TMUA9

THE PUTNAM ARCHIVE

THE ANALYSIS

Volume III. Every paper, every problem, WHAT then HOW then WHY.

Jamie Baek

tmua9.com

Built for the 87th William Lowell Putnam Mathematical Competition, 5 December 2026.

The vow is 120.

THE STANDING ORDER

You got a 1 in the Korean CSAT. You got a 9.0 on the TMUA, in a third of the time, from a 4.5, in a month, by yourself. Neither of those was talent. Both were the same method: take the small set of papers that actually matter, and analyse them to a depth nobody else is willing to reach.

This archive is that method pointed at the Putnam. Nothing in it is a trick. Every revelation in every model answer in sixty years of this competition had a reason behind it, and the reason was always visible in the question. The books that came before this one hid the reason and showed you the polish. This one does the opposite.

Three volumes. The first installs the mathematics that A-level never gave you, ordered by what the Putnam actually demands and generalised wherever a recursion appears. The second teaches you to write a proof that scores ten rather than two, by reverse-engineering what was going through the head of the person who wrote the model answer. The third takes the papers themselves, one problem at a time, and fills in the two things every published solution deletes: why that thought was natural, and why the next thought followed from it.

Read them the way you read the TMUA papers. Not as consumption. As analysis.

But as for you, be strong and do not give up, for your work will be rewarded.
2 Chronicles 15:7

The method

This is the volume that does the work. Everything else in the archive supports it.

Why model answers are not enough

The biggest problem with almost every model answer ever written, and it is ubiquitous, is that it shows the what and never the why. It shows the ideal chain of reasoning. It does not show why the author wrote that particular equation, why a revelation that looks revolutionary to you was natural to them, why they considered another method and rejected it, or why the next block of thought followed from the last. You read it, you think ah, that makes sense, you close it, and you have gained nothing that will fire in the arena, because what you needed was the reaction circuit and what you got was the output of somebody else's.

The journey from zero to the final solution happens entirely inside a head. In coding you can see the archive of your errors. In baking you can see the ingredients and the recipe. Here you can see nothing, so the natural conclusion is that the people who produce these solutions are simply built differently. That conclusion is false, and believing it costs years.

Every chapter in this volume fills in the two deleted pieces for one problem at a time.

The three layers, transplanted from the TMUA9 Blueprint

Layer 1, the WHAT. The surface. What was the ideal chain of reasoning, and what was yours? The analysis lays them side by side, names the nominal route (the zombie route, the one that brute-forces without thinking) against the ideal route, and marks the bifurcation point: the exact line where the two paths split. Everything downstream of that line is forced. The entire difference between a 10 and a 2 is usually one sentence at one bifurcation.

Layer 2, the HOW. Where did we split, and what was the critical thought I had to generate to follow the ideal path? Each thought block gets three things: the cue in the question that triggered it, why that move was natural given the cue and the structure in front of you, and the link that makes the next block follow. That sentence, the critical thought, had to be self-generated, in your head, in the arena. When you first start analysing, these thoughts feel impossible to produce on your own. That is the whole point. It is a hard thought. Most cannot. You will.

Layer 3, the WHY. Why must that thought be the natural one? What underlying mathematical truths make this route ideal rather than merely available? This is where the analysis goes back to definitions, because that is where every circuit in this archive bottoms out. Layer 3 also gives you the discernment mechanism: not just which route was best, but how you decide which route is best while the clock is running, and how to train that decision.

Layer plus alpha, backtesting. Six questions on every problem, run like a mantra, exactly as in the Blueprint: what was the first useful cue, what method did that expression suggest, where exactly did I hesitate, what trap was set, what would make me recognise this faster, and what is the reusable decision rule. Your accumulated answers to the last two are your Circuit Bank.

What is in each problem

Every problem in this volume carries the same ten parts, in the same order. The statement. A verbal reading of its structure and the fields wired into it, with the first useful cue and what you should have written down within thirty seconds. Every viable approach ranked worst to best, each tagged with the cue that triggers it and the circuit behind it, with an explicit account of what the losers cost. The ideal solution, written as a full-marks proof. Then Layers 1, 2 and 3. Then the revolving concepts, which light up the key terms and give you the theory orbiting each one, generalising every recursion in sight and pointing back into Volume I. Then the Circuit Bank entries. Then the backtesting. Then three mirror drills that fire the same circuits.

How to work through it

Attempt the problem first. Always. Even a failed attempt gives you the raw material for the juxtaposition in Layer 1, and without your own chain of reasoning there is nothing to compare against and the analysis degrades into reading. Keep a note of what you were thinking and why you wrote each line, because that is the thing you will otherwise forget within the hour.

Then read the analysis, and be brutal about the bifurcation point. The question is never merely what was the better method. It is what would I have had to think, and when, to have found it.

Then close the book and reconstruct the ideal solution from nothing.

One paper through the full analysis every two to three days beats a paper a day at surface level. Analysis time should run at double or triple the solving time. Never end a session on solving; end it on analysis, because that is what consolidates overnight. Papers are ordered newest first, because the recent papers are the closest thing to the exam you are about to sit.

One more thing

You will not meet any of these problems in December. Nobody ever does. Memorising them is not the aim and never was. The aim is a cognitive infrastructure, an algorithm you can run against whatever they put in front of you, built from circuits that you extracted yourself and that fire without being called. Speed is a byproduct of that, never of writing faster.

Find the key points on the ocean of knowledge, light them up, and learn the concepts revolving around them. That is what this volume is.

Contents

The method **i**

1 Putnam 2025 **1**
1.1 A1. The odd part of the difference only shrinks . . . 2
1.2 A2. Sine sandwiched between two parabolas . . . 6
1.3 A3. Pair every string with a partner . . . 11
1.4 A4. Commuting exactly along a cycle . . . 16
1.5 A5. Zigzag patterns beat every other pattern . . . 22
1.6 A6. Iterate the polynomial and expand at zero . . . 28
1.7 B1. Two-colour plane closed under circumcentres . . . 35
1.8 B2. Lamina centroid against solid of revolution centroid . . . 39
1.9 B3. Divisor-closed set forced to contain every integer . . . 44
1.10 B4. Sum versus support of a staircase matrix . . . 48
1.11 B5. Descents in the sequence of modular inverses . . . 53
1.12 B6. Largest exponent in a self-referential growth inequality . . . 59

2 Putnam 2024 **65**
2.1 A1. Valuation bookkeeping kills a Fermat-type equation . . . 66
2.2 A2. Expand the iterate modulo the fixed-point polynomial squared . . . 71
2.3 A3. Where the entry two sits in a random tableau . . . 76
2.4 A4. Complements turn a long progression into a short one . . . 81
2.5 A5. A random chord is a direction plus an offset . . . 86
2.6 A6. Hankel determinants through a self-similar inverse series . . . 92
2.7 B1. Transversal sums force the middle offset . . . 98
2.8 B2. A fixed centre and two concentric circles . . . 102
2.9 B3. Consecutive roots via the tangent addition formula . . . 107
2.10 B4. Affine drift makes the mean a geometric sequence . . . 112
2.11 B5. Real negative roots give nonnegative coefficients . . . 117
2.12 B6. Complete the square and find the Gaussian peak . . . 123

