or two witnesses, $n = 1$ and $n = 2$, already force the conclusion, before trying to use the full family at once **BECAUSE** over determined hypotheses usually collapse to a minimal witness set, and identifying it shortens the proof and exposes the equation's true rigidity
- **WHEN** you have a value level identity such as $f'(t+1) = f'(t)$ but do not know f' is itself differentiable **DO** rename the original defining relation's right side as a new function g built from shifts of f, and differentiate g instead, using only that f is differentiable **BECAUSE** shifting and subtracting a differentiable function never demands extra regularity, so this route never smuggles in an assumption the problem did not grant
- **WHEN** a step n relation and a step 1 relation hold for the same function **DO** telescope the step n gap into n consecutive step 1 gaps **BECAUSE** $f(x+n) - f(x) = \sum_{i=0}^{n-1}(f(x+i+1) - f(x+i))$ is always available and converts an unfamiliar gap into gaps you already have a formula for

Backtesting

1. First useful cue: the $n = 1$ instance turns the right side into the forward difference $f(x+1) - f(x)$.
2. Method the expression suggested: write the $n = 1$ and $n = 2$ relations as identities in a dummy variable, then combine them.
3. Where you would hesitate, and the thought to reinforce: wanting to differentiate $f'(t+1) = f'(t)$ directly; reinforce that only f, not f', is known to be differentiable, so differentiate the shifted difference function g instead, whose derivative equals exactly that value level statement.
4. The trap the question sets: assuming every one of the infinitely many hypotheses, one per n, must be invoked, when in fact exactly two suffice and the rest are automatically verified once the closed form is known.
5. What makes you recognise it faster next time: seeing "derivative equals an average rate of change" phrasing is your cue to isolate the smallest one or two witnesses rather than reasoning about the family in the abstract.
6. The reusable decision rule: verify sufficiency of the guessed closed form first; for necessity, telescope two adjacent witnesses to extract a periodicity of the derivative, then differentiate the original defining relation's right side, not the derivative itself, to collapse that periodicity to a constant.

Mirror drills

1. Check directly, without redoing the proof, that $f(x) = 7x - 3$ satisfies the equation for $n = 5$. *Answer:* $f'(x) = 7$; $(f(x+5) - f(x))/5 = (7(x+5) - 3 - (7x-3))/5 = 35/5 = 7$, matching.
2. Solve the discrete analogue: find all $f : \mathbb{Z} \to \mathbb{R}$ with $\Delta f(x) = f(x+n) - f(x))/n$ where $\Delta f(x) := f(x+1) - f(x)$, again for all positive integers n. *Answer:* $n = 1$ is a tautology, but $n = 2$ gives $2\Delta f(x) = f(x+2) - f(x) = \Delta f(x+1) + \Delta f(x)$, forcing $\Delta f(x+1) = \Delta f(x)$, a constant first difference, so f is an arithmetic progression, the discrete shadow of $f(x) = cx + d$.
3. Suppose the hypothesis held only for $n = 1$ and $n = 3$, skipping $n = 2$. Does the telescoping argument still force $f'(t+1) = f'(t)$ directly? *Hint:* telescoping $n = 3$ through three $n = 1$ gaps gives $3f'(t) = f'(t) + f'(t+1) + f'(t+2)$, that is $2f'(t) = f'(t+1) + f'(t+2)$, a genuinely different looking relation from the $n = 1, n = 2$ case; do not assume any two witnesses behave identically without checking.

16.3 A3. why a bounded directional eigenfunction must vanish

Suppose that the function $h : \mathbb{R}^2 \to \mathbb{R}$ has continuous partial derivatives and satisfies the equation

$$h(x,y) = a\frac{\partial h}{\partial x}(x,y) + b\frac{\partial h}{\partial y}(x,y)$$

for some constants a, b. Prove that if there is a constant M such that $|h(x,y)| \leq M$ for all $(x,y) \in \mathbb{R}^2$, then h is identically zero.

Read it out loud

This is a partial differential equation wearing an analysis problem's clothes. Read the right side out loud: $a\,\partial h/\partial x + b\,\partial h/\partial y$, the same two constants a, b multiplying h_x and h_y respectively. That exact combination has a name, the directional derivative of h in the direction (a, b), so the equation says nothing more exotic than "the directional derivative of h in a fixed direction equals h itself." Once you have said that sentence to yourself, the problem has already told you what to do: directional derivatives become ordinary one variable derivatives the instant you restrict to the line running in that exact direction.

The field wired in is multivariable calculus, partial derivatives and the chain rule along a parametrised path, collapsing into one variable ODE theory the moment you make that restriction. What is really being tested is restraint: whether you try to solve the PDE in general, a formula for h valid across both variables, when the problem only asks you to prove h is identically zero, a far narrower target that one well chosen line through each point can hit directly, without ever writing down a general solution formula.

The first useful cue, inside thirty seconds you should have written: $ah_x + bh_y$ is $\nabla h \cdot (a, b)$, the directional derivative in direction (a, b); and the second, immediately after: restrict to $(x_0 + at,\ y_0 + bt)$ and see what the chain rule hands you for free.

Approaches, ranked worst to best

1. **guess a separated form $h(x,y) = X(x)Y(y)$.** *Cue:* two variables, one equation. *Circuit:* separation of variables. (nothing in the hypotheses forces h to separate; even after finding the separable solutions of the PDE you would still need a separate argument that no other bounded solution exists, more work for a narrower target than the problem asks for.)

2. **solve the PDE in full generality by the method of characteristics.** *Cue:* a first order linear constant coefficient PDE. *Circuit:* general characteristic solution formula. (correct in principle: one can derive $h(x,y) = e^t\Phi(\text{coordinate orthogonal to } (a,b))$ for an arbitrary function Φ along characteristic coordinates, then impose the bound on that formula. This works, but it spends ink deriving the entire two parameter family of solutions when the problem only needs pointwise vanishing, and setting up characteristic coordinates correctly is exactly where an algebra slip costs you marks.)

3. **restrict to the single characteristic line through an arbitrary point.** *Cue:* the matching constants a, b on both partials. *Circuit:* directional derivative reduction. (fix one point, follow the one line through it in direction (a, b), reduce to the ODE $\phi' = \phi$, and let the global bound do the rest. Reaches the conclusion pointwise, with no machinery beyond the ordinary chain rule and a single elementary ODE.)

The ideal solution

If $a = b = 0$, the given equation reads $h(x,y) = 0$ for every (x,y) directly, and there is nothing further to prove. So assume from now on that $(a,b) \neq (0,0)$, a genuine direction in the plane.

Fix an arbitrary point $(x_0, y_0) \in \mathbb{R}^2$, and let $L(t) = (x_0 + at,\, y_0 + bt)$ for $t \in \mathbb{R}$ be the line through (x_0, y_0) in direction (a, b). Since h has continuous partial derivatives, h is differentiable at every point, so the multivariable chain rule applies to the composition $\phi(t) := h(L(t))$, giving

$$\phi'(t) = a\,\frac{\partial h}{\partial x}(L(t)) + b\,\frac{\partial h}{\partial y}(L(t)).$$

The given equation, evaluated at the point $L(t)$, says the right side equals $h(L(t)) = \phi(t)$. So

$$\phi'(t) = \phi(t) \qquad \text{for all } t \in \mathbb{R}.$$

This is the most elementary linear ODE there is, with general solution $\phi(t) = \phi(0)e^t$.

Since $|h(x, y)| \le M$ for every $(x, y) \in \mathbb{R}^2$, in particular $|\phi(t)| \le M$ for every $t \in \mathbb{R}$. But $|\phi(t)| = |\phi(0)|e^t \to \infty$ as $t \to \infty$ unless $\phi(0) = 0$. A bounded function cannot equal an unbounded one, so $\phi(0) = 0$, that is,

$$h(x_0, y_0) = \phi(0) = 0.$$

Since (x_0, y_0) was an arbitrary point of $\mathbb{R}^2$, this holds everywhere, so

$$\boxed{h(x, y) \equiv 0 \text{ on } \mathbb{R}^2.}$$

Layer 1: WHAT

Block 1: dispatch $a = b = 0$ in one line. Block 2: fix an arbitrary point and build the line through it in direction (a, b). Block 3: restrict h to that line and apply the chain rule, converting the PDE into $\phi' = \phi$. Block 4: solve the ODE and use the global bound to force $\phi(0) = 0$. Block 5: universally quantify over the arbitrary starting point to conclude $h \equiv 0$.

Against the nominal route, deriving the full two variable solution formula for h by characteristic coordinates before imposing the bound, the ideal route never writes down a general solution at all. The bifurcation point sits at the very first reading of the equation: the zombie response to "a PDE with continuous partial derivatives" is to reach for general PDE solving machinery; the trained response is to notice that $ah_x + bh_y$ is definitionally a directional derivative, and that a directional derivative restricted to its own direction is just an ordinary derivative in disguise.

Layer 2: HOW

Block 1. **Cue.** The equation is stated "for some constants a, b," which explicitly includes the possibility $a = b = 0$. **Why natural.** If $a = b = 0$, substituting into the right side gives 0 with no calculation at all, so the conclusion is free; always clear a degenerate parameter case first in a "for some constants" problem, so the main argument can assume the parameters are not simultaneously trivial. **Link to the next block.** This lets everything that follows treat (a, b) as a genuine nonzero direction in the plane, which is exactly what is needed to define a line worth restricting to.

Block 2. **Cue.** The right side is $ah_x + bh_y$, the same constants multiplying each partial, which is the definitional fingerprint of a directional derivative $\nabla h \cdot (a, b)$. **Why natural.** Recognising this dictionary entry is the whole solve: a directional derivative is, by definition, the ordinary derivative of h restricted to a line running in exactly that direction, so the equation is quietly telling you which line to draw before you have drawn anything. **Link to the next block.** Fixing an arbitrary point and following the line $(x_0 + at, y_0 + bt)$ through it converts a two variable hypothesis into a one variable object you can differentiate directly.

Block 3. **Cue.** h has continuous, not merely existing, partial derivatives. **Why natural.** Continuity of the partials is exactly the standard sufficient condition for h to be differentiable at each point, which is what licenses the multivariable chain rule along the path $L(t)$; partial derivatives can exist everywhere without the function being differentiable if they fail to be continuous, so this hypothesis is not decorative, it is load bearing. **Link to the next block.** Applying the chain rule to $\phi(t) = h(L(t))$ reproduces exactly $ah_x + bh_y$ evaluated along the line, which by the given PDE equals $h(L(t)) = \phi(t)$ itself, so the chain rule computation and the hypothesis collapse onto the same expression.

Block 4. **Cue.** $\phi' = \phi$ is the simplest first order linear ODE available. **Why natural.** Its solution $\phi(t) = \phi(0)e^t$ is immediate, and exponential growth is the one behaviour categorically incompatible with a uniform bound over an unbounded domain. **Link to the next block.** The global bound on h restricts to a bound on ϕ over all $t \in \mathbb{R}$, so $\phi(0)$, which is exactly h at the original point, must be 0.

Block 5. **Cue.** The starting point (x_0, y_0) was never given any special property. **Why natural.** A statement proved for an arbitrary element of a set is proved for the whole set; this is ordinary universal quantification, but it is worth stating explicitly rather than leaving it implied. **Link to the next block.** Conclude $h \equiv 0$ on all of $\mathbb{R}^2$.

Layer 3: WHY

The truth underneath this problem is an eigenfunction rigidity principle. Along every line in direction (a, b), h behaves as an eigenfunction of the directional derivative operator $D_{(a,b)}$ with eigenvalue 1, and an eigenvalue 1 solution of a linear autonomous first order ODE is, with no exceptions, a genuine exponential, Ce^t, unless $C = 0$. Exponential growth is the unique obstruction to boundedness on an infinite ray, so a global bound annihilates the solution completely, one characteristic line at a time, and since the characteristic lines through every point of $\mathbb{R}^2$ in direction (a, b) sweep out the entire plane, the pointwise conclusion becomes a global one for free.

This generalises past the specific eigenvalue 1 given here. If the equation instead read $c \cdot \nabla h = \lambda h$ for a constant $\lambda \neq 0$ and a fixed direction c, the identical restriction gives $\phi' = \lambda\phi$, so $\phi(t) = \phi(0)e^{\lambda t}$; for $\lambda > 0$ the same argument forces $\phi(0) = 0$ by letting $t \to +\infty$, while for $\lambda < 0$ the blow up happens as $t \to -\infty$ instead, and boundedness on the whole line still forces $\phi(0) = 0$ by that end. Only $\lambda = 0$ escapes this, since then ϕ is itself constant and boundedness imposes no constraint. The discernment mechanism to train: whenever a first order linear PDE has constant coefficients and expresses a linear combination of the partials as a constant multiple of the function itself, restrict to the characteristic line through an arbitrary point in the coefficient direction; this always converts the PDE into an exactly solvable one variable ODE, and any global bound hypothesis can then be tested against that ODE's solution directly, with no need to ever write down h as a function of both variables at once.

Revolving concepts

Directional derivative. $D_v h(x_0, y_0) = ah_x(x_0, y_0) + bh_y(x_0, y_0) = \nabla h(x_0, y_0) \cdot v$ for $v = (a, b)$, equal to $\frac{d}{dt}\big|_{t=0} h(x_0 + at, y_0 + bt)$. Recognising an expression as a directional derivative is the single most useful pattern match in any two variable calculus problem carrying constant coefficients on both partials. See Book 1, field: Calculus and integrals, topic: directional derivatives.