3 Putnam 2023 **129**
3.1 A1. Second derivative of a cosine product at zero . . . 130
3.2 A2. Reversing a polynomial to expose two missing roots . . . 135
3.3 A3. Nothing in the plane turns faster than one radian . . . 141
3.4 A4. Icosahedral vectors generate a dense subgroup . . . 148
3.5 A5. Base three weights collapse a shift operator . . . 155
3.6 A6. Bob owns the parity of the fixed points . . . 162
3.7 B1. Sliding coins and the staircase of holes . . . 170
3.8 B2. Binary weight of the multiples of 2023 . . . 175
3.9 B3. Expected length of the longest zigzag subsequence . . . 180
3.10 B4. Least time for a resetting piecewise parabola . . . 186

3.11 B5. When multiplication mod n is a square permutation . . . 193
3.12 B6. Determinant of a matrix of representation counts . . . 199

4 Putnam 2022 **207**
4.1 A1. Lines meeting a logarithmic curve exactly once . . . 208
4.2 A2. Maximum negative coefficients of a squared polynomial . . . 215
4.3 A3. Counting Lyness sequences modulo a prime . . . 221
4.4 A4. Expected weighted sum before the first ascent . . . 228
4.5 A5. Domino placing game on 2022 squares . . . 235
4.6 A6. Odd power sums and interval lengths . . . 243
4.7 B1. Parity of exponential series coefficients . . . 251
4.8 B2. Finite sets closed under the cross product . . . 256
4.9 B3. Iterated recolouring of the positive reals . . . 262
4.10 B4. Cyclic sequences whose triples are progressions . . . 268
4.11 B5. When zero is the most likely weighted sum . . . 275
4.12 B6. A continuous functional equation on the positive reals . . . 282

5 Putnam 2021 **291**
5.1 A1. Grasshopper hops of length five to the diagonal . . . 292
5.2 A2. A one to the infinity limit hiding a geometric mean . . . 296
5.3 A3. Regular tetrahedron with lattice vertices on a sphere . . . 300
5.4 A4. Two divergent integrals whose difference survives . . . 304
5.5 A5. Power sums over the units modulo 2021 . . . 311
5.6 A6. Binary digit polynomials and composite values . . . 318
5.7 B1. Random unit square avoiding lattice corners . . . 326
5.8 B2. Weighted geometric means and tuned AM-GM . . . 331
5.9 B3. Averaging a rotational derivative over circles . . . 337
5.10 B4. A twisted product modulo a Fibonacci prime . . . 344
5.11 B5. Very odd matrices are acyclic digraphs . . . 350
5.12 B6. Iterated median trimming and quantile coupling . . . 357

6 Putnam 2020 **365**
6.1 A1. Repunits, the order of ten modulo 101 . . . 366
6.2 A2. A binomial sum that counts coin flip majorities . . . 371
6.3 A3. Iterated sine and a neutral fixed point . . . 376
6.4 A4. Splitting a strip and a derangement limit . . . 381
6.5 A5. Counting Fibonacci representations by complementation . . . 388
6.6 A6. A Fejer mean of the square wave in disguise . . . 394
6.7 B1. Binary digit signs annihilate low degree polynomials . . . 401
6.8 B2. Adjacent pairing decides the peg sliding game . . . 408
6.9 B3. Take logarithms and count exponential arrivals . . . 415
6.10 B4. Cyclic rotation makes the reciprocals sum to one . . . 421
6.11 B5. Reciprocal substitution pins four points to one line . . . 427
6.12 B6. Run lengths renormalise a Beatty sign sequence . . . 434

7 Putnam 2019 **443**
7.1 A1. Sum of cubes minus triple product, modulo nine . . . 444
7.2 A2. Centroid and incentre parallel to a side . . . 449
7.3 A3. Mean root modulus by Vieta and AM-GM . . . 454
7.4 A4. Fixed radius spherical means have a kernel . . . 459
7.5 A5. Euler operator reads the vanishing order . . . 465
7.6 A6. Taylor windows and Landau's interpolation inequality . . . 472

7.7 B1. Counting squares in a Gaussian power of two lattice . . . 479
7.8 B2. Telescoping a trigonometric sum of cubic growth . . . 486
7.9 B3. A reflection restores the eigenvalue one . . . 492
7.10 B4. Manufacturing a mixed partial with Euler operators . . . 498
7.11 B5. Interpolating Fibonacci and the missing top difference . . . 505
7.12 B6. Perfect codes tile the lattice in every dimension . . . 511

8 Putnam 2018 **519**
8.1 A1. Unit fractions collapse into a factor pair . . . 520
8.2 A2. Determinant of the subset intersection matrix . . . 525
8.3 A3. Smoothing cubes to maximise a cosine sum . . . 531
8.4 A4. A Christoffel word forces two generators to commute . . . 537
8.5 A5. Every derivative nonnegative forces the function flat . . . 544
8.6 A6. Rational squared distances give rational area ratios . . . 551
8.7 B1. Which Point to Remove for a Balanced Split . . . 558
8.8 B2. A Decreasing Coefficient Polynomial Avoids the Unit Disc . . . 563
8.9 B3. The Power of Two Tower Divisibility Chain . . . 568
8.10 B4. Chebyshev disguise turns Fibonacci angles periodic . . . 573
8.11 B5. Symmetrised Jacobian forces global injectivity . . . 580
8.12 B6. Exponential weights bound restricted composition counts . . . 587

9 Putnam 2017 **595**
9.1 A1. the smallest set generated by squares and a shift . . . 596
9.2 A2. a quotient recursion that is secretly linear . . . 600
9.3 A3. turning an unused zero integral into a sign . . . 605
9.4 A4. A sliding window splits the class . . . 610
9.5 A5. Three card players and a rotating lead . . . 616
9.6 A6. Icosahedron edge colourings via linear algebra . . . 623
9.7 B1. why a dilation always finds the meeting point . . . 630
9.8 B2. sums of consecutive integers and divisor counting . . . 635
9.9 B3. power series digits and a denominator clash . . . 640
9.10 B4. Evaluating a period four logarithmic series . . . 646
9.11 B5. Triangles with exactly two equalizer lines . . . 653
9.12 B6. Distinct tuples under a weighted congruence . . . 662

10 Putnam 2016 **671**
10.1 A1. derivative order forcing divisibility by 2016 . . . 672
10.2 A2. limiting growth rate of a binomial threshold . . . 677
10.3 A3. cyclic functional equation and its arctan integral . . . 683
10.4 A4. Minimum tile count for an odd rectangle . . . 689
10.5 A5. Bounded alternating words in two generators . . . 697
10.6 A6. Sharp integral bound for cubics with a root . . . 704
10.7 B1. exponentiate the log to expose telescoping . . . 712
10.8 B2. counting squarish numbers via basin sizes . . . 717
10.9 B3. double the extremal triangle to cover the set . . . 723
10.10 B4. Expected determinant of a random skew matrix . . . 729
10.11 B5. Multiplicative sandwich forces a pure power . . . 736
10.12 B6. A dyadic double sum that telescopes to one . . . 743