Differentiability from continuous partial derivatives. If the partial derivatives of h exist in a neighbourhood of a point and are continuous there, h is differentiable at that point, and the chain rule applies to h composed with any differentiable path through it. This is the standard lemma that licenses every chain rule computation in this solution; existence of partials alone does not suffice,

the classical counterexample being a function with well defined partials at the origin that is not even continuous there. See Book 1, field: Real analysis, topic: differentiability in several variables.

Method of characteristics. The line $L(t) = (x_0 + at, y_0 + bt)$ is the characteristic curve of the PDE $ah_x + bh_y = h$ through (x_0, y_0); restricting any first order linear constant coefficient PDE to its characteristics is the general technique of which this solution is the minimal, single line instance. See Book 1, field: Calculus and integrals, topic: first order linear PDEs.

Exponential incompatibility with global boundedness. $Ce^{\lambda t}$ for $\lambda \neq 0$ is unbounded on at least one end of $\mathbb{R}$, so any hypothesis forcing an exponential solution, combined with a two sided bound, forces the constant C to vanish. See Book 1, field: Real analysis, topic: growth rates and boundedness.

Circuit Bank

- **WHEN** an equation contains $af_x + bf_y$ with the same constants multiplying each partial **DO** recognise it as the directional derivative $D_{(a,b)}f$ and restrict to the line through an arbitrary point in that direction **BECAUSE** this is definitionally what the expression means, and restricting collapses the two variable statement into a one variable ODE via the ordinary chain rule
- **WHEN** a restricted single variable function satisfies $\phi' = \lambda\phi$ for a nonzero constant λ, and the original function is globally bounded **DO** compare the exponential solution $\phi(0)e^{\lambda t}$ against the bound as t runs toward whichever end makes $e^{\lambda t}$ blow up, and conclude $\phi(0) = 0$ **BECAUSE** $Ce^{\lambda t}$ is unbounded on at least one end of the real line unless $C = 0$, and boundedness of the original function restricts to boundedness of every line through it
- **WHEN** a problem grants "continuous partial derivatives" rather than merely "partial derivatives exist" **DO** treat that continuity as licensing the multivariable chain rule along any path, not as decorative phrasing **BECAUSE** partials can exist at a point without the function being differentiable there if they are not continuous, and the chain rule genuinely needs differentiability

Backtesting

1. First useful cue: matching constants a, b multiply h_x and h_y, the directional derivative fingerprint.
2. Method the expression suggested: restrict h to the line through an arbitrary point in direction (a, b), converting the PDE into an ODE via the chain rule.
3. Where you would hesitate, and the thought to reinforce: whether $a = b = 0$ needs separate handling; reinforce that without it, direction (a, b) is not even genuine, and the case costs nothing since the equation then gives $h \equiv 0$ directly.
4. The trap the question sets: reaching for the general two variable solution formula of the PDE when the problem only needs pointwise vanishing, spending ink on machinery the proof never uses.
5. What makes you recognise it faster next time: any first order PDE of the form (constant coefficient linear combination of partials) equals (a multiple of the function) is your cue to restrict to the line in the coefficient direction.
6. The reusable decision rule: dispatch the degenerate parameter case first; for the genuine case, restrict to the characteristic line through an arbitrary point, reduce to $\phi' = \lambda\phi$, and compare the exponential solution against the given global bound to force the value at that point to zero.

Mirror drills

1. Confirm the argument still applies when $b = 0$, say $h = 2h_x$. *Answer:* the line is horizontal, $L(t) = (x_0 + 2t, y_0)$, $\phi(t) = h(L(t))$ still satisfies $\phi' = \phi$ by the same chain rule computation, so $h(x_0, y_0) = 0$ for every point exactly as before; $b = 0$ needs no special handling once $(a, b) \neq (0, 0)$.
2. Does the sign of a matter? Take $h = -h_x$ (so $a = -1, b = 0$). *Answer:* no; the chain rule reproduces $ah_x + bh_y$ along the line regardless of the sign of a, so $\phi' = \phi$ still holds and the same exponential blow up argument forces $h \equiv 0$; only the literal direction the line runs changes, not the eigenvalue.
3. Suppose instead $-h = ah_x + bh_y$, eigenvalue -1 rather than 1, still with $|h| \leq M$. Does h still vanish identically? *Answer:* yes; now $\phi' = -\phi$, so $\phi(t) = \phi(0)e^{-t}$, which blows up as $t \to -\infty$ instead of $t \to +\infty$; boundedness over all real t still forces $\phi(0) = 0$, only the end of the line doing the work has switched.

16.4 A4. Towers of ten factored by base swapping

Prove that for each positive integer n, the number

$$10^{10^{10^n}} + 10^{10^n} + 10^n - 1$$

is not prime.

Read it out loud

This is a primality claim about a number written in base 10, assembled from a three storey tower of tens with a -1 bolted onto the end. Said out loud, the fields announce themselves: elementary number theory, and inside that, divisibility read off a base 10 representation. Nothing else is in the room. No counting, no analysis, no algebra past congruences. And there is a standing rule about the command term. When a Putnam problem says *prove that this is not prime* about an object you could never write down, it is not asking for a factorisation. It is asking you to exhibit one divisor and to prove that the divisor is proper. Your entire job is to find the modulus.

Put $S = 10^n$ and $T = 10^{10^n}$ and look at the digits. The -1 never reaches the two leading ones; it eats into 10^n alone, and $10^n - 1$ is a run of n nines. So

$$N = 1\underbrace{0\cdots0}_{T-S-1}1\underbrace{0\cdots0}_{S-n}\underbrace{9\cdots9}_{n},$$

a string of $T + 1$ digits. That picture belongs on your paper inside thirty seconds, because a digit string made of two isolated ones and a tail of nines fires the schoolbook divisibility circuits at once: digit sums for 3 and 9, alternating digit sums for 11.

The digit sum is $1 + 1 + 9n \equiv 2 \pmod 3$, so 3 and 9 are dead and you lose nothing by checking. Now the alternating sum. Both S and T are even, being powers of ten with positive exponent, so the two isolated ones sit in even positions and contribute $+1$ each, while the n nines contribute $9(1 - 1 + 1 - \cdots)$, which is 9 for odd n and 0 for even n. Hence $N \equiv 2 + 9 \equiv 0 \pmod{11}$ when n is odd, and $N \equiv 2 \pmod{11}$ when n is even. Half the problem has fallen to a test you learnt at twelve.

What is really being tested is the next sentence, and it is a sentence about failure. The test died for even n for exactly one reason: casting out elevens is the statement $10 \equiv -1 \pmod{11}$, which turns 10^n into $(-1)^n$, and that is $+1$ and useless when n is even. So you need a modulus in which the ground floor of the tower still lands on -1. That is the whole problem: strip the powers of two out of n by changing base.

Approaches, ranked worst to best

1. **Compute it and factor it.** *Cue:* "prove it is not prime" misread as "produce the factorisation". *Circuit:* no circuit at all, pure consumption. Even at $n = 1$ the number has $10^{10} + 1$ digits, so no machine will ever hold it. This is not a method, it is a wish, and it ranks last.

2. **Hunt a polynomial identity in $x = 10^n$.** *Cue:* a sum of powers of ten ending in -1 smells like a factorisable form. *Circuit:* Sophie Germain, difference of two squares, cyclotomic factorisation. Setting $x = 10^n$ turns the tail into $x - 1$ but turns the middle term into 10^x, which is not a polynomial in x. The three floors are never simultaneously polynomial in one variable, so the route stalls on line one. Worth ten seconds, because problems such as "$m^4 + 4$ is composite for $m > 1$" fall to precisely this circuit, but not one second longer.

3. **Blind search over small primes.** *Cue:* no structural idea, so test $7, 13, 37, 41, 101, \ldots$ in turn. *Circuit:* brute force modular arithmetic. It finds 11 for odd n and 101 for $n \equiv 2 \pmod 4$, then stalls at $n = 4$ unless you happen to try 10001. Right answers with no reason attached: no reusable circuit, and no way to know you have covered every n.

4. **Casting out elevens.** *Cue:* two ones in even digit positions and a tail of nines. *Circuit:* $10 \equiv -1 \pmod{11}$, so base ten collapses to a sign. Instant, complete for odd n, dead for even n. It ranks second because its failure is informative: it isolates the one feature of n that mattered, the parity of n itself.

5. **Run the same digit test in base 10^{2^m}.** *Cue:* parity of n was the only obstruction, and parity is the $m = 0$ case of the 2 adic valuation. *Circuit:* when a sign argument dies on an even exponent, change base until the exponent becomes odd. The ideal route. Four lines, every n at once, and it contains the previous route as its own special case $m = 0$.

The ideal solution

Lemma 16.4.1. *For every integer $m \geq 0$ we have $2^m \geq m + 1$.*

Proof. Induction on m. For $m = 0$ both sides equal 1. If $2^m \geq m + 1$, then $2^{m+1} = 2 \cdot 2^m \geq 2m + 2 \geq m + 2$, since $m \geq 0$. □

Fix a positive integer n and put

$$N = 10^{10^{10^n}} + 10^{10^n} + 10^n - 1.$$

Write $n = 2^m k$ with $m \geq 0$ an integer and k a positive odd integer, so that 2^m is the exact power of two dividing n. Put

$$d = 2^m, \qquad M = 10^d + 1.$$

Then $10^d \equiv -1 \pmod{M}$ by construction, so for every nonnegative integer j,

$$10^{dj} \equiv (-1)^j \pmod{M}. \tag{$*$}$$

Everything now reduces to writing each of the three exponents as d times an integer and reading off the parity of that integer.

Ground floor. $n = dk$ with k odd, so $(*)$ gives $10^n \equiv -1 \pmod{M}$.

First floor. By the Lemma, $n \geq 2^m \geq m + 1$, so 2^{m+1} divides 2^n, which divides 10^n. Hence $10^n = dj$ with $j = 10^n / 2^m$ an even integer, and $(*)$ gives $10^{10^n} \equiv 1 \pmod{M}$.

Second floor. Also $10^n \geq n \geq m + 1$, so 2^{m+1} divides 2^{10^n}, which divides 10^{10^n}. Hence $10^{10^n} = dj'$ with j' even, and $(*)$ gives $10^{10^{10^n}} \equiv 1 \pmod{M}$.

Adding the four terms,

$$N \equiv 1 + 1 + (-1) - 1 = 0 \pmod{M},$$

so M divides N. It remains to check that M is a proper divisor. On the one hand $M = 10^d + 1 \geq 11 > 1$. On the other hand $d = 2^m \leq n$, so $M \leq 10^n + 1$; and since $10^n \geq n + 1$ for every $n \geq 1$,

$$N > 10^{10^n} \geq 10^{n+1} = 10 \cdot 10^n > 10^n + 1 \geq M.$$

Thus $1 < M < N$ and $M \mid N$, so N is composite. ■

Remark 16.4.2. For odd n this is $M = 11$, the schoolbook test. For $n \equiv 2 \pmod{4}$ it is $M = 101$. For $n \equiv 4 \pmod{8}$ it is $M = 10001 = 73 \times 137$, which is not itself prime, and that costs nothing: a proper divisor is not required to be prime.

Layer 1: WHAT

Block 1. Read the command term. "Not prime" for an uncomputable number means: exhibit a divisor M and prove $1 < M < N$.

Block 2. Write N as a digit string. Two isolated ones at the even positions 10^n and 10^{10^n}, and n nines at the bottom.

Block 3. Fire the base 10 tests. Digit sum kills nothing; the alternating sum gives $11 \mid N$ exactly when n is odd.

Block 4. Diagnose the failure. The only thing that broke for even n is the parity of the exponent in $10^n \equiv (-1)^n$.

Block 5. Repair by base swapping. Replace base 10 by $B = 10^{2^m}$, where 2^m is the exact power of two dividing n. Then $n/2^m$ is odd by construction, and $B \equiv -1 \pmod{B+1}$.

Block 6. Check the upper floors. Their exponents are B times an even number, because 10^n and 10^{10^n} carry gigantic powers of two; the only arithmetic you need is $2^m \geq m+1$.

Block 7. Size check, then conclude.

The nominal route runs Block 1, Block 2, Block 3, and then does the zombie thing: "eleven failed, try thirteen, try thirty seven, try one hundred and one". You will burn twenty minutes and finish with a case analysis you cannot close, because for each new n you would need a new prime found by luck.

The bifurcation point is Block 4, and it is one sentence long. Zombie: "11 does not always work, so I need a different prime." Ideal: "11 failed only because n was even, so I will keep the same argument and change the base until the exponent is odd." Same observation, opposite move. One asks for a new object, the other asks what the old object actually depended on.

Layer 2: HOW

Block 1. **Cue.** The words "is not prime" attached to a number with more digits than the universe has particles. **Why natural.** Primality is an existence statement about factors, so its negation is an existence statement you can satisfy by exhibiting one witness. Nothing else is possible here, since evaluation is off the table. **Link to the next block.** Once you have committed to finding a modulus, the presentation of N becomes the only source of candidate moduli, so you look at how N is written.

Block 2. **Cue.** N is written in base 10, and the sole subtraction is -1 against the smallest term. **Why natural.** A -1 against 10^n is the definition of a run of nines. Converting a formula into its digit string is free, and digit strings are the objects on which the base 10 divisibility tests act. **Link to the next block.** A digit string of ones and nines is exactly the input format for casting out threes and elevens.

Block 3. **Cue.** Two isolated ones and a block of nines. **Why natural.** The divisibility tests are not folklore, they are the statements $10 \equiv 1 \pmod 9$ and $10 \equiv -1 \pmod{11}$ applied to $\sum d_i 10^i$. Applying them costs two lines and either wins outright or tells you which structural feature is in charge. **Link to the next block.** The eleven test wins for odd n and dies for even n, so the next question is forced: which step used the parity?

Block 4. **Cue.** A method that works for half the cases and fails for the other half by a single sign. **Why natural.** Never abandon a method that half works. Localise the failure instead. Here 10^{10^n} and $10^{10^{10^n}}$ both reduced to $+1$ regardless of n, because their exponents are even for trivial reasons; only $10^n \equiv (-1)^n$ consulted the parity of n. **Link to the next block.** Fixing the sign of one term means changing the modulus, and the modulus you have is $10^1 + 1$, so the family to vary is $10^d + 1$.

Block 5. Cue. The modulus $11 = 10^1 + 1$ has an exponent slot in it. **Why natural.** In the family $M = 10^d + 1$ you always have $10^d \equiv -1$, hence $10^{dj} \equiv (-1)^j$. The ground floor now contributes -1 precisely when n/d is an odd integer, so choose d to be the exact power of two dividing n: that is the unique way to make the quotient odd while keeping d a divisor of 10^n. **Link to the next block.** Having chosen $d = 2^m$, you must now verify that the two upper floors still contribute $+1$, that is, that their exponents are d times an even number.

Block 6. Cue. Exponents of the form 10^n and 10^{10^n}, and a required divisibility by 2^{m+1}. **Why natural.** Ten is even, so 10^t is divisible by 2^t. The demand $2^{m+1} \mid 10^n$ therefore reduces to $n \geq m+1$, and $n \geq 2^m \geq m+1$ holds because exponentials beat linear functions from the very first term. Every floor above the ground is drowning in factors of two; the ground floor is the only delicate one. **Link to the next block.** With all three congruences in hand, the sum is 0 modulo M, and only the size check remains.

Block 7. Cue. A divisibility statement with no size statement is worth zero marks. **Why natural.** $M \mid N$ makes N composite only if $1 < M < N$; a grader will look for that line and nothing else at the end. Both inequalities are one step: $M \geq 11$, and $M \leq 10^n + 1 < 10^{10^n} < N$. **Link to the next block.** Done.

Layer 3: WHY

The mathematical truth under this route is the behaviour of the multiplicative order. For $\gcd(a, M) = 1$, the value of $a^E \bmod M$ depends only on E modulo $\mathrm{ord}_M(a)$. Choosing $M = a^d + 1$ engineers $\mathrm{ord}_M(a) = 2d$ with $a^d \equiv -1$, which means the exponent map restricted to multiples of d becomes the sign character $j \mapsto (-1)^j$. Every congruence in the solution is that one character evaluated three times. The schoolbook eleven test is the case $a = 10$, $d = 1$; you have been using this theorem since primary school without naming it.

The discernment mechanism for "prove this is composite" problems is a scan of exactly three engines, in this order. First, an algebraic identity: difference of squares, Sophie Germain $x^4 + 4y^4 = (x^2 + 2y^2 - 2xy)(x^2 + 2y^2 + 2xy)$, or a cyclotomic factorisation of $a^N \pm 1$. Second, a congruence exhibiting a small factor. Third, a crude parity or size argument. The presentation decides which engine fires: a number given as a polynomial in a variable points at the first, a number given by its base 10 digits with a lonely -1 points at the second. Here the tower makes the first engine impossible, since the exponents are not polynomial in any common variable, so the second engine is not a guess, it is the only survivor.

Train the discernment like this: whenever a method covers some cases and fails on others, write one sentence naming the exact step that consumed the hypothesis you lack. Not "eleven does not work", but "eleven consumed the parity of n and nothing else". That sentence converts a dead end into a parametrised family, because the offending step always has a parameter hiding in it, and here the parameter was the 1 in $10^1 + 1$.

The examiners nudged in three ways, and you should be able to name all three. They wrote the number in base 10 rather than as an abstract $a^{a^{a^n}}$, which is an instruction to look at digits. They put a -1 at the end, which is the only way to make an alternating sum land on a multiple of eleven rather than on 2. And they left n completely free, which guarantees that the easy half of the cases falls out immediately and the other half forces the generalisation. A problem whose easy special case solves itself is a problem asking you to generalise the special case, not to abandon it.

Revolving concepts

Multiplicative order. For $\gcd(a, M) = 1$, $\mathrm{ord}_M(a)$ is the least $t \geq 1$ with $a^t \equiv 1$, and $a^E \equiv a^{E \bmod \mathrm{ord}_M(a)}$. The order divides $\varphi(M)$ and, more sharply, divides the Carmichael function $\lambda(M)$. For $M = a^d + 1$

the order is exactly $2d$. See Book 1, field: Number theory, topic: multiplicative order.

The factorisation $a^d+1 \mid a^n+1$ for n/d odd. Predicated on $a^n+1=(a^d)^k+1$ with k odd and the identity $x^k+1=(x+1)(x^{k-1}-x^{k-2}+\cdots+1)$. Its contrapositive is the Fermat number statement: a^n+1 can be prime only if n is a power of two. See Book 1, field: Number theory, topic: Fermat numbers.

The 2 adic valuation. $v_2(n)$ is the exponent of the exact power of two dividing n, and $n=2^{v_2(n)}k$ with k odd is the canonical splitting. Every argument that consumes the parity of an exponent is secretly a statement about v_2, and the way to generalise such an argument is always to replace "odd" by "odd after dividing out 2^{v_2}". See Book 1, field: Number theory, topic: p adic valuation.

Base B representation and its two tests. Writing $N=\sum d_i B^i$ gives $N \equiv \sum d_i \pmod{B-1}$ and $N \equiv \sum (-1)^i d_i \pmod{B+1}$. This problem is the second test performed in base $B=10^{2^m}$: in that base N has digits 1, 1 and a tail of k copies of $B-1$, and the alternating sum is $1+1+(B-1)=B+1$. See Book 1, field: Number theory, topic: base representation.

The tower recursion, generalised. Define $t_0=n$ and $t_{j+1}=b^{t_j}$. Then $v_2(t_{j+1})=t_j\,v_2(b)$, so for even b the valuations explode: $v_2(t_1)\geq n$ and $v_2(t_2)\geq b^n$. The general moral, and it applies to every tower problem you will ever meet: only the ground floor of a tower has small arithmetic, and every floor above it is divisible by anything you care to ask for. The companion computational recursion is the standard one for evaluating a tower modulo M: to find $b^t \bmod M$, find $t \bmod \lambda(M)$ and recurse down the tower, handling $\gcd(b,M)\neq 1$ by lifting the exponent above $\log_2 M$. See Book 1, field: Number theory, topic: towers and Euler's theorem.

Circuit Bank

- **WHEN** a problem says "prove N is not prime" for an N you cannot compute **DO** exhibit one explicit divisor M, then write the line $1<M<N$ **BECAUSE** primality is an existence claim about factors, and the size line is where marks are actually lost
- **WHEN** the number is presented in base ten and ends in -1 or a run of nines **DO** compute the digit sum modulo 3 and 9 and the alternating digit sum modulo 11 before anything else **BECAUSE** those tests are the congruences $10\equiv 1 \pmod 9$ and $10\equiv -1 \pmod{11}$, they cost two lines, and they are free information
- **WHEN** a sign argument dies because an exponent turned out even **DO** re-run the identical argument in base a^{2^m}, where 2^m is the exact power of two dividing that exponent **BECAUSE** a^d+1 divides $a^{dj}-(-1)^j$, so the sign survives exactly when the quotient exponent is odd
- **WHEN** you meet a tower $b^{b^{b^n}}$ with b even **DO** treat every floor above the ground as divisible by any power of two you need, and check only the ground floor **BECAUSE** $v_2(b^t)=t\,v_2(b)$ outgrows any linear demand, so the delicacy is always at the bottom
- **WHEN** a method solves half the cases and fails on the rest **DO** name in one sentence the single step that consumed the missing hypothesis **BECAUSE** that step always contains a parameter, and varying the parameter is the generalisation you need

Backtesting

1. First useful cue: the -1 sitting against 10^n in a base ten expression, which converts the tail into n nines and makes the whole object a digit string.
2. Method the expression suggested: alternating digit sums, that is, congruences modulo 10^d+1 where $10^d\equiv -1$.
3. Where you would hesitate, and the thought to reinforce: at even n, when eleven dies. Reinforce this: a half working method is a parametrised method with the parameter still set to its default value. Find the parameter, here the d in 10^d+1, before you look for a different method.

4. The trap the question sets: the tower invites you to treat the upper floors as the hard part. They are the trivial part, since their exponents are divisible by every power of two you could want. All the arithmetic content sits in the single term 10^n.

5. What makes you recognise it faster next time: the shape $a^{a^{a^n}} + a^{a^n} + a^n - 1$ has four terms whose signs must sum to zero modulo something, and $1 + 1 - 1 - 1 = 0$ is the only way four terms of size one can cancel. Seeing that target sum in advance tells you that you need two even exponents and one odd multiple of d.

6. The reusable decision rule: to kill a number of the form (tower) + (small stuff) -1, look for a modulus in which the base has order $2d$, and choose d so that the smallest exponent is an odd multiple of d.

Mirror drills

1. Prove that $10^{10^n} + 10^n + 1$ is composite for every positive integer n. *Answer:* its digit sum is 3, so 3 divides it, and it plainly exceeds 3.

2. Let $a \geq 2$ and let $n = 2^m k$ with k odd. Prove that $a^{2^m} + 1$ divides $a^n + 1$, and deduce that $a^n + 1$ can be prime only when n is a power of two. *Answer:* $a^{2^m} \equiv -1$ modulo $a^{2^m} + 1$ and k is odd, so $a^n = (a^{2^m})^k \equiv -1$; if $k > 1$ the divisor is proper.

3. For which integers $b \geq 2$ does the proof above show that $b^{b^{b^n}} + b^{b^n} + b^n - 1$ is composite for all $n \geq 1$? *Answer:* for every even b, since then $v_2(b^t) \geq t$ makes the upper floors even multiples of 2^m; for odd b the ground floor argument survives but the upper floors are odd, so the sign pattern collapses and the proof gives nothing.

16.5 A5. The cross product cannot host a group

Let G be a group, with operation $*$. Suppose that

(i) G is a subset of $\mathbb{R}^3$ (but $*$ need not be related to addition of vectors);

(ii) For each $\mathbf{a}, \mathbf{b} \in G$, either $\mathbf{a} \times \mathbf{b} = \mathbf{a} * \mathbf{b}$ or $\mathbf{a} \times \mathbf{b} = \mathbf{0}$ (or both), where $\times$ is the usual cross product in $\mathbb{R}^3$.

Prove that $\mathbf{a} \times \mathbf{b} = \mathbf{0}$ for all $\mathbf{a}, \mathbf{b} \in G$.

Read it out loud

An abstract group has been dropped onto a subset of $\mathbb{R}^3$, and the only bridge between the algebra and the geometry is a single dichotomy: for every pair, either the group product equals the cross product, or the cross product is zero. Said out loud: this is a group theory problem with a vector algebra weapon, and the fields are the group axioms (identity, inverses, associativity, nothing deeper), the algebra of the cross product in $\mathbb{R}^3$, and one line of linear algebra about spanning. There is no structure theory here, no classification, no finiteness. You are given four axioms and one dichotomy, and that is the entire toolkit.

The first move, inside thirty seconds, is to rewrite (ii) so that it is usable. As a disjunction it says almost nothing. As an implication it is precise and strong:

$$\mathbf{x} \times \mathbf{y} \neq \mathbf{0} \implies \mathbf{x} * \mathbf{y} = \mathbf{x} \times \mathbf{y}.$$

In other words, wherever the cross product is alive, the mysterious group operation is completely known, and wherever the cross product is dead, the group operation is completely unknown. All your information lives on the nonzero cross products, which is exactly the set of pairs the conclusion says cannot exist. So the shape of the proof is forced: assume some pair has $\mathbf{a} \times \mathbf{b} \neq \mathbf{0}$, mine that assumption for all the information it gives, and hit a contradiction.

The second thing to write down, before any calculation, is the list of ways in which $\times$ fails to be a group operation, because the contradiction has to come from one of them. It is anticommutative, so $\mathbf{y} \times \mathbf{x} = -(\mathbf{x} \times \mathbf{y})$. It kills every vector against itself, $\mathbf{x} \times \mathbf{x} = \mathbf{0}$. It has no identity element, since $\mathbf{e} \times \mathbf{x}$ is orthogonal to $\mathbf{x}$ and can never equal $\mathbf{x}$ unless it is zero. And it is not associative: $\mathbf{x} \times (\mathbf{x} \times \mathbf{y}) = -|\mathbf{x}|^2 \mathbf{y}$ for $\mathbf{x} \perp \mathbf{y}$, while $(\mathbf{x} \times \mathbf{x}) \times \mathbf{y} = \mathbf{0}$. Each of those four failures becomes a lemma. That is the whole problem, and if you write that list first, the solution is bookkeeping.