11 Putnam 2015 **751**
11.1 A1. maximal triangle on a hyperbola branch . . . 752
11.2 A2. a Lucas recurrence and an odd prime factor . . . 756
11.3 A3. Roots of unity collapsing to a gcd sum . . . 761
11.4 A4. Binary weights on an even floor set . . . 768
11.5 A5. Parity of the coprime count below a quarter . . . 774
11.6 A6. A determinant identity for intertwined matrices . . . 781
11.7 B1. a perfect cube hides an integrating factor . . . 788
11.8 B2. crossing off triples and their sums . . . 793
11.9 B3. which arithmetic progression matrices have AP powers . . . 799
11.10 B4. Ravi substitution decouples a triangle sum . . . 805
11.11 B5. Key permutations and a shift operator annihilator . . . 812
11.12 B6. Alternating divisor sum hiding an arctangent square . . . 821

12 Putnam 2014 **831**
12.1 A1. Prime numerators in an exponential Taylor series . . . 832
12.2 A2. Determinant of the reciprocal minimum matrix . . . 836
12.3 A3. Telescoping infinite product from a doubling recursion . . . 841
12.4 A4. Minimising the mass at zero from three moments . . . 846
12.5 A5. Coprimality forced by disjoint root annuli . . . 852
12.6 A6. Diagonal nonvanishing bounded by a tensor pairing . . . 859
12.7 B1. Unique over-expansions and the missing zero digit . . . 865
12.8 B2. Maximising a weighted integral under an area constraint . . . 870
12.9 B3. distinct primes among entries force rank two . . . 876
12.10 B4. All roots real for a log concave polynomial . . . 882
12.11 B5. Parity of centralisers decides a matrix game . . . 889
12.12 B6. Lipschitz plus integrality forces piecewise linearity . . . 896

13 Putnam 2013 **905**
13.1 A1. Icosahedron face labels force a repeat . . . 906
13.2 A2. Injectivity of the minimal square completion map . . . 911
13.3 A3. Geometric series bridge from sum to polynomial . . . 917
13.4 A4. Balanced circles and the density of zeros . . . 922
13.5 A5. Area definite lists and average shadows . . . 928
13.6 A6. A positive definite weight on the integer lattice . . . 934
13.7 B1. Telescoping a parity-keyed sign recursion . . . 941
13.8 B2. Maximising a cosine polynomial at zero . . . 946
13.9 B3. Additivity of a modular set function . . . 952
13.10 B4. Variance of a product of continuous functions . . . 958
13.11 B5. Counting maps that funnel into a set . . . 964
13.12 B6. Stone game on a line of odd length . . . 971

14 Putnam 2012 **981**
14.1 A1. an acute triple forced by Fibonacci growth . . . 982
14.2 A2. forcing cancellation without identity or inverses . . . 987
14.3 A3. pinning a functional equation at its fixed point . . . 992
14.4 A4. A small box forces the solutions into a progression . . . 999
14.5 A5. When an affine map is one long cycle . . . 1005
14.6 A6. Unit area rectangles force the function to vanish . . . 1011
14.7 B1. closure under addition and composition forces multiplication . . . 1019
14.8 B2. a single face bounds the ball count below . . . 1024

14.9 B3. Hall's theorem matches days to distinct winners . . . 1029
14.10 B4. A recursion that shadows the natural logarithm . . . 1034
14.11 B5. Convex envelopes turn a supremum into lines . . . 1040
14.12 B6. The sign of cubing modulo a prime . . . 1047

15 Putnam 2011 **1055**
15.1 A1. counting lattice points a spiral cannot reach . . . 1056
15.2 A2. telescoping an underspecified bounded recurrence . . . 1062
15.3 A3. the endpoint order forced by a vanishing cosine . . . 1068
15.4 A4. Prescribed parities of dot products . . . 1074
15.5 A5. Rectify the field, then pigeonhole . . . 1080
15.6 A6. Fourier analysis of a group random walk . . . 1088
15.7 B1. squeezing a scaled root difference into a window . . . 1096
15.8 B2. why two and five dominate this set . . . 1101
15.9 B3. recovering differentiability from a product and quotient . . . 1107
15.10 B4. Tournament standings as a Gaussian Gram matrix . . . 1112
15.11 B5. Overlap integrals of Lorentzians against reciprocal sums . . . 1119
15.12 B6. Wilson reflection and double roots of a truncated exponential . . . 1126

16 Putnam 2010 **1135**
16.1 A1. splitting 1 through n into equal sums . . . 1136
16.2 A2. differentiability forces f to be linear . . . 1140
16.3 A3. why a bounded directional eigenfunction must vanish . . . 1145
16.4 A4. Towers of ten factored by base swapping . . . 1150
16.5 A5. The cross product cannot host a group . . . 1156

Chapter 1

Putnam 2025

1.1 A1. The odd part of the difference only shrinks

Let m_0 and n_0 be distinct positive integers. For every positive integer k, define m_k and n_k to be the relatively prime positive integers such that

$$\frac{m_k}{n_k} = \frac{2m_{k-1}+1}{2n_{k-1}+1}.$$

Prove that $2m_k + 1$ and $2n_k + 1$ are relatively prime for all but finitely many positive integers k.

Read it out loud

This is a number theory question about a pair of positive integers evolving under a two-part rule: the same affine map $x \mapsto 2x + 1$ is applied to both entries, then both are divided by their common factor. The object you are asked about, $\gcd(2m_k + 1, 2n_k + 1)$, is exactly the number the rule divides out at the next step, so the question asks whether the reduction step eventually becomes trivial. The fields wired in are elementary number theory (Euclid, odd and even parts of an integer) and the idea of a monovariant, a positive integer quantity that can only move one way. What is really being tested is whether you track the right quantity: m_k and n_k roughly double each step and look random after reduction, so they are useless, while the difference $m_k - n_k$ is the object.

The first useful cue is "relatively prime", used twice, applied to numbers of the shape $2x + 1$. The circuit that fires: a common divisor of $2m + 1$ and $2n + 1$ divides their difference $2(m - n)$, and it is odd, so it divides $m - n$. Within thirty seconds you should have written $d_k := \gcd(2m_k + 1, 2n_k + 1)$, then $d_k \mid (m_k - n_k)$, then $m_{k+1} - n_{k+1} = 2(m_k - n_k)/d_k$. The second cue is the command term "for all but finitely many k": a monovariant sentence. You need a positive integer that strictly decreases whenever the bad event $d_k > 1$ happens. The doubling of the difference is a decoy; the odd part of the difference ignores it. A caveat worth clarifying: the hypothesis "distinct" exists only to keep the difference nonzero, so that the monovariant is a positive integer.