Third, note the free resources. A group hands you an identity $\mathbf{e}$ that commutes with everything, and inverses. In this setting "commutes" has a geometric consequence, because anticommutativity means a commuting pair cannot have a live cross product. You have not touched the problem yet and you already own a lemma.

Approaches, ranked worst to best

1. **Classify the possible sets G.** *Cue:* the conclusion describes all admissible G, so try to find them all. *Circuit:* no circuit, wishful classification. You would be trying to describe every subset of $\mathbb{R}^3$ carrying some unspecified group law. There is no traction, since $*$ is not assumed continuous, bilinear, or related to the linear structure in any way at all. Last place.

2. **Coordinates.** *Cue:* $\mathbb{R}^3$ invites a basis and nine unknowns. *Circuit:* coordinate bash. Write $\mathbf{a} = (a_1, a_2, a_3)$ and expand. The cross product becomes explicit and the group product stays an unknown function of six variables, so you have added notation and no information. The problem gives no bilinearity to exploit, which is exactly what a coordinate bash needs.

3. **Lengths and angles.** *Cue:* $|\mathbf{x} \times \mathbf{y}| = |\mathbf{x}||\mathbf{y}| \sin\theta$ suggests a size argument. *Circuit:* metric bookkeeping, extremal choice. You can extract facts such as "orthogonal nonzero elements

have nonzero cross product", and you will need that. But no size argument can finish, because nothing forces $*$ to interact with lengths; the group could be anything on the pairs where $\times$ dies.

4. **Squeeze the identity element first.** *Cue:* every group has an $\mathbf{e}$, and $\mathbf{e}$ commutes with everything. *Circuit:* use free structure before assumed structure. Anticommutativity turns commuting into $\mathbf{e} \times \mathbf{x} = \mathbf{0}$ for all $\mathbf{x} \in G$, and if G contains three independent vectors this forces $\mathbf{e} = \mathbf{0}$. This is the correct opening and it is genuinely free, but on its own it does not close: knowing $\mathbf{e} = \mathbf{0}$ is useless until you have produced elements whose squares are zero.
5. **Collide associativity with the vector triple product.** *Cue:* $*$ is associative, $\times$ is not, and the dichotomy forces them to agree on live pairs. *Circuit:* find where the two operations must agree, then evaluate the same expression two ways. The ideal route. Build an orthogonal triple inside G, prove that squares vanish, note that $\mathbf{e} = \mathbf{0}$, and then two elements are forced to commute that anticommutativity forbids. Every step is three lines and every step is an axiom failure of $\times$ cashed in.

The ideal solution

Throughout, $\cdot$ is the usual dot product, and "$\mathbf{u}$ is a multiple of $\mathbf{v}$" allows the multiple $\mathbf{0}$. Recall two standard facts about $\mathbb{R}^3$: nonzero orthogonal vectors have nonzero cross product, and the vector triple product identity $\mathbf{u} \times (\mathbf{v} \times \mathbf{w}) = (\mathbf{u} \cdot \mathbf{w})\mathbf{v} - (\mathbf{u} \cdot \mathbf{v})\mathbf{w}$, whose special case $\mathbf{x} \perp \mathbf{y}$ reads

$$\mathbf{x} \times (\mathbf{x} \times \mathbf{y}) = -|\mathbf{x}|^2 \, \mathbf{y}. \tag{$*$}$$

Hypothesis (ii) will be used only in the implication form: if $\mathbf{x} \times \mathbf{y} \neq \mathbf{0}$ then $\mathbf{x} * \mathbf{y} = \mathbf{x} \times \mathbf{y}$; in particular $\mathbf{x} \times \mathbf{y}$ then lies in G, by closure.

Lemma 16.5.1. *If $\mathbf{x}, \mathbf{y} \in G$ satisfy $\mathbf{x} * \mathbf{y} = \mathbf{y} * \mathbf{x}$, then $\mathbf{x} \times \mathbf{y} = \mathbf{0}$.*

Proof. Suppose $\mathbf{x} \times \mathbf{y} \neq \mathbf{0}$. Then $\mathbf{y} \times \mathbf{x} = -(\mathbf{x} \times \mathbf{y}) \neq \mathbf{0}$ as well, so hypothesis (ii) applies to both orders and gives $\mathbf{x} * \mathbf{y} = \mathbf{x} \times \mathbf{y}$ and $\mathbf{y} * \mathbf{x} = \mathbf{y} \times \mathbf{x} = -(\mathbf{x} \times \mathbf{y})$. The assumed commutation forces $\mathbf{x} \times \mathbf{y} = -(\mathbf{x} \times \mathbf{y})$, hence $\mathbf{x} \times \mathbf{y} = \mathbf{0}$, a contradiction. □

Lemma 16.5.2. *If $\mathbf{x}, \mathbf{y} \in G$ are nonzero and orthogonal, then $\mathbf{x} * \mathbf{x}$ is a multiple of $\mathbf{y}$.*

Proof. Since $\mathbf{x}, \mathbf{y}$ are nonzero and orthogonal, $\mathbf{z} := \mathbf{x} \times \mathbf{y} \neq \mathbf{0}$, so $\mathbf{z} = \mathbf{x} * \mathbf{y} \in G$, and $\mathbf{x}, \mathbf{y}, \mathbf{z}$ are nonzero and mutually orthogonal. Then $\mathbf{x} \times \mathbf{z} \neq \mathbf{0}$ as well, so

$$\mathbf{w} := \mathbf{x} \times \mathbf{z} = \mathbf{x} * \mathbf{z} = \mathbf{x} * (\mathbf{x} * \mathbf{y}) = (\mathbf{x} * \mathbf{x}) * \mathbf{y},$$

the last equality being associativity of $*$. On the other hand $(*)$ gives $\mathbf{w} = \mathbf{x} \times (\mathbf{x} \times \mathbf{y}) = -|\mathbf{x}|^2 \mathbf{y}$, a nonzero multiple of $\mathbf{y}$.

Now suppose $(\mathbf{x} * \mathbf{x}) \times \mathbf{y} \neq \mathbf{0}$. Then hypothesis (ii) gives $(\mathbf{x} * \mathbf{x}) * \mathbf{y} = (\mathbf{x} * \mathbf{x}) \times \mathbf{y}$, so $\mathbf{w} = (\mathbf{x} * \mathbf{x}) \times \mathbf{y}$ is orthogonal to $\mathbf{y}$, whence $\mathbf{w} \cdot \mathbf{y} = 0$. But $\mathbf{w} = -|\mathbf{x}|^2 \mathbf{y}$ gives $\mathbf{w} \cdot \mathbf{y} = -|\mathbf{x}|^2 |\mathbf{y}|^2 \neq 0$. Contradiction. Hence $(\mathbf{x} * \mathbf{x}) \times \mathbf{y} = \mathbf{0}$, which for $\mathbf{y} \neq \mathbf{0}$ says exactly that $\mathbf{x} * \mathbf{x}$ is a multiple of $\mathbf{y}$. □

Lemma 16.5.3. *If $\mathbf{x} \in G$ is nonzero and some nonzero $\mathbf{y} \in G$ is orthogonal to $\mathbf{x}$, then $\mathbf{x} * \mathbf{x} = \mathbf{0}$.*

Proof. As above $\mathbf{x} \times \mathbf{y} \in G$ is nonzero and orthogonal to $\mathbf{x}$. Apply Lemma 2 twice, first to the pair $(\mathbf{x}, \mathbf{y})$ and then to the pair $(\mathbf{x}, \mathbf{x} \times \mathbf{y})$: the vector $\mathbf{x} * \mathbf{x}$ is a multiple of $\mathbf{y}$ and also a multiple of $\mathbf{x} \times \mathbf{y}$. Those two vectors are nonzero and orthogonal to each other, so the only common multiple is $\mathbf{0}$. □

Now the proof. Suppose, for contradiction, that there exist $\mathbf{a}, \mathbf{b} \in G$ with $\mathbf{a} \times \mathbf{b} \neq \mathbf{0}$. Put $\mathbf{c} = \mathbf{a} \times \mathbf{b} = \mathbf{a} * \mathbf{b} \in G$. Then $\mathbf{a}, \mathbf{b}$ are independent and $\mathbf{c}$ is nonzero and orthogonal to both, so $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are linearly independent and span $\mathbb{R}^3$.

Let $\mathbf{e}$ be the identity of G. It commutes with $\mathbf{a}$, $\mathbf{b}$ and $\mathbf{c}$, so Lemma 1 gives $\mathbf{e} \times \mathbf{a} = \mathbf{e} \times \mathbf{b} = \mathbf{e} \times \mathbf{c} = \mathbf{0}$. The map $\mathbf{v} \mapsto \mathbf{e} \times \mathbf{v}$ is linear and vanishes on a spanning set, so it vanishes identically on $\mathbb{R}^3$. A vector whose cross product with every vector is zero is zero, so

$$\mathbf{e} = \mathbf{0}.$$

Next, $\mathbf{b}$ and $\mathbf{c}$ are nonzero and orthogonal, so $\mathbf{p} := \mathbf{b} \times \mathbf{c} \neq \mathbf{0}$ and $\mathbf{p} = \mathbf{b} * \mathbf{c} \in G$, and $\mathbf{b}, \mathbf{c}, \mathbf{p}$ are nonzero and mutually orthogonal. Lemma 3 applies three times: to $\mathbf{b}$ with witness $\mathbf{c}$, to $\mathbf{c}$ with witness $\mathbf{b}$, and to $\mathbf{p}$ with witness $\mathbf{b}$. Hence

$$\mathbf{b} * \mathbf{b} = \mathbf{c} * \mathbf{c} = \mathbf{p} * \mathbf{p} = \mathbf{0} = \mathbf{e}.$$

So in the group G, each of $\mathbf{b}$, $\mathbf{c}$ and $\mathbf{p} = \mathbf{b} * \mathbf{c}$ is its own inverse. Therefore

$$\mathbf{b} * \mathbf{c} = \mathbf{p} = \mathbf{p}^{-1} = (\mathbf{b} * \mathbf{c})^{-1} = \mathbf{c}^{-1} * \mathbf{b}^{-1} = \mathbf{c} * \mathbf{b},$$

so $\mathbf{b}$ and $\mathbf{c}$ commute. Lemma 1 then forces $\mathbf{b} \times \mathbf{c} = \mathbf{0}$, contradicting $\mathbf{p} \neq \mathbf{0}$.

Hence no such pair $\mathbf{a}, \mathbf{b}$ exists, that is, $\mathbf{a} \times \mathbf{b} = \mathbf{0}$ for all $\mathbf{a}, \mathbf{b} \in G$. ■

Remark 16.5.4. The conclusion says that all elements of G are pairwise parallel, so G lies on a single line through the origin. That is sharp: take G to be the x axis with $*$ equal to vector addition. Every cross product is zero, so (ii) holds vacuously in its second branch.

Layer 1: WHAT

Block 1. Rewrite (ii) as the implication "live cross product forces $* = \times$", and negate the goal: assume $\mathbf{a} \times \mathbf{b} \neq \mathbf{0}$.

Block 2. Anticommutativity: a commuting pair in G cannot have a live cross product (Lemma 1).

Block 3. The identity is free, and it commutes with everything, so $\mathbf{e}$ has zero cross product against the spanning set $\mathbf{a}, \mathbf{b}, \mathbf{c}$, giving $\mathbf{e} = \mathbf{0}$.

Block 4. Manufacture an orthogonal triple inside G: $\mathbf{b}$, $\mathbf{c} = \mathbf{a} \times \mathbf{b}$, and $\mathbf{p} = \mathbf{b} \times \mathbf{c}$, all in G by the implication.

Block 5. Associativity evaluated against the vector triple product: $\mathbf{x} * (\mathbf{x} * \mathbf{y}) = (\mathbf{x} * \mathbf{x}) * \mathbf{y}$ while $\mathbf{x} \times (\mathbf{x} \times \mathbf{y}) = -|\mathbf{x}|^2 \mathbf{y}$, which pins $\mathbf{x} * \mathbf{x}$ to a line, twice, hence to zero (Lemmas 2 and 3).

Block 6. Three squares equal the identity, so $\mathbf{b} * \mathbf{c} = (\mathbf{b} * \mathbf{c})^{-1} = \mathbf{c} * \mathbf{b}$, and Lemma 1 kills it.

The nominal route is Block 1 followed by coordinates: name nine unknowns, expand cross products, and try to solve. You will fill a page and learn nothing, because $*$ has no coordinate description to solve for. A second nominal route is to hunt for a slick one line contradiction from $\mathbf{x} \times \mathbf{x} = \mathbf{0}$ alone; it does not exist, because $\mathbf{x} * \mathbf{x}$ is unconstrained by (ii) precisely when $\mathbf{x} \times \mathbf{x}$ is zero, which is always.

The bifurcation point is the sentence after Block 1. Zombie: "what does G look like?" Ideal: "which group axioms can I collide with the failures of $\times$?" The first question asks about an object you cannot see. The second asks about a list you can write down in ten seconds.