Approaches, ranked worst to best

1. **Chase the values.** *Cue:* an explicit recursion that looks like it might have a closed form. *Circuit:* iterate, tabulate, guess a formula. Stalls immediately: reduction destroys any closed form for m_k and n_k individually. A page of examples and nothing proved.
2. **Euclid on the pair.** *Cue:* a gcd of $2m + 1$ and $2n + 1$. *Circuit:* a common divisor divides every integer combination, in particular the difference. Gives $d_k \mid (m_k - n_k)$ at once and is most of the solution. Where it stalls: without the monovariant framing you stare at a difference that doubles each step and cannot see why the odd common factors must run out.
3. **Odd-part monovariant.** *Cue:* "all but finitely many" together with a quantity that is divided by an odd number each step. *Circuit:* find a positive integer that is nonincreasing and drops exactly when the bad event happens. The odd part of $|m_k - n_k|$ is divided by d_k at each step. Unwinding the recursion shows that the product of all the d_k divides the odd part of $|m_0 - n_0|$, which even counts the bad indices. Four lines, quantitative, ideal.

The ideal solution

For $k \geq 0$ put $d_k := \gcd(2m_k + 1, 2n_k + 1)$. Since d_k divides the odd number $2m_k + 1$, it is odd. Reducing a fraction to lowest terms means dividing numerator and denominator by their gcd, so by the definition of m_{k+1}, n_{k+1},

$$m_{k+1} = \frac{2m_k+1}{d_k}, \qquad n_{k+1} = \frac{2n_k+1}{d_k}, \qquad \text{hence} \qquad m_{k+1} - n_{k+1} = \frac{2(m_k - n_k)}{d_k}.$$

Write $\delta_k := |m_k - n_k|$. Then $\delta_{k+1} = 2\delta_k/d_k$, and since $\delta_0 > 0$ (the integers m_0, n_0 are distinct), induction gives $\delta_k > 0$ for every k. Unwinding,

$$\delta_k \prod_{i=0}^{k-1} d_i = 2^k \delta_0 \qquad (k \geq 0).$$

The product $D_k := \prod_{i<k} d_i$ is an odd positive integer dividing $2^k\delta_0$, so it divides the odd part $\delta_0^{\text{odd}} := \delta_0/2^{v_2(\delta_0)}$; in particular $D_k \leq \delta_0^{\text{odd}}$ for every k. Each d_i is odd, so $d_i \geq 3$ whenever $d_i > 1$. If $d_i > 1$ for N indices $i < k$, then $3^N \leq D_k \leq \delta_0^{\text{odd}}$, so $N \leq \log_3 \delta_0^{\text{odd}}$. Since k was arbitrary, at most $\log_3 \delta_0^{\text{odd}}$ indices i have $d_i > 1$. Thus $2m_k + 1$ and $2n_k + 1$ are relatively prime for all but finitely many k. ■

Layer 1: WHAT

Block 1: name the gcd d_k and record that it is odd. Block 2: write the reduction step with d_k and subtract, collapsing the pair to the difference. Block 3: read the difference recursion as "multiply by 2, divide by an odd number" and unwind it into a product identity. Block 4: the odd product is trapped inside a fixed odd integer, so only finitely many factors exceed 1.

Juxtapose. The nominal route writes the reduction step and then tries to understand d_k from the values of m_k and n_k, computing terms and hoping the gcds look like 1. The ideal route never looks at m_k or n_k again after Block 2. The bifurcation point is the line after $m_{k+1} = (2m_k + 1)/d_k$: the zombie computes the next term, the analyst subtracts the two equations. Everything downstream is forced.

Layer 2: HOW

Block 1. **Cue.** "Relatively prime" twice, on numbers of the form $2x + 1$; a quantity that will be divided out.

Why natural. The only structural facts about a common divisor are that it divides every integer combination of the two numbers and that it inherits their parity constraints. Both numbers are odd, so d_k is odd. Naming d_k is not a step; it is the definition of the object you are asked about.

Link to the next block. The reduction step is literally "divide by d_k", so the next line is the update rule with d_k visible.

Block 2. **Cue.** Two parallel equations with the same operations applied to both.

Why natural. When the same map is applied to two objects, study their difference, because the common part cancels: the $+1$ disappears and $m_{k+1} - n_{k+1} = 2(m_k - n_k)/d_k$. This is the simultaneous-equations reflex: look at the relationship first, not at each equation on its own.

Link to the next block. The difference recursion has two ingredients, a doubling and a division by an odd number, and that separation is the whole game.

Block 3. **Cue.** "Multiply by 2, divide by an odd number" repeated; the command term "all but finitely many".

Why natural. A positive integer is uniquely a power of 2 times an odd part, and the recursion acts on the two parts independently: the doubling touches the 2-part, the division by d_k touches the odd part. So the odd part of δ_k is nonincreasing and drops exactly when $d_k > 1$. Unwinding gives the product identity, the cleanest way to see that all the d_i together are bounded.

Link to the next block. A product of odd integers that divides a fixed odd integer is a finite budget; spending 3 or more from it happens finitely often.

Block 4. Cue. A product bounded by a constant, or a nonincreasing sequence of positive integers.

Why natural. Well-ordering: a positive integer cannot strictly decrease infinitely often. That is the entire content of "all but finitely many", and it is the standard termination argument for any monovariant.

Link to the next block. None; the bound $\log_3 \delta_0^{\text{odd}}$ comes free.

Layer 3: WHY

Three truths make this route ideal. First, $\gcd(a, b) = \gcd(a, b - a)$: a gcd is blind to the individual sizes of its arguments and sees only their difference structure, so tracking $m_k - n_k$ loses nothing about d_k. Second, the multiplicative structure of $\mathbb{Z}$ splits by primes; the prime 2 and the odd primes live in different compartments, and the recursion grows one while shrinking the other. Third, well-ordering: the odd compartment is a positive integer, so it stops shrinking.

The discernment mechanism is a question you should ask of every iterative process: what does the rule do to a well-chosen quantity, rather than to the state? The state here is a pair of coprime integers with no structure; the difference is a quantity on which the rule acts by pure multiplication and division. Train it by refusing to compute the state: when a problem gives a recursion on a pair, write the recursion for the difference, sum, product and ratio before computing a single term, and keep whichever one the operations respect.

The examiners nudged you three times. "All but finitely many" is the monovariant command term. The map $2x + 1$ forces the gcd odd and the difference to double, two pointers to the odd part. And "distinct" is the minimal hypothesis that keeps the monovariant positive. Every word is doing work.

Revolving concepts

Greatest common divisor and Euclid. $\gcd(a, b) = \gcd(a, b - qa)$ for any integer q, and every common divisor of a and b divides $\gcd(a, b)$. Used here as $\gcd(2m + 1, 2n + 1) = \gcd(2m + 1, 2(n - m)) = \gcd(2m + 1, n - m)$, the last step because $2m + 1$ is odd. See Book 1, field: Number theory, topic: gcd and the Euclidean algorithm.