Layer 2: HOW

Block 1. Cue. Hypothesis (ii) is a disjunction, and the conclusion is that the second branch always holds. **Why natural.** A disjunction is used by negating the branch you do not want: $\mathbf{x} \times \mathbf{y} \neq \mathbf{0}$ forces $\mathbf{x} * \mathbf{y} = \mathbf{x} \times \mathbf{y}$. That implication is the only channel through which the geometry can speak to the group, so all information lives on live pairs. Since the goal denies that live pairs exist, contradiction is the only available frame. **Link to the next block.** Assuming a live pair immediately produces new elements of G, because $\mathbf{a} * \mathbf{b}$ lies in G by closure and equals $\mathbf{a} \times \mathbf{b}$.

Block 2. **Cue.** $\times$ is anticommutative and $*$ has no commutativity assumption. **Why natural.** If $\mathbf{x}$ and $\mathbf{y}$ commute under $*$ and their cross product were live, then $*$ would have to equal $\times$ in both orders, and $\times$ reverses sign. Two vectors equal to their own negatives are zero. This is the cheapest of the four axiom failures, so it is proved first and used everywhere. **Link to the next block.** Commuting pairs are handed to you by the group: the identity commutes with everything.

Block 3. **Cue.** Every group has an identity, and you have not used it. **Why natural.** Free structure before assumed structure. Lemma 1 converts "commutes with" into "has zero cross product with", so the identity is orthogonally deficient against every element of G. Once G contains a spanning triple, linearity of $\mathbf{v} \mapsto \mathbf{e} \times \mathbf{v}$ upgrades three vanishings to all of $\mathbb{R}^3$, and only the zero vector kills everything. **Link to the next block.** Knowing $\mathbf{e} = \mathbf{0}$ is only useful if you can produce elements whose $*$ square is the zero vector, so the next task is to compute squares.

Block 4. **Cue.** You need orthogonal pairs inside G, and the cross product manufactures orthogonality for free. **Why natural.** $\mathbf{a} \times \mathbf{b}$ is orthogonal to both factors by definition, and it is in G whenever it is nonzero. Iterating gives a mutually orthogonal triple $\mathbf{b}, \mathbf{c}, \mathbf{p}$ inside G, which is the richest configuration the hypothesis can produce. **Link to the next block.** An orthogonal pair is exactly the input Lemma 2 needs.

Block 5. **Cue.** $*$ is associative, and $\times$ is not; a repeated factor is where non associativity shows. **Why natural.** Evaluate $\mathbf{x} * (\mathbf{x} * \mathbf{y})$ two ways. Read as $\mathbf{x} * \mathbf{z}$ with $\mathbf{z} = \mathbf{x} \times \mathbf{y}$ live, it equals $\mathbf{x} \times (\mathbf{x} \times \mathbf{y}) = -|\mathbf{x}|^2\mathbf{y}$, which points along $\mathbf{y}$. Read as $(\mathbf{x} * \mathbf{x}) * \mathbf{y}$, it would be orthogonal to $\mathbf{y}$ if $(\mathbf{x} * \mathbf{x}) \times \mathbf{y}$ were live. Along $\mathbf{y}$ and orthogonal to $\mathbf{y}$ at once is impossible for a nonzero vector, so $\mathbf{x} * \mathbf{x}$ is pinned to the line through $\mathbf{y}$. Running the same argument with the orthogonal witness $\mathbf{x} \times \mathbf{y}$ pins it to a second, perpendicular line, and two perpendicular lines meet only at the origin. **Link to the next block.** Squares are the zero vector, and the zero vector is the identity, so you now have three involutions.

Block 6. **Cue.** $\mathbf{b}^2 = \mathbf{c}^2 = (\mathbf{b} * \mathbf{c})^2 = \mathbf{e}$ is the standard configuration that forces commuting. **Why natural.** In any group, $(gh)^{-1} = h^{-1}g^{-1}$; if g, h, gh are all involutions then $gh = (gh)^{-1} = h^{-1}g^{-1} = hg$. Nothing geometric is used here, it is pure group theory, and it delivers a commuting pair whose cross product you already know is nonzero. **Link to the next block.** Lemma 1 closes the contradiction.

Layer 3: WHY

The mathematical truth underneath is that $(\mathbb{R}^3, \times)$ is a Lie algebra, not an associative algebra. Its correct axiom is the Jacobi identity, and its associator is genuinely nonzero: for orthogonal nonzero $\mathbf{x}, \mathbf{y}$ you have $\mathbf{x} \times (\mathbf{x} \times \mathbf{y}) = -|\mathbf{x}|^2\mathbf{y}$ while $(\mathbf{x} \times \mathbf{x}) \times \mathbf{y} = \mathbf{0}$. A group law is associative by fiat. So the dichotomy (ii) is an attempt to let an associative operation impersonate a non associative one, and the impersonation can only survive on the pairs where $\times$ degenerates. The proof consists of trapping $*$ into a configuration where it must agree with $\times$ on enough products that associativity and anticommutativity can be pointed at each other.

The discernment mechanism generalises past this problem. When you are handed an exotic structure defined by "an operation with axioms A agrees, sometimes, with a concrete operation B", never study the structure. Study the axiom failures of B, list them, and then engineer configurations that force agreement on the products where the failure lives. Here the list has four entries and three of them become lemmas: anticommutativity gives Lemma 1, non associativity gives Lemma 2, and the absence of an identity for $\times$ is what makes $\mathbf{e} = \mathbf{0}$ so damaging. The fourth, $\mathbf{x} \times \mathbf{x} = \mathbf{0}$, is the reason (ii) tells you nothing about squares, which is why squares had to be computed the long way round through associativity.

To train it: whenever an operation appears in a problem, write its axiom table before you write anything else. Commutative or anticommutative. Associative or not, and if not, what the associator is. Identity, or no identity. Zero divisors, or none. For $\times$: anticommutative, non associative with $\mathbf{u} \times (\mathbf{v} \times \mathbf{w}) = (\mathbf{u} \cdot \mathbf{w})\mathbf{v} - (\mathbf{u} \cdot \mathbf{v})\mathbf{w}$, no identity, and zero divisors everywhere since parallel vectors annihilate. That table is the solution in compressed form.

What the examiners nudged toward: the phrase "but $*$ need not be related to addition of vectors" is there to stop you from assuming linearity, which is the same as telling you that only the group axioms are available. The "or both" in (ii) is there to stop you from treating the dichotomy as exclusive, which would be a false extra hypothesis. And placing the problem in $\mathbb{R}^3$ rather than in an abstract Lie algebra guarantees the vector triple product is available in closed form.

Revolving concepts

Group axioms and involutions. An element with $g * g = e$ is an involution and equals its own inverse. The key local lemma: if $g^2 = h^2 = (gh)^2 = e$ then $gh = (gh)^{-1} = h^{-1}g^{-1} = hg$, so g and h commute. Globalised: a group in which every element is an involution is abelian, and is a vector space over the field of two elements, hence has order a power of two when finite. See Book 1, field: Abstract algebra, topic: involutions and elementary abelian groups.

Inverse of a product. $(g * h)^{-1} = h^{-1} * g^{-1}$, with the order reversed. The reversal is the entire content of Block 6: without it the identity $gh = hg$ does not appear. See Book 1, field: Abstract algebra, topic: group axioms.

Cross product. $\mathbf{x} \times \mathbf{y}$ is orthogonal to both factors, $|\mathbf{x} \times \mathbf{y}| = |\mathbf{x}||\mathbf{y}| \sin\theta$, and $\mathbf{x} \times \mathbf{y} = \mathbf{0}$ if and only if the two are parallel or one is zero. Anticommutative, bilinear, and satisfying the Jacobi identity $\mathbf{u} \times (\mathbf{v} \times \mathbf{w}) + \mathbf{v} \times (\mathbf{w} \times \mathbf{u}) + \mathbf{w} \times (\mathbf{u} \times \mathbf{v}) = \mathbf{0}$. See Book 1, field: Geometry, topic: vector product in three dimensions.

Vector triple product. $\mathbf{u} \times (\mathbf{v} \times \mathbf{w}) = (\mathbf{u} \cdot \mathbf{w})\mathbf{v} - (\mathbf{u} \cdot \mathbf{v})\mathbf{w}$. If this is not installed, install it now: it is the single computational fact this problem needs, and it is the standard way to convert a double cross product into a linear combination of the original vectors. See Book 1, field: Geometry, topic: triple products.

The recursion hidden in $\mathbf{x}\times$. Fix $\mathbf{x} \neq \mathbf{0}$ and $\mathbf{y}$ orthogonal to it, and define $\mathbf{w}_0 = \mathbf{y}$, $\mathbf{w}_{k+1} = \mathbf{x} \times \mathbf{w}_k$. The triple product identity gives the linear recursion

$$\mathbf{w}_{k+2} = -|\mathbf{x}|^2 \, \mathbf{w}_k,$$

whose characteristic roots are $\pm i|\mathbf{x}|$: on the plane orthogonal to $\mathbf{x}$, the map $\mathbf{w} \mapsto \mathbf{x} \times \mathbf{w}$ is $|\mathbf{x}|$ times a quarter turn, so the orbit is a four cycle up to scaling. Generalised statement: any linear map A with $A^2 = -\lambda I$ on a subspace produces the recursion $\mathbf{w}_{k+2} = -\lambda \mathbf{w}_k$, solved by $\mathbf{w}_{2k} = (-\lambda)^k \mathbf{w}_0$ and $\mathbf{w}_{2k+1} = (-\lambda)^k \mathbf{w}_1$, and is a rotation by a quarter turn after rescaling when $\lambda > 0$. Recognising that $\mathbf{x}\times$ is a rotation in disguise is what makes Lemma 2 predictable rather than surprising. See Book 1, field: Linear algebra, topic: maps with $A^2 = -I$.

Spanning and the kernel of $\mathbf{v} \mapsto \mathbf{e} \times \mathbf{v}$. For $\mathbf{e} \neq \mathbf{0}$ this linear map has kernel exactly the line through $\mathbf{e}$, so it cannot vanish on a spanning set. See Book 1, field: Linear algebra, topic: rank and kernel.

Circuit Bank

- **WHEN** a hypothesis reads "either P or Q" **DO** immediately rewrite it as "not Q implies P" and note where the information actually lives **BECAUSE** a disjunction is inert, an implication is a tool, and the branch you are told to prove is the branch you must assume fails
- **WHEN** the conclusion says some quantity is always degenerate **DO** assume one nondegenerate instance and mine it for new elements and new configurations **BECAUSE** a live instance is the only source of information the hypothesis can convert, so it is both the enemy and the fuel

- **WHEN** a group law is imposed on a set that already carries another operation **DO** write the axiom table of the other operation, commutativity, associativity, identity, zero divisors, before touching the problem **BECAUSE** every contradiction available to you is one of those axiom failures, so the table is the solution list
- **WHEN** you have $g^2 = h^2 = (gh)^2 = e$ **DO** write $gh = (gh)^{-1} = h^{-1}g^{-1} = hg$ and conclude that g and h commute **BECAUSE** inverses reverse order, so involutions convert squaring information into commuting information
- **WHEN** you need a nonzero vector orthogonal to two given ones **DO** take their cross product, and note that membership in the ambient structure is often free **BECAUSE** orthogonality is manufactured, not found, and in this problem the manufactured vector is automatically in G

Backtesting

1. First useful cue: the "either or" in hypothesis (ii), rewritten as "$\mathbf{x} \times \mathbf{y} \neq \mathbf{0}$ implies $\mathbf{x} * \mathbf{y} = \mathbf{x} \times \mathbf{y}$".
2. Method the expression suggested: contradiction driven by the axiom failures of $\times$, one lemma per failure, with associativity of $*$ as the crowbar.
3. Where you would hesitate, and the thought to reinforce: at "how do I ever compute $\mathbf{x} * \mathbf{x}$, given that (ii) says nothing about it?" Reinforce this: when an operation is opaque on a product, compute that product inside a longer associative chain where the neighbouring products are transparent. Associativity is a transport mechanism for information.
4. The trap the question sets: believing you must understand G as a set. You never learn a single element of G; you only learn relations. The problem is testing whether you can work with an object you cannot see.
5. What makes you recognise it faster next time: the phrase "$*$ need not be related to addition" is an explicit instruction that only the four group axioms are in play, and the presence of a concrete non associative operation next to an associative one is the standing signal to evaluate one expression two ways.
6. The reusable decision rule: to prove that a concrete operation cannot support an abstract structure, force the two operations to agree on a configuration large enough to expose the axiom the concrete operation violates.

Mirror drills

1. Prove that a group in which every element satisfies $g * g = e$ is abelian. *Answer:* $g * h = (g * h)^{-1} = h^{-1} * g^{-1} = h * g$.
2. Suppose $\mathbf{e} \in \mathbb{R}^3$ satisfies $\mathbf{e} \times \mathbf{v} = \mathbf{0}$ for three linearly independent $\mathbf{v}$. Show $\mathbf{e} = \mathbf{0}$. *Answer:* the map $\mathbf{v} \mapsto \mathbf{e} \times \mathbf{v}$ is linear, so it vanishes on all of $\mathbb{R}^3$; if $\mathbf{e} \neq \mathbf{0}$, pick $\mathbf{v}$ not parallel to $\mathbf{e}$ to get a nonzero value.
3. For $\mathbf{x}$ a unit vector, show that $\mathbf{y} \mapsto \mathbf{x} \times \mathbf{y}$ restricted to the plane orthogonal to $\mathbf{x}$ squares to $-I$, and say what that means geometrically. *Answer:* the triple product identity gives $\mathbf{x} \times (\mathbf{x} \times \mathbf{y}) = -\mathbf{y}$ there, so the map is a quarter turn in that plane.

16.6 A6. A shrinking ratio contradicts a convergent tail

Let $f : [0, \infty) \to \mathbb{R}$ be a strictly decreasing continuous function such that $\lim_{x\to\infty} f(x) = 0$. Prove that

$$\int_0^\infty \frac{f(x) - f(x+1)}{f(x)}\, dx$$

diverges.

Read it out loud

An integral over an infinite ray of a quantity that measures, at each point, the relative drop of f over one unit step. Say the integrand out loud in its true form:

$$\frac{f(x) - f(x+1)}{f(x)} = 1 - \frac{f(x+1)}{f(x)}.$$

That rewriting is compulsory and it is free, and it tells you two things at once. First, the problem is scale invariant: replacing f by λf for $\lambda > 0$ changes nothing, so no absolute size of f can ever appear in the proof, only ratios. Second, the integrand lies strictly between 0 and 1, so the integral of a positive function is at stake and divergence can only mean divergence to $+\infty$.

The fields are real analysis and nothing else: improper Riemann integrals, monotone functions, and the theory of infinite products hiding one layer down. There is no formula for f and there never will be, so every step must be soft: comparison, telescoping, monotonicity, contradiction. If you catch yourself trying to compute, you have misread the problem.

Spend sixty seconds on reconnaissance, because it calibrates everything. For $f(x) = e^{-cx}$ the integrand is the constant $1 - e^{-c}$ and the integral diverges linearly. For $f(x) = 1/(1+x)$ the integrand is $1/(x+2)$ and it diverges logarithmically. For $f(x) = 1/\log x$ on $[3, \infty)$ the integrand behaves like $1/(x \log x)$ and it diverges like $\log\log x$. The pattern is the message: the slower f decays, the smaller the integrand, and yet the divergence survives every time, arriving more and more slowly. So the theorem is tight, no crude bound will prove it, and the mechanism must be something that converts "f reaches zero" into "the total relative drop is infinite" without ever looking at the rate.

That mechanism is visible if you sample at the integers. Put $t_n = 1 - f(n+1)/f(n) \in (0, 1)$. Then

$$\prod_{n=0}^{N-1} (1 - t_n) = \frac{f(N)}{f(0)} \longrightarrow 0,$$

and an infinite product of factors $1 - t_n$ tends to zero exactly when $\sum t_n$ diverges. So at the integers the statement is a restatement of the infinite product criterion, which is the honest reason the problem is true. The first useful cue, on paper within thirty seconds, is the rewritten integrand together with the sentence "this is an infinite product in disguise". The difficulty, and the reason this sits at A6, is that the integral is not the integer sample: at a non integer x the integrand compares $f(x+1)$ with $f(x)$, a sliding window, and sliding windows are not controlled by integer windows.

Approaches, ranked worst to best

1. **Test cases and extrapolate.** *Cue:* no formula for f, so try the standard decays. *Circuit:* pattern spotting. Mandatory as sixty seconds of reconnaissance, worthless as a proof: it establishes nothing about a general f, which may be flat for a million units and then plunge. Last place as a route, first place as a calibration.

2. **Bound the integrand pointwise from below.** *Cue:* a divergent integral usually wants a divergent minorant. *Circuit:* comparison test. Hopeless, and knowing why is worth more

than the attempt. Given any $\varepsilon > 0$ you can build a strictly decreasing f whose relative drop over a single unit step is below ε on an interval as long as you please. No fixed minorant exists, so comparison must be applied to a rearranged or aggregated quantity, never to the raw integrand.

3. **Take logarithms and telescope.** *Cue:* the product $\prod f(x+n+1)/f(x+n)$ telescopes to $f(x+N)/f(x)$, which tends to zero. *Circuit:* convert products into sums with log. Correct in spirit, and it is the official first route. Write $-\log(1-t) \le t + 2t^2 \le 2t$ for $t \in [0, 1/2]$, so the integrand dominates $\frac{1}{2}\log(f(x)/f(x+1))$, whose integral telescopes to $\int \log(f(x+N)/f(x+n))$ and blows up. The obstruction is uniformity: no constant C satisfies $-\log(1-t) \le Ct$ for all $t \in [0, 1)$, so the bound is available only where the one step drop is at most a half, and the two regimes interleave in x in an uncontrolled way. Repairing that costs Lebesgue measure and the monotone convergence theorem, or a careful split at half integers. Correct, but expensive in both ink and installed theory.

4. **Block telescoping with a frozen denominator.** *Cue:* the denominator $f(x)$ is the only obstacle to telescoping the numerator. *Circuit:* replace a varying denominator by its largest value on the block. For integers $a < b$, since $f(x+k) \le f(x+a)$ for $k \ge a$,

$$\int_a^b \frac{f(x) - f(x+1)}{f(x)} dx \ge \int_0^1 \frac{f(x+a) - f(x+b)}{f(x+a)} dx,$$

the numerator having telescoped. Then choose b so far out that $f(b) < f(a+1)/2$, which makes the last integrand at least $1/2$; iterate to get infinitely many disjoint blocks each contributing at least $1/2$. Fully elementary, about ten lines, and it is the route to write if you cannot see the next one. Very high ranking, and the safest under time pressure.

5. **Contradiction from the vanishing tail.** *Cue:* convergence of a positive integral is a statement about tails, and the integrand is built from a ratio. *Circuit:* assume convergence, and sandwich a ratio between two things the tail controls. The ideal. Six lines, no measure theory, no case analysis, no constructed sequence. The tail of a convergent integral bounds $f(a+1)/f(a)$ from above; a small ratio makes the integrand close to 1; an integrand close to 1 makes the integral diverge. The assumption of convergence eats itself.

The ideal solution

Step 0: the integral makes sense. First, $f(x) > 0$ for all $x \ge 0$. If $f(x_0) \le 0$ for some x_0, then for every $x > x_0$ strict decrease gives $f(x) < f(x_0) \le 0$, so $\lim_{x\to\infty} f(x) \le f(x_0+1) < 0$, contradicting the hypothesis that the limit is 0. Hence $f > 0$, the function

$$g(x) := \frac{f(x) - f(x+1)}{f(x)} = 1 - \frac{f(x+1)}{f(x)}$$

is continuous on $[0, \infty)$, and $0 < g(x) < 1$ because $0 < f(x+1) < f(x)$. Since $g > 0$, the function $T \mapsto \int_0^T g$ is strictly increasing, so the improper integral either converges to a finite limit or increases to $+\infty$; there is no oscillation to worry about.

Step 1: a shift identity. For real $0 \le a < T$, substituting $x \mapsto x+1$ in the second piece,

$$\int_a^T \big(f(x) - f(x+1)\big) dx = \int_a^T f - \int_{a+1}^{T+1} f = \int_a^{a+1} f - \int_T^{T+1} f.$$

Since f is decreasing and positive, $0 < \int_T^{T+1} f \le f(T) \to 0$ as $T \to \infty$. Therefore

$$\int_a^\infty \big(f(x) - f(x+1)\big) dx = \int_a^{a+1} f(x)\, dx < \infty. \tag{1}$$

This is telescoping wearing continuous clothes: the total of all one step drops from a onwards equals the mass of f over the single window $[a, a+1]$.

Step 2: assume convergence. Suppose, for contradiction, that $\int_0^\infty g$ converges, with value $L < \infty$. Write $T(a) = \int_a^\infty g(x)\,dx$ for the tail. Since $\int_0^a g \to L$ as $a \to \infty$, we get

$$T(a) \longrightarrow 0 \qquad (a \to \infty). \tag{2}$$

Step 3: the tail dominates the ratio. Fix any $a \geq 0$. Because f is strictly decreasing and continuous, $f(x) > f(a+1)$ for $x \in [a, a+1)$, so $\int_a^{a+1} f > f(a+1)$. Because $0 < f(x) \leq f(a)$ for $x \geq a$, and $f(x) - f(x+1) > 0$, we have the pointwise bound $\frac{f(x)-f(x+1)}{f(a)} \leq \frac{f(x)-f(x+1)}{f(x)}$ on $[a, \infty)$. Chaining these with (1),

$$0 < \frac{f(a+1)}{f(a)} < \frac{1}{f(a)} \int_a^{a+1} f(x)\,dx = \frac{1}{f(a)} \int_a^\infty \big(f(x) - f(x+1)\big)dx \leq \int_a^\infty \frac{f(x) - f(x+1)}{f(x)}\,dx = T(a).$$

Every integral here converges: the middle ones by (1), the last by the assumption in Step 2.

Step 4: the assumption eats itself. By (2) and the squeeze, $f(a+1)/f(a) \to 0$ as $a \to \infty$, hence

$$g(a) = 1 - \frac{f(a+1)}{f(a)} \longrightarrow 1.$$

So there is $A \geq 0$ with $g(x) \geq \frac{1}{2}$ for all $x \geq A$, and then for $T > A$,

$$\int_0^T g \geq \int_A^T g \geq \tfrac{1}{2}(T - A) \longrightarrow \infty,$$

contradicting convergence. Therefore the integral does not converge, and being an integral of a positive function, it diverges to $+\infty$. ■

Remark 16.6.1. Strict decrease is used only to guarantee $f > 0$ and to make one inequality strict. The same proof, with $<$ weakened to $\leq$ in Step 3, gives the result for any positive decreasing continuous f with limit 0. Continuity is used only so that the Riemann integrals exist.

Remark 16.6.2. The divergence can be arbitrarily slow. For $f(x) = 1/\log x$ on $[3, \infty)$ the integrand is $\big(\log(x+1) - \log x\big)/\log(x+1)$, of order $1/(x \log x)$, so the integral grows like $\log\log x$. No proof of this problem can produce a rate, which is exactly why every viable route is a contradiction or an aggregation argument.

Layer 1: WHAT

Block 1. Rewrite the integrand as $1 - f(x+1)/f(x)$; record scale invariance and $0 < g < 1$; prove $f > 0$ so that the integral is defined.

Block 2. Sample at the integers to see the mechanism: $\prod(1 - t_n) = f(N)/f(0) \to 0$, so this is the infinite product criterion in disguise. This block produces no proof, only the certainty that the theorem is about f reaching zero and nothing else.

Block 3. Assume convergence. Write down the one free consequence: the tail $T(a) \to 0$.

Block 4. Telescope the numerator over the whole ray: $\int_a^\infty (f(x) - f(x+1))dx = \int_a^{a+1} f$.

Block 5. Sandwich the ratio: $f(a+1)/f(a) < \frac{1}{f(a)} \int_a^{a+1} f \leq T(a)$, the first step by monotonicity of f on the window, the second by replacing the denominator $f(x)$ by the larger $f(a)$.

Block 6. Squeeze: the ratio tends to 0, so the integrand tends to 1, so the integral diverges. Contradiction.

The nominal route stops at Block 1 and attacks the integrand pointwise, looking for a minorant like c/x. It fails, and it fails silently, which is the worst kind of failure: you can spend twenty minutes producing bounds that are true and useless. The second nominal route goes through

logarithms, gets the telescoping right, and then hits the uniformity wall at $-\log(1-t) \le Ct$; that route is salvageable but only with measure theory.

The bifurcation point is Block 3, and it is a decision about what "converges" is for. Zombie: convergence is the thing to be refuted, so I must find a lower bound for the integral. Ideal: convergence is a hypothesis with consequences, and its consequence, a vanishing tail, is an upper bound for anything I can fit underneath the tail. Ask what fits underneath, and the answer is the ratio $f(a+1)/f(a)$, which is the very quantity the integrand is built from. That self reference is the whole solution.

Layer 2: HOW

Block 1. **Cue.** A quotient whose numerator is a difference of the same function at two points. **Why natural.** Dividing through gives $1 - f(x+1)/f(x)$, which exposes scale invariance and bounds the integrand in $(0,1)$. Scale invariance is not decoration: it tells you in advance that no argument using the size of f can work, which deletes half the possible attacks before you try them. **Link to the next block.** Once the integrand is a ratio, the natural object is a product, and products over a ray sample naturally at the integers.

Block 2. **Cue.** The step size is exactly 1, and $f(x+1)/f(x)$ telescopes when sampled at integers. **Why natural.** Multiplying the sampled ratios gives $f(N)/f(0)$, and the hypothesis $f \to 0$ says the product collapses to zero. An infinite product of factors in $(0,1)$ collapses to zero precisely when the complementary series diverges, so the integer version of the claim is a standard theorem. This is reconnaissance, not proof, but it fixes the mechanism in your head: the only hypothesis doing work is $f \to 0$. **Link to the next block.** The continuum version cannot be read off from the integer version, so you need an argument that never localises to a window. Contradiction is the frame that lets you use global information.