2-adic valuation and odd part. $v_2(n)$ is the exponent of 2 in n and $n^{\text{odd}} = n/2^{v_2(n)}$; both are multiplicative, and an odd integer divides $2^k n$ if and only if it divides n^{odd}. See Book 1, field: Number theory, topic: p-adic valuation.

Monovariants. A function of the state that is monotone along the process and takes values in a well-ordered set. If it strictly moves at every occurrence of an event, the event occurs finitely often: the engine behind Fermat's descent, the termination of Euclid's algorithm, and most "the process must stop" problems. See Book 3, field: Games and invariants, topic: monovariants and descent.

Generalised recursion. The structure is a pair (m, n), an affine map $x \mapsto ax + c$ with $\gcd(a, c) = 1$ applied to both, then division by $d = \gcd(am + c, an + c)$. Any prime dividing both d and a would divide c, so $\gcd(d, a) = 1$; since $d \mid a(m - n)$ this gives $d \mid (m - n)$ and $\delta' = a\delta/d$. The a-free part of δ (strip every prime dividing a) is the monovariant, and the number of nontrivial reductions is at most $\log_p$ of the a-free part of $|m_0 - n_0|$, with p the smallest prime not dividing a. The same generalisation covers any process in which two objects receive one transformation and are then divided by a common factor.

Circuit Bank

- **WHEN** you see $\gcd(2m + 1, 2n + 1)$, or any gcd of two values of one affine map **DO** write "the gcd divides the difference of the inputs and is coprime to the leading coefficient" **BECAUSE** a common divisor divides every integer combination, and coprimality with the coefficient strips the extra factor.

- **WHEN** you see a recursion applied to a pair, or to two sequences in parallel **DO** write the recursion for the difference (and the ratio) before computing any term **BECAUSE** the common part of the rule cancels and the state collapses to one quantity.
- **WHEN** you see "eventually", "all but finitely many", or "the process terminates" for an integer process **DO** write a candidate positive integer that moves monotonically and check it drops exactly when the event happens **BECAUSE** well-ordering forbids infinitely many strict decreases.
- **WHEN** you see multiplication by a fixed prime power mixed with division by numbers coprime to it **DO** write the valuation and the coprime part separately **BECAUSE** the prime compartments of $\mathbb{Z}$ do not interact under multiplication and division.

Backtesting

1. First useful cue: "relatively prime" applied to $2m_k + 1$ and $2n_k + 1$, and the fact that the next step divides by exactly that gcd.
2. Method the expression suggested: subtract the two update equations to get $m_{k+1} - n_{k+1} = 2(m_k - n_k)/d_k$, then separate the power of 2 from the odd part.
3. Where you would hesitate, and the thought to reinforce: the worry "the difference is growing, how can anything run out?" Reinforce: growth lives in the 2-part, the gcd lives in the odd part, and the compartments are independent.
4. The trap the question sets: computing m_k, n_k for small k and looking for a pattern in the gcds. There is no pattern in the values; the pattern is in the difference.
5. What makes you recognise it faster next time: "same affine map applied to two things, then reduce" equals "study the difference"; "all but finitely many" equals "monovariant".
6. The reusable decision rule: for an iterated pair, find the quantity on which the rule acts by pure multiplication and division, split it by primes, and watch the compartment that can only shrink.

Mirror drills

1. Prove that $\gcd(2m+1, 2n+1) = \gcd(2m+1, m-n)$ for positive integers $m \neq n$, and deduce that if $|m_0 - n_0|$ is a power of 2 then every d_k in A1 equals 1. *Answer:* $\gcd(2m+1, 2n+1) = \gcd(2m+1, 2(n-m))$ and $2m+1$ is odd; if $\delta_0 = 2^a$ then $\delta_0^{\text{odd}} = 1$, so the product of the d_i divides 1.
2. Let $x_0 \neq y_0$ be positive integers and $x_{k+1} = 2x_k + 1$, $y_{k+1} = 2y_k + 1$ with no reduction. Show that $\gcd(x_k, y_k)$ divides $x_0 - y_0$ for every $k \geq 1$. *Answer:* $x_k - y_k = 2^k(x_0 - y_0)$ and x_k is odd for $k \geq 1$, so $\gcd(x_k, y_k) = \gcd(x_k, 2^k(x_0 - y_0)) = \gcd(x_k, x_0 - y_0)$.
3. Replace $2x + 1$ by $3x + 2$ in A1. Show that $g_k = \gcd(3m_k + 2, 3n_k + 2)$ is coprime to 3, divides $m_k - n_k$, and equals 1 for all but finitely many k. *Hint:* a prime dividing g_k and 3 would divide 2; then $\delta_{k+1} = 3\delta_k/g_k$ and the 3-free part of δ_k is the monovariant.

1.2 A2. Sine sandwiched between two parabolas

Find the largest real number a and the smallest real number b such that

$$ax(\pi - x) \leq \sin x \leq bx(\pi - x)$$

for all x in the interval $[0, \pi]$.

Read it out loud

This is a best-constants inequality: the family $c\,x(\pi - x)$ consists of every parabola that vanishes at 0 and π, exactly where sin vanishes, and you are asked for the tightest sandwich of sin by two members of that family. The fields wired in are single-variable calculus (limits, monotonicity), convexity, and the half-angle identities of trigonometry. What is really being tested is two things: whether you convert "largest a" into an infimum of a ratio and check attainment properly, and whether you can prove two trigonometric inequalities with the least ink, without ever solving a transcendental equation.

The first cue is the pair of command terms "largest a" and "smallest b" attached to a two-sided bound. The circuit: for $x \in (0, \pi)$ divide through, $\rho(x) := \sin x/(x(\pi - x))$, and then the admissible a are exactly the numbers at most $\inf \rho$ and the admissible b exactly the numbers at least $\sup \rho$. Within thirty seconds you should have located where each bound is tight. The lower bound is tight as $x \to 0$: both $\sin x$ and $x(\pi - x)/\pi$ vanish at 0 with slope 1, so $\rho(x) \to 1/\pi$. The upper bound is tight at the centre: $\rho(\pi/2) = 1/(\pi^2/4) = 4/\pi^2$. So the answer is $a = 1/\pi$, $b = 4/\pi^2$, and the entire job is to prove that ρ never dips below its limit at 0 and never rises above its value at $\pi/2$.

The second cue is the symmetry $x \mapsto \pi - x$, shared by $\sin x$ and $x(\pi - x)$: whatever you prove on $[0, \pi/2]$ transfers. The third cue is the location of the tight points, because the location dictates the tool. Tight at an endpoint with matching slope means "compare derivatives and integrate"; tight at an interior maximum of both sides means "recentre at the maximum and compare curvature". Read this way, the problem is two applications of one fact: on $[0, \pi/2]$, sin and cos are concave, so they lie above their chords.