Block 3. **Cue.** "Prove the integral diverges", with a positive integrand. **Why natural.** For a positive integrand, convergence is equivalent to the tails tending to zero, and there is no other content in the word "converges". Assuming convergence therefore hands you a free family of small quantities indexed by a, and small quantities are useful only as upper bounds. So you should immediately go hunting for something to place underneath $T(a)$. **Link to the next block.** The integrand contains $f(x)$ in the denominator, so anything you place underneath $T(a)$ will involve ratios of values of f.

Block 4. **Cue.** A difference $f(x) - f(x+1)$ integrated over an unbounded interval. **Why natural.** Shifting the variable in the second half turns $\int_a^T f(x+1)dx$ into $\int_{a+1}^{T+1} f$, and the two integrals overlap on almost all of their range. What survives is the head $\int_a^{a+1} f$ minus the tail $\int_T^{T+1} f$, and the tail dies because $f \to 0$. This is the exact continuous analogue of $\sum_{k=a}^{b-1}(u_k - u_{k+1}) = u_a - u_b$, and you should reach for it the instant a one step difference appears under an integral sign. **Link to the next block.** You now have a finite, explicit value for the integral of the numerator alone, which is the only part of the integrand you can compute.

Block 5. **Cue.** The denominator $f(x)$ varies and is the only thing preventing the numerator's telescoping from being useful. **Why natural.** Monotonicity gives $f(x) \le f(a)$ on the tail, so replacing $f(x)$ by $f(a)$ weakens the integrand in the safe direction: $T(a) \ge \frac{1}{f(a)} \int_a^\infty (f(x) - f(x+1))dx = \frac{1}{f(a)} \int_a^{a+1} f$. And $\int_a^{a+1} f > f(a+1)$ because f exceeds its right endpoint value across the window. The chain closes on $f(a+1)/f(a)$. **Link to the next block.** The quantity now bounded by the tail is exactly the quantity appearing in the integrand.

Block 6. Cue. A positive quantity squeezed under something tending to zero, which also sits inside the integrand. **Why natural.** If $f(a+1)/f(a) \to 0$ then $g(a) \to 1$, so g is eventually at least $\frac{1}{2}$, and an integrand bounded below by a positive constant on an infinite ray has infinite integral. The contradiction is with the assumption that started the argument, so the assumption is false. **Link to the next block.** Nothing remains: positivity of g upgrades "does not converge" to "diverges to $+\infty$".

Layer 3: WHY

The mathematical truth beneath the problem is the infinite product criterion. For $t_n \in [0,1)$, the product $\prod(1-t_n)$ has a nonzero limit if and only if $\sum t_n$ converges; equivalently, the product collapses to zero exactly when the series diverges. The hypothesis $f \to 0$ says that the product of one step ratios collapses, so the total relative drop must be infinite. Everything else in this problem is the technical work of passing from the integers to the continuum.

That passage is the real difficulty, and it is worth naming precisely why it is hard. The integrand at x compares $f(x+1)$ to $f(x)$, a window that slides continuously. Knowing the drops across $[n, n+1]$ for every integer n tells you nothing about the drop across $[x, x+1]$ for irrational x, because f may do all of its descending in a tiny subinterval. The logarithm route feels natural and is natural, but it needs the inequality $-\log(1-t) \le 2t$, which holds only for $t \le \frac{1}{2}$, and the set of x where the one step drop exceeds a half can be a complicated set that interleaves with its complement. Kedlaya's official route pays for that with Lebesgue measure: it isolates a set of positive measure inside $[0,1]$ on which the bound is valid for all shifts, and then applies monotone convergence. Paul Allen's route refuses to localise at all, aggregating over blocks and freezing the denominator. Joshua Rosenberg's route, the one written above, refuses even to look at the integrand, and works only with global tails.

The discernment mechanism, and this is the transferable part: for "prove that this integral diverges" with an unspecified function, there are exactly three engines. First, exhibit a positive lower bound for the integrand on a set of infinite measure. Second, aggregate over blocks and show each block contributes at least a fixed amount. Third, assume convergence and mine it. Engine three is the cheapest whenever the integrand is built from a ratio, because convergence controls tails, tails control averages, and averages of a monotone function control ratios. Scan these three in order and commit within two minutes; the ranking above shows that engines two and three both close this problem while engine one cannot.

Train the reflex like this. Whenever you assume convergence of $\int_0^\infty g$ with $g \ge 0$, write two lines immediately, before thinking: the tail $\int_a^\infty g \to 0$, and g cannot be bounded below by a positive constant on any set of infinite measure. Those two lines are the entire content of the assumption. Then ask the only remaining question: which quantity built from the problem's data can I trap underneath the tail? Here the answer arrives by asking what the numerator integrates to on its own, which is what makes Step 1 the pivot of the proof.

The examiners nudged in several ways worth naming. The integrand is presented as $(f(x) - f(x+1))/f(x)$ rather than as $1 - f(x+1)/f(x)$, which hides the scale invariance and hides the product structure. The step size is 1 and the domain is $[0,\infty)$, so the integers are an available but treacherous scaffolding. "Strictly decreasing" is there to keep f positive and for no other reason. And $\lim f = 0$ is the only hypothesis with real content: drop it, replace it with $f \to c > 0$, and the integrand becomes integrable for the obvious examples, so any proof that does not use $f \to 0$ decisively is wrong.

Revolving concepts

Improper integrals of nonnegative functions. For $g \ge 0$ the map $T \mapsto \int_0^T g$ is increasing, so the improper integral converges if and only if these partial integrals are bounded, and convergence is equivalent

to $\int_a^\infty g \to 0$ as $a \to \infty$. There is no conditional convergence to worry about. See Book 1, field: Real analysis, topic: improper integrals and tails.

Telescoping, continuous form. The identity used in Step 1 generalises: if $f \geq 0$ is decreasing with $f \to 0$ then for any $h > 0$,

$$\int_a^\infty \big(f(x) - f(x+h)\big)dx = \int_a^{a+h} f(x)\,dx.$$

The discrete parent is $\sum_{k=a}^{b-1}(u_k - u_{k+1}) = u_a - u_b$ with $u_b \to 0$. The general recursion to install: whenever a problem contains the one step difference operator $(\Delta_h f)(x) = f(x) - f(x+h)$, its sum or integral over a ray telescopes to a head term, and the head term is a window average rather than a point value. See Book 1, field: Real analysis, topic: telescoping and difference operators.

Infinite products. For $t_n \in [0,1)$, $\prod(1-t_n)$ converges to a nonzero limit if and only if $\sum t_n < \infty$; if $\sum t_n = \infty$ the product tends to 0. The proof is log of the product, plus the two sided bound $t \leq -\log(1-t) \leq 2t$ valid on $[0, \frac{1}{2}]$, plus separate treatment of the case where t_n does not tend to 0. This is the theorem the problem is a disguise for. See Book 1, field: Real analysis, topic: infinite products.

Halving times. Given a positive quantity decaying to zero, define $a_0 = 0$ and let a_{n+1} be the first integer beyond a_n with $f(a_{n+1}) < f(a_n + 1)/2$. This recursion is well defined precisely because $f \to 0$, it produces infinitely many disjoint blocks, and any argument extracting a fixed amount of budget per block then diverges. Generalised: to prove a sum or integral is infinite when you know only that some quantity decays to zero, cut the domain at the halving times of that quantity and prove a uniform positive lower bound per piece. This is the engine of the block telescoping route. See Book 1, field: Real analysis, topic: stopping times and block decomposition.

Monotone function facts. A decreasing f with limit 0 is positive; on $[a, a+1]$ it satisfies $f(a) \geq f(x) \geq f(a+1)$, so $f(a+1) \leq \int_a^{a+1} f \leq f(a)$, and this two sided window bound is what converts integrals back into point values. See Book 1, field: Real analysis, topic: monotone functions and integral bounds.

Knowledge gaps, named without disguise. If any of the following is not installed, this problem is not approachable and no amount of cleverness will substitute. One: the tail characterisation of convergence for improper integrals of nonnegative functions, including the fact that a convergent integral forces the integrand below any positive constant on arbitrarily late sets. Two: infinite products and their equivalence with series, which is the actual theorem in play. Three: the inequality $-\log(1-t) \leq t + 2t^2$ on $[0, \frac{1}{2}]$ and, more importantly, the fact that no linear bound holds uniformly on $[0,1)$; that failure is the entire reason A6 is not A2. Four: for the official first route only, Lebesgue measure, sets of positive measure, and the monotone convergence theorem. You can score full marks without item four by taking the block route or the tail route, and you should know that in advance so that you do not stall waiting for measure theory you have not installed.

Circuit Bank

- **WHEN** an integrand is a quotient whose numerator is a difference of the same function **DO** divide through to expose $1 - f(x+h)/f(x)$, and say the words "infinite product" **BECAUSE** ratios multiply and telescope, so a sum or integral of $1 -$ ratio is a statement about a product collapsing
- **WHEN** you must prove an integral of a positive function diverges **DO** assume convergence and write the two consequences at once: the tail tends to zero, and the integrand cannot stay above a positive constant late in the ray **BECAUSE** those two lines are the complete content of convergence, and one of them will contradict something you can build
- **WHEN** a one step difference $f(x) - f(x+h)$ sits under an integral over a ray **DO** shift the second copy and telescope, obtaining the head window $\int_a^{a+h} f$ **BECAUSE** overlapping ranges

cancel, and the surviving boundary term dies exactly when $f \to 0$

- **WHEN** a varying denominator blocks a telescoping numerator **DO** freeze it at its largest value on the block using monotonicity, and check that the inequality moves in the direction you need **BECAUSE** a lower bound survives replacing the denominator by a bigger one, and telescoping is worth far more than the constant you lose
- **WHEN** the only hypothesis is that some quantity decays to zero **DO** cut the domain at halving times of that quantity and extract a fixed budget from each block **BECAUSE** infinitely many halvings exist precisely because the limit is zero, so any per block bound sums to infinity

Backtesting

1. First useful cue: the integrand rewritten as $1 - f(x+1)/f(x)$, which is scale invariant, lies in $(0,1)$, and telescopes multiplicatively when sampled at integers.
2. Method the expression suggested: assume convergence, use the vanishing tail as an upper bound, and trap the ratio $f(a+1)/f(a)$ underneath it using the telescoped numerator.
3. Where you would hesitate, and the thought to reinforce: after seeing that the integer sampled statement is the infinite product criterion, you will want to reduce the integral to that sample, and there is no such reduction. Reinforce this: when a discrete model of the problem is easy and the continuous version is not, do not force the reduction; find an argument that never localises. Global tails are the tool that never localises.
4. The trap the question sets: attempting a pointwise minorant for the integrand. No minorant exists, because f may be nearly flat over arbitrarily long stretches, so time spent here is unrecoverable.
5. What makes you recognise it faster next time: an integral whose integrand is 1 minus a ratio of the same function at shifted arguments is always a product in disguise; and the presence of $\lim f = 0$ as the only real hypothesis says that the proof must convert "reaches zero" into "infinitely many multiplicative halvings".
6. The reusable decision rule: to prove divergence of a positive integral built from ratios, assume convergence, telescope the numerator over the tail, freeze the denominator by monotonicity, and squeeze the ratio to zero; a ratio squeezed to zero drives the integrand to 1 and destroys the assumption.

Mirror drills

1. Let $t_n \in [0,1)$. Prove that $\prod_{n\geq 0}(1-t_n) = 0$ if and only if $\sum_n t_n = \infty$. *Answer:* if $t_n \not\to 0$ both statements hold trivially; otherwise take logarithms and use $t \leq -\log(1-t) \leq 2t$ for $t \in [0, \frac{1}{2}]$, valid for all large n.
2. Let f be positive, decreasing, with $f \to 0$. Prove $\int_a^\infty (f(x) - f(x+1))dx = \int_a^{a+1} f(x)dx$. *Answer:* shift the second copy to $\int_{a+1}^{T+1} f$, cancel the overlap, and note the boundary term $\int_T^{T+1} f \leq f(T) \to 0$.
3. Let $a_n > 0$ be decreasing with $a_n \to 0$. Prove $\sum_{n\geq 0}\left(1 - a_{n+1}/a_n\right)$ diverges. *Answer:* group indices into blocks on which a at least halves; within a block starting at N, $\sum(a_n - a_{n+1})/a_n \geq \sum(a_n - a_{n+1})/a_N \geq \frac{1}{2}$, and there are infinitely many blocks.

16.7 B1. power sums forced into a false inequality

Is there an infinite sequence of real numbers $a_1, a_2, a_3, \ldots$ such that

$$a_1^m + a_2^m + a_3^m + \cdots = m$$

for every positive integer m?

Read it out loud

Read this out loud and notice what kind of object you are being handed. It is not one equation in the unknowns $a_1, a_2, a_3, \ldots$, it is infinitely many equations sharing the same unknowns, one for every positive integer m, and every single one of them must hold at once. The fields wired into that sentence are real analysis, because you are silently being told each of these infinite sums converges, and inequalities, because the only honest way to relate several different power sums of one fixed sequence to each other is through an inequality that compares them.

Within thirty seconds you should have peeled off the first few instances explicitly, since a statement true for every positive integer m is never meant to be used in full generality on a first pass. Write

$$\sum a_i = 1, \qquad \sum a_i^2 = 2, \qquad \sum a_i^3 = 3, \qquad \sum a_i^4 = 4,$$

and look at what you now have: three consecutive exponents, 2, 3 and 4, each pinned to a fixed number, on the same underlying sequence. The moment three consecutive exponents like that appear together, the guiding light is Cauchy Schwarz, because a_i^3 splits exactly as the product $a_i \cdot a_i^2$ of an exponent 1 term and an exponent 2 term, and Cauchy Schwarz is precisely the inequality that bounds a sum of products by the two sums of squares of the factors, exponents 2 and 4, both of which you already have. Once you see that split, the rest of the problem is arithmetic, not insight.

Approaches, ranked worst to best

1. **explicit construction by trial.** *Cue:* the word sequence invites you to write one down. *Circuit:* guess and check on geometric or finitely supported sequences. (even correctly suspecting the answer is negative, trying candidate sequences can never prove nonexistence: ruling out infinitely many sequences by exhibiting failures in a handful of them is not a proof, and this route never terminates.)

2. **casework on $|a_i| \le 1$ against $|a_i| > 1$.** *Cue:* the exponents keep climbing while the targets m only grow linearly. *Circuit:* compare termwise growth rates directly. (if every $a_i^2 \le 1$ then $a_i^4 \le a_i^2$ termwise, giving $4 = \sum a_i^4 \le \sum a_i^2 = 2$, an immediate contradiction; otherwise some $a_k^2 > 1$, and you must further show a_k^{2m} eventually exceeds $2m$, forcing $\sum a_i^{2m} \neq 2m$ for m large. Correct, and close to the ideal route in spirit, but it costs two branches and an extra limiting argument where the winning route needs neither.)

3. **Cauchy Schwarz on the pair (a_i) and (a_i^2).** *Cue:* three consecutive integer exponents pinned to fixed values. *Circuit:* the general power sum bound $S_{p+q}^2 \le S_{2p} S_{2q}$. (one inequality, one numerical contradiction, no casework at all. This is the ideal route: the exponents in the hypothesis were already telling you which inequality to reach for.)

The ideal solution

No such sequence exists.

Suppose toward a contradiction that a sequence $a_1, a_2, a_3, \ldots$ satisfies $\sum_{i=1}^{\infty} a_i^m = m$ for every positive integer m. Taking $m = 2$ and $m = 4$ in particular,

$$\sum_{i=1}^{\infty} a_i^2 = 2, \qquad \sum_{i=1}^{\infty} a_i^4 = 4,$$

and both series have nonnegative terms, so both converge absolutely, with every partial sum bounded above by the full sum.

Fix a positive integer N. Applying the Cauchy Schwarz inequality to the finite real sequences $u_i = a_i$ and $v_i = a_i^2$ for $1 \le i \le N$ gives

$$\left(\sum_{i=1}^{N} a_i^3\right)^2 = \left(\sum_{i=1}^{N} u_i v_i\right)^2 \le \left(\sum_{i=1}^{N} u_i^2\right)\left(\sum_{i=1}^{N} v_i^2\right) = \left(\sum_{i=1}^{N} a_i^2\right)\left(\sum_{i=1}^{N} a_i^4\right).$$

Since both factors on the right are partial sums of nonnegative series bounded by their full sums,

$$\left(\sum_{i=1}^{N} a_i^3\right)^2 \le \left(\sum_{i=1}^{\infty} a_i^2\right)\left(\sum_{i=1}^{\infty} a_i^4\right) = 2 \times 4 = 8$$

for every N. By hypothesis, taking $m = 3$, the partial sums $\sum_{i=1}^{N} a_i^3$ converge to 3 as $N \to \infty$, so letting $N \to \infty$ in the bound above,

$$3^2 = 9 \le 8.$$

This is false, so no such sequence exists.

Layer 1: WHAT

Block 1: read off the specific instances of the hypothesis you actually need, at $m = 2, 3, 4$, rather than trying to use the hypothesis in full generality.

Block 2: notice the exponent identity $a_i^3 = a_i \cdot a_i^2$, which turns $\sum a_i^3$ into an inner product of the two sequences (a_i) and (a_i^2).

Block 3: apply Cauchy Schwarz to the Nth partial sums of those two sequences, bounding $\left(\sum_{i=1}^{N} a_i^3\right)^2$ by the product of the two known convergent totals, 2 and 4.

Block 4: pass to the limit $N \to \infty$, using the given convergence of $\sum a_i^3$ to 3, to obtain the false inequality $9 \le 8$ and close the proof.

The nominal route tries to construct or eliminate candidate sequences directly, or splits into cases on the size of $|a_i|$; the ideal route never touches an individual a_i at all, it only ever manipulates the three totals 2, 3, 4 through one inequality. The bifurcation point sits right after you write down $\sum a_i^2 = 2, \sum a_i^3 = 3, \sum a_i^4 = 4$: the question is whether you treat the a_i as unknowns to search over, or treat the three totals as data to feed into a known inequality relating power sums. Taking the second option is the entire difference in cost between the routes.

Layer 2: HOW

Block 1. **Cue.** The same sequence has its second, third and fourth power sums all pinned to fixed numbers. **Why natural.** Powers only relate to each other through multiplication, and $a_i^3 = a_i \cdot a_i^2$ is the one algebraic identity connecting the exponent 3 term to the exponent 1 and exponent 2 terms; writing it out is reading the exponents present, not insight. **Link to the next block.** Once a_i^3 is seen as the product $a_i \cdot a_i^2$, the two factors are exactly a pair of real sequences whose own sums of squares, $\sum a_i^2 = 2$ and $\sum (a_i^2)^2 = \sum a_i^4 = 4$, are the two other numbers the hypothesis already hands you.

Block 2. **Cue.** Two real sequences with known, finite sums of squares. **Why natural.** Cauchy Schwarz is the definitional fact that an inner product cannot exceed the product of the two norms, and $\sum u_i v_i$, $\sum u_i^2$, $\sum v_i^2$ are exactly an inner product and two squared norms once you name $u_i = a_i, v_i = a_i^2$. **Link to the next block.** Applying it produces an upper bound on $\left(\sum a_i^3\right)^2$ built purely from the two totals 2 and 4, entirely independent of what the hypothesis says $\sum a_i^3$ equals.

Block 3. **Cue.** The bound obtained, 8, is a fixed number that does not depend on the sequence at all. **Why natural.** The hypothesis independently supplies a second, competing value for the same quantity, 9; two honest derivations of one quantity that disagree is the cleanest possible contradiction, since no further casework is needed once both numbers are in hand. **Link to the next block.** This numerical clash is the whole proof; nothing about the individual terms a_i was ever pinned down or needed to be.

Block 4. **Cue.** The sum $\sum a_i^3$ that appears is an infinite sum, and the Cauchy Schwarz inequality as usually memorised is a finite statement. **Why natural.** A finite inequality does not automatically hold in a limit without justification, so you must apply it to partial sums, which are always finite, and only then let the index tend to infinity, using convergence you were already given. **Link to the next block.** This turns the numerical bound into a fully rigorous statement about the infinite sums, with no hand waving about an inequality obviously extending.

Layer 3: WHY

The underlying truth is that Cauchy Schwarz is a statement about the geometry of square summable sequences: any two sequences whose squares sum to something finite behave like vectors, and their inner product is capped by the product of their lengths. Every family of power sums of one fixed sequence is secretly a family of such inner products of the sequence with powers of itself, so different power sums of the same object are never independent data, they are linked by this one inequality, and more generally by Holder's inequality for exponent pairs beyond the square case.

The discernment mechanism to train is this: whenever a problem fixes several power sums of one sequence and asks about existence, before considering any construction, write the given totals as a short table indexed by exponent and scan for an exponent identity $p + q = r$ among the exponents present. If you find one, Cauchy Schwarz very likely closes the problem in one inequality, and the split needs the lower exponent in the pair to be an honest integer power of the sequence, here $p = 1, q = 2$, since a fractional power of a possibly negative real number is not defined; that restriction is why the trick uses exponents $2, 3, 4$ rather than, say, $1, 2, 3$, and it is worth noticing which exponent triples admit the split and which do not.

What the examiners were nudging toward is visible in the phrase "for every positive integer m": insisting the equality hold for the entire infinite family hands you far more than you need, since only three values close the argument. Whenever a problem supplies an infinite family of constraints and asks a yes or no existence question, check first whether a small finite subset already contradicts itself, because setters frequently oversupply constraints exactly when the intended answer is negative.

Revolving concepts

Cauchy Schwarz inequality. For real sequences $(u_i), (v_i)$ with $\sum u_i^2$ and $\sum v_i^2$ convergent, $\left(\sum u_i v_i\right)^2 \leq \left(\sum u_i^2\right)\left(\sum v_i^2\right)$, with equality exactly when (u_i) and (v_i) are proportional. This is the $p = q = 2$ instance of Holder's inequality $\sum |u_i v_i| \leq \left(\sum |u_i|^p\right)^{1/p} \left(\sum |v_i|^q\right)^{1/q}$ for conjugate exponents $1/p + 1/q = 1$. See Book 1, field: Inequalities, topic: Cauchy Schwarz and Holder.

Power sums of a sequence. Writing $S_m = \sum a_i^m$, the general lemma actually used here is $S_{p+q}^2 \leq S_{2p} S_{2q}$ for nonnegative integers p, q, obtained by applying Cauchy Schwarz to $u_i = a_i^p, v_i = a_i^q$. More

broadly, the moments of a fixed object are log convex in the exponent, a fact known in probability as Lyapunov's inequality; installing the general $S_{p+q}^2 \leq S_{2p} S_{2q}$ form directly is the efficient way to carry this problem's method into other years. See Book 1, field: Sequences and recurrences, topic: power sum and moment inequalities.

Series of nonnegative terms and the partial sum limit technique. A series of nonnegative reals converges exactly when its partial sums are bounded above, and any finite inequality that holds for every partial sum of two such series passes to the limit; this is the standard, necessary device for legally extending Cauchy Schwarz, the triangle inequality or AM GM from finite sums to infinite ones. See Book 1, field: Real analysis, topic: series convergence.

Newton's identities. For finitely many variables the power sums p_k and the elementary symmetric polynomials e_k satisfy the recursion $p_k - e_1 p_{k-1} + e_2 p_{k-2} - \cdots + (-1)^{k-1} e_{k-1} p_1 + (-1)^k k e_k = 0$, determining each p_k from the earlier power sums and the symmetric functions, or vice versa. Not load bearing here, but it is the standard orbiting machinery around power sums of a sequence and worth keeping distinct from the inequality route used in this solution. See Book 1, field: Polynomials, topic: Newton's identities.

Circuit Bank

- **WHEN** a problem fixes several power sums S_m of one real sequence and asks about existence or impossibility **DO** write the given values as a short table against their exponents and scan for a pair p, q with $2p, 2q$ and $p+q$ all present among the given exponents **BECAUSE** Cauchy Schwarz turns S_{2p} and S_{2q} into an upper bound on S_{p+q}^2, and this is almost always cheaper than direct construction or termwise growth comparisons
- **WHEN** you need to extend a finite algebraic inequality, Cauchy Schwarz, the triangle inequality or AM GM, to an infinite sum **DO** apply the finite inequality to the Nth partial sums, keep the bound valid for every N, then let $N \to \infty$ using whatever convergence the hypothesis already grants **BECAUSE** finite inequalities do not automatically survive the limit without this step, and skipping it costs rigour marks even when the final conclusion is correct
- **WHEN** an existence question hands you infinitely many simultaneous constraints, for every m, for every n, and similar phrasing **DO** check whether a small finite handful of the constraints already contradicts itself before attempting any construction **BECAUSE** setters who quantify over every instance almost always oversupply data when the intended answer is negative, and the redundant data is usually the fastest route to the contradiction

Backtesting

1. First useful cue: the exponents $2, 3, 4$ sitting among the for every m constraints, since $3 = 1 + 2$ while 2 and 4 are twice 1 and twice 2.
2. Method the expression suggested: Cauchy Schwarz applied to the pair of sequences (a_i) and (a_i^2), because a_i^3 is exactly their termwise product.
3. Where you would hesitate, and the thought to reinforce: doubting whether Cauchy Schwarz is valid for an infinite sum at all; reinforce by recalling the partial sum then limit fix rather than abandoning the approach.
4. The trap the question sets: quantifying over every positive integer m tempts you to think you must use all of that data, or construct an explicit sequence; you only ever need three specific values.
5. What makes you recognise it faster next time: seeing two or more power sums of one sequence fixed simultaneously should fire the Cauchy Schwarz reflex before construction is even considered.

6. The reusable decision rule: when a sequence's power sums are pinned at several exponents, hunt for an exponent identity among them and reach for Cauchy Schwarz or Holder before anything else.

Mirror drills

1. Is there a sequence of reals with $\sum a_i^2 = 3$, $\sum a_i^3 = 4$ and $\sum a_i^4 = 5$? *Answer:* no, by the identical argument, since Cauchy Schwarz would force $16 \leq 15$.
2. A sequence of nonnegative reals has $\sum a_i^2 = 5$ and $\sum a_i^4 = 5$. What is the largest possible value of $\sum a_i^3$, and what does achieving it tell you about the sequence? *Answer:* at most 5, by Cauchy Schwarz, with equality exactly when (a_i) and (a_i^2) are proportional, forcing every nonzero term to share one common value.