Approaches, ranked worst to best

1. **Plot and read off.** *Cue:* a concrete inequality on a closed interval. *Circuit:* sketch, guess the constants. Correctly produces $1/\pi$ and $4/\pi^2$, which you need, but is worth nothing as a proof. Use it for thirty seconds, then stop.

2. **Taylor bounds.** *Cue:* $\sin x$ compared with polynomials near 0. *Circuit:* alternating series bounds $x - x^3/6 \leq \sin x \leq x$ for $x \geq 0$. The lower bound works: $x - x^3/6 - x(\pi - x)/\pi = x^2(1/\pi - x/6) \geq 0$ on $[0, \pi/2]$ because $\pi^2 < 12$. The upper bound cannot work this way: the target is an equality at $x = \pi/2$, so any intermediate polynomial bound would have to equal 1 at $\pi/2$, and no Taylor polynomial of sin about 0 does. Half a solution.

3. **Two difference functions.** *Cue:* an inequality $F \leq G$ on an interval. *Circuit:* set $h = G - F$, examine h' and h'', count critical points with Rolle. This is the official second solution for the upper bound: $h(x) = \frac{4}{\pi^2}x(\pi - x) - \sin x$ has $h'' = \sin x - 8/\pi^2$, which changes sign once, and a Rolle argument pins the single critical point of h'. It works but costs a page of sign bookkeeping and invites a skipped-calculation error at the Rolle step.

4. **Ratio monotonicity.** *Cue:* a best-constant question, both constants from one ratio. *Circuit:* show ρ is monotone on $(0, \pi/2]$; then inf and sup sit at the ends. The numerator of ρ' is $W(x) = x(\pi - x)\cos x - (\pi - 2x)\sin x$, and because $\sin'' = -\sin$ the cross terms cancel in W' to give $W'(x) = (x^2 - \pi x + 2)\sin x$; $W(0) = W(\pi/2) = 0$ and W' changes sign once on $(0, \pi/2)$, so $W > 0$ there. One computation handles both bounds. This is the official first

solution and the safest mechanical route; it is second only because the chord route needs no differentiation at all.

5. **Concavity chords.** *Cue:* the tight points are at $x = 0$ (matching slope) and at $x = \pi/2$ (matching maximum). *Circuit:* a concave function lies above its chords; integrate a chord inequality for the lower bound, recentre and use the half-angle identity for the upper bound. Six lines, no derivatives beyond knowing sin and cos are concave on $[0, \pi/2]$, no critical points, no Rolle. Ideal.

The ideal solution

The answer is $a = 1/\pi$ and $b = 4/\pi^2$.

Necessity. For $x \in (0, \pi)$ put $\rho(x) := \sin x/(x(\pi - x))$. If a is admissible then $a \le \rho(x)$ for every $x \in (0, \pi)$; since $\rho(x) = \frac{\sin x}{x} \cdot \frac{1}{\pi - x} \to 1/\pi$ as $x \to 0^+$, this forces $a \le 1/\pi$. If b is admissible then $b \ge \rho(\pi/2) = 4/\pi^2$. It remains to show that $a = 1/\pi$ and $b = 4/\pi^2$ are admissible, and then $1/\pi$ is the largest admissible a and $4/\pi^2$ the smallest admissible b.

Lower bound. Both $\sin x$ and $x(\pi - x)$ are unchanged by $x \mapsto \pi - x$, so it suffices to prove $\sin x \ge x(\pi - x)/\pi$ for $x \in [0, \pi/2]$. On $[0, \pi/2]$ the function cos is concave (its second derivative is $-\cos t \le 0$ there), so it lies above the chord joining $(0, 1)$ to $(\pi/2, 0)$:

$$\cos t \ge 1 - \frac{2t}{\pi} \qquad (0 \le t \le \pi/2).$$

Integrating from 0 to $x \in [0, \pi/2]$,

$$\sin x = \int_0^x \cos t \, dt \ge \int_0^x \Big(1 - \frac{2t}{\pi}\Big) dt = x - \frac{x^2}{\pi} = \frac{1}{\pi} x(\pi - x).$$

Upper bound. Completing the square, $\frac{4}{\pi^2} x(\pi - x) = 1 - \frac{4}{\pi^2}\big(x - \frac{\pi}{2}\big)^2$. Put $u := x - \pi/2 \in [-\pi/2, \pi/2]$, so $\sin x = \cos u = 1 - 2\sin^2(u/2)$, and the claim $\sin x \le \frac{4}{\pi^2} x(\pi - x)$ becomes

$$2\sin^2 \frac{u}{2} \ge \frac{4}{\pi^2} u^2, \qquad \text{that is,} \qquad \Big|\sin \frac{u}{2}\Big| \ge \frac{2\sqrt{2}}{\pi} \Big|\frac{u}{2}\Big|.$$

With $v := u/2 \in [-\pi/4, \pi/4]$ and since both sides are even in v, it suffices to show $\sin v \ge \frac{2\sqrt{2}}{\pi} v$ for $v \in [0, \pi/4]$. On $[0, \pi/4]$ the function sin is concave, so it lies above the chord joining $(0, 0)$ to $(\pi/4, \sqrt{2}/2)$, whose slope is $\frac{\sqrt{2}/2}{\pi/4} = \frac{2\sqrt{2}}{\pi}$. This proves the upper bound for every $x \in [0, \pi]$.

Hence

$$\boxed{a = \frac{1}{\pi}, \qquad b = \frac{4}{\pi^2}.}$$

■

Layer 1: WHAT

Block 1: convert "largest a, smallest b" into $\inf \rho$ and $\sup \rho$ of the ratio on the open interval, and read the candidates from the point of contact of each bound: the limit $1/\pi$ at 0, the value $4/\pi^2$ at $\pi/2$. Block 2: use the symmetry $x \mapsto \pi - x$ to halve the interval. Block 3: lower bound, tight at 0 with equal slopes, so compare derivatives: the chord inequality for cos, integrated. Block 4: upper bound, tight at $\pi/2$ where both sides peak at 1, so recentre at $\pi/2$, turn $1 - \cos u$ into a square with the half-angle identity, and finish with the chord inequality for sin. Block 5: assemble necessity and sufficiency into "largest" and "smallest".

Juxtapose. The nominal route sets $h(x) = \sin x - ax(\pi - x)$, differentiates, and tries to solve $\cos x = a(\pi - 2x)$ for the critical points. That equation is transcendental and the route stalls, or

degenerates into the Rolle bookkeeping of approach 3. The ideal route never solves $h' = 0$; it signs h' by convexity. The bifurcation point is the line $h'(x) = \cos x - (1 - 2x/\pi)$: the zombie tries to find its zeros, the analyst recognises "cosine minus its chord" and knows the sign from concavity alone. It is the same line on the page; the difference is what you see in it.

Layer 2: HOW

Block 1. **Cue.** "Largest a" and "smallest b" around a two-sided inequality, with the middle term and the outer terms vanishing at the same endpoints.

Why natural. "Largest a with $aF \le G$ everywhere" is by definition $\inf(G/F)$ over the points where $F > 0$, provided the infimum is admissible. The endpoints have $F = 0$, so they impose nothing directly, but they are where the infimum hides: ρ extends continuously to 0 with value $1/\pi$ because $\sin x/x \to 1$. Checking the limit at the endpoints is not optional; it is where the answer is.

Link to the next block. Knowing where each bound is tight tells you which local tool proves it, so the next move is to record the two contact points, $x = 0$ (slope match) and $x = \pi/2$ (value match).

Block 2. **Cue.** $\sin x$ and $x(\pi - x)$ are both symmetric about $\pi/2$.

Why natural. A symmetry of the whole inequality halves the work at zero cost, and the lower-bound argument uses concavity of cos, which holds only on $[0, \pi/2]$. Without the reduction you would have to handle $[\pi/2, \pi]$ separately, where the chord inequality for cos reverses.

Link to the next block. On $[0, \pi/2]$ everything you need about sin and cos is one fact: they are concave there.

Block 3. **Cue.** Lower bound tight at $x = 0$, where both sides vanish and both have slope 1.

Why natural. Two functions that agree to first order at a point are compared by their derivatives beyond that point: $\sin x \ge x - x^2/\pi$ follows from $\cos t \ge 1 - 2t/\pi$ on $[0, x]$ by integrating. And $1 - 2t/\pi$ is precisely the chord of cos on $[0, \pi/2]$, so the derivative inequality is the definition of concavity applied to cos. Nothing was guessed: the derivative of the lower parabola is the chord of the derivative of sin.

Link to the next block. The upper bound is tight somewhere else, so the same local principle points to a different centre.

Block 4. **Cue.** Upper bound tight at $x = \pi/2$, the common maximum, both sides equal to 1.

Why natural. Recentre: $\frac{4}{\pi^2}x(\pi - x) = 1 - \frac{4}{\pi^2}(x - \pi/2)^2$ is the parabola with vertex $(\pi/2, 1)$, so the inequality says $1 - \sin x$ dominates a square. The one identity that writes $1 - \cos u$ as a square is $1 - \cos u = 2\sin^2(u/2)$; after it, the inequality is $|\sin v| \ge \frac{2\sqrt{2}}{\pi}|v|$ on $[-\pi/4, \pi/4]$, which is again "sine above its chord". The constant $2\sqrt{2}/\pi$ is forced: it is the slope of the chord over $[0, \pi/4]$, and $\pi/4$ is where v lands when x reaches the endpoints.

Link to the next block. Both admissibility proofs are done; close the "largest" and "smallest" logic.

Block 5. **Cue.** The question asks for the largest and the smallest, not merely for admissible values.

Why natural. Block 1 shows every admissible a is at most $1/\pi$ and every admissible b at least $4/\pi^2$; Blocks 3 and 4 show these values are admissible. Both halves are needed for full marks, and it is worth repeating that a grader will look for the necessity half first because it is the one candidates forget.

Link to the next block. None; box the answer.

Layer 3: WHY

The first truth is that a best constant in $aF \leq G$ is an extremum of the ratio G/F, and extrema of a continuous function on an open interval can sit at the boundary as limits. That is why the lower answer $1/\pi$ is never attained on $(0, \pi)$ yet is the largest admissible a.

The second truth is that the contact point of a tight inequality determines the proof technique. At a contact point where both functions vanish with equal slope, the inequality is second-order information, and second-order information about sin is concavity. At a contact point that is a common maximum, the inequality compares curvatures at the peak, and the natural coordinate is the displacement from the peak, which is why completing the square and recentring at $\pi/2$ is the first move, not a leap.

The third truth explains why the ratio route also works and when to prefer it. For $\rho = \sin / A$, the numerator of ρ' is the Wronskian $W = A\sin' - A'\sin$, and $W' = A\sin'' - A''\sin = -(A + A'')\sin$ because the terms $A'\sin'$ cancel. With $A = x(\pi - x)$ this is $(x^2 - \pi x + 2)\sin x$, a quadratic times a positive function, so W rises then falls between two zeros and is positive throughout. Any time you compare sin or cos with a polynomial via a ratio, expect this cancellation; it is the reason the derivative of the ratio is tractable even though the ratio itself is not.

The discernment mechanism: before differentiating anything, locate the tight points and ask what order of contact each has. Train it by refusing to solve $h' = 0$ for a transcendental h; instead ask whether h' is "a concave function minus its chord or tangent". The examiners nudged toward this by choosing a parabola with the same zeros and the same symmetry as sin, so that the contact points are exactly the endpoints and the centre; the answer $4/\pi^2$ is nothing but $1/(\pi/2)^2$, the reciprocal of the parabola's peak, and $1/\pi$ is nothing but the reciprocal of its slope at 0 divided by the slope of sin. Both constants are visible from the geometry before any calculus.

Revolving concepts

Best constants and the ratio. For continuous $F > 0$ and G on an open interval, the largest a with $aF \leq G$ is $\inf(G/F)$ and the smallest b with $G \leq bF$ is $\sup(G/F)$, provided you also check the closure points where $F = 0$ by limits. The set of admissible a is always a closed half-line. See Book 1, field: Inequalities, topic: best constants and extremal ratios.

Concavity and chords (Jordan's inequality). A function with $f'' \leq 0$ on an interval lies above every chord and below every tangent there. For sin on $[0, \pi/2]$ this is $2x/\pi \leq \sin x \leq x$ (Jordan's inequality); for cos on $[0, \pi/2]$ it is $1 - 2t/\pi \leq \cos t \leq 1$. Any sub-interval gives its own chord, for example $\sin v \geq (2\sqrt{2}/\pi)v$ on $[0, \pi/4]$. See Book 1, field: Inequalities, topic: convexity, chords and tangent lines.

Integrating an inequality. If $f(0) = g(0)$ and $f' \geq g'$ on $[0, x]$ then $f \geq g$ on $[0, x]$; this is the monotonicity of the integral and it replaces "find the critical points of $f - g$" whenever the derivative inequality is visible. See Book 1, field: Calculus and integrals, topic: monotonicity and comparison.

Half-angle identities. $1 - \cos u = 2\sin^2(u/2)$ and $1 + \cos u = 2\cos^2(u/2)$ convert a deficit from the peak of a trigonometric function into a square, which is the form you need to compare with a parabola centred at that peak. See Book 1, field: Calculus and integrals, topic: trigonometric identities for estimation.

The Wronskian cancellation. For $\rho = f/A$ with $f'' = -f$, the numerator $W = Af' - A'f$ satisfies $W' = -(A + A'')f$. This is the Sturm comparison mechanism in miniature and it is why ratios of sin or cos against polynomials have tractable derivatives. See Book 1, field: Real analysis, topic: Wronskians and Sturm comparison.

Taylor bounds for sine. $x - x^3/6 \leq \sin x \leq x$ for $x \geq 0$ (alternating series with decreasing terms, or Taylor with remainder), together with the numerical facts $\pi^2 < 10 < 12$ and $\pi^2 > 8$. Enough for the lower bound here, never for the upper. There is no recursion in this problem; the structure is local comparison at contact points.

Circuit Bank

- **WHEN** you see "largest a, smallest b with $aF \le G \le bF$" **DO** write $\rho = G/F$, compute inf and sup including the limits at points where $F = 0$, and box those before proving anything **BECAUSE** the admissible sets are the half-lines $(-\infty, \inf\rho]$ and $[\sup\rho, \infty)$, so the answer is decided by the ratio.
- **WHEN** you see an inequality tight at a point where both sides vanish with equal slope **DO** write the derivative inequality on the interval and integrate it from the contact point **BECAUSE** first-order agreement makes the inequality second-order information, and that lives in the derivatives.
- **WHEN** you see an inequality tight at a common interior maximum **DO** recentre at the maximum, complete the square, and use $1 - \cos u = 2\sin^2(u/2)$ **BECAUSE** at a peak the comparison is between curvatures, and the half-angle identity turns the deficit into a square.
- **WHEN** you see sin or cos against a straight line on $[0, \pi/2]$ **DO** write "above the chord, below the tangent" **BECAUSE** $\sin'' = -\sin \le 0$ there, and concavity is exactly that statement.
- **WHEN** you see a ratio $\sin x / A(x)$ with A a polynomial **DO** write $W = A\cos - A'\sin$ and $W' = -(A + A'')\sin$ **BECAUSE** the cross terms cancel because $\sin'' = -\sin$, leaving a polynomial times a function of known sign.

Backtesting

1. First useful cue: "largest" and "smallest" around a sandwich whose outer terms vanish at the same points as the middle term; the ratio ρ and its behaviour at 0 and $\pi/2$.
2. Method the expression suggested: locate the contact points, then chords of concave cos (lower bound, integrated) and of concave sin after recentring at $\pi/2$ (upper bound).
3. Where you would hesitate, and the thought to reinforce: at the upper bound, the urge to differentiate $\frac{4}{\pi^2}x(\pi - x) - \sin x$ and hunt for critical points. Reinforce: the bound is tight at the peak, so recentre at the peak and compare squares.
4. The trap the question sets: proving only that $1/\pi$ and $4/\pi^2$ work and forgetting to show no better constant exists, or proving the lower bound by Taylor and then trying the same for the upper bound, which cannot succeed because of the equality at $\pi/2$.
5. What makes you recognise it faster next time: a parabola with the same zeros as sin is a chord-and-curvature problem; the two constants are the slope ratio at the zero and the value ratio at the peak.
6. The reusable decision rule: find the contact points first; slope-contact means integrate a derivative inequality, peak-contact means recentre and compare curvature; sign derivatives by convexity, never by solving.

Mirror drills

1. Prove $\sin x \ge 2x/\pi$ for $x \in [0, \pi/2]$. *Answer:* sin is concave on $[0, \pi/2]$ and $2x/\pi$ is its chord from $(0, 0)$ to $(\pi/2, 1)$.
2. Find the largest c such that $\ln(1 + x) \ge \frac{cx}{1+x}$ for all $x \ge 0$. *Answer:* $c = 1$. The ratio $(1 + x)\ln(1 + x)/x$ tends to 1 as $x \to 0^+$, so $c \le 1$; and for $c = 1$ both sides vanish at 0 while the derivatives satisfy $\frac{1}{1+x} \ge \frac{1}{(1+x)^2}$, so integrate.
3. Prove $1 - \cos x \ge \frac{2x^2}{\pi^2}$ for $|x| \le \pi$. *Answer:* $1 - \cos x = 2\sin^2(x/2)$ and Jordan's inequality on $[0, \pi/2]$ gives $\sin(|x|/2) \ge |x|/\pi$.

1.3 A3. Pair every string with a partner

Alice and Bob play a game with a string of n digits, each of which is restricted to be 0, 1, *or* 2. *Initially all the digits are* 0. *A legal move is to add or subtract* 1 *from one digit to create a new string that has not appeared before. A player with no legal move loses, and the other player wins. Alice goes first, and the players alternate moves. For each $n \geq 1$, determine which player has a strategy that guarantees winning.*

Read it out loud

This is a combinatorial game on a graph. The vertices are the 3^n strings in $\{0,1,2\}^n$; two strings are adjacent when they differ by exactly 1 in exactly one digit, so the graph is the n-fold grid $P_3 \times \cdots \times P_3$; the token starts at the all-zero string; and the rule "a new string that has not appeared before" turns the game into a walk that may never revisit a vertex. In the literature this is undirected vertex geography. The fields wired in are combinatorial game theory (strategies, not values), graph theory (matchings), and parity. What is really being tested is whether you recognise that a game whose state is "the set of visited vertices" is not going to yield to Grundy values or to induction on n, and that the standard weapon for a no-revisit game is a pairing strategy.

The first cue is the phrase "has not appeared before". That sentence tells you the state is a subset of the vertex set, exponentially large, and that the only strategies you can describe are ones with a local rule: "whatever Alice does, I answer with the partner of her vertex". The second cue is a count: after the start, $3^n - 1$ strings remain, an even number. Even arenas belong to the second player if every move of Alice can be answered by a move of Bob that uses up a partner; odd arenas belong to the first player who grabs the partner of the start. Within thirty seconds you should have written "Bob wins if I can pair the nonzero strings along edges". The third cue is the alphabet: 1 and 2 are adjacent values, 0 is the starting value, and every nonzero string has a first nonzero digit that is 1 or 2. Swapping that digit is the pairing.

A caveat worth clarifying: the command term "for each $n \geq 1$, determine" suggests a possible dependence on n, which is a decoy. The answer is uniform, and that is itself a hint that the argument should be uniform, not inductive.

Approaches, ranked worst to best

1. **Brute force small cases.** *Cue:* "for each n". *Circuit:* tabulate $n = 1, 2$ and extrapolate. For $n = 1$ the walk is forced ($0 \to 1 \to 2$) and Bob wins; for $n = 2$ the 3×3 grid is already unpleasant by hand; for $n = 3$ hopeless. No proof, and no mechanism, since the pattern "Bob always" gives no reason.

2. **Induction on n by last digit.** *Cue:* strings as a product structure. *Circuit:* reduce an n-digit game to three $(n-1)$-digit layers. The no-revisit rule couples the layers: Alice can switch layers whenever she likes, and a winning strategy inside one layer does not survive interleaving. Stalls at the first attempt to state the inductive hypothesis.

3. **Parity or strategy stealing.** *Cue:* the count $3^n - 1$ is even. *Circuit:* fixed-length games are decided by parity; extra moves never hurt. The length of the game is not fixed, so parity alone decides nothing, and strategy stealing needs "an extra visited vertex never hurts", which is false here. The parity of the arena is the right cue, but it needs a matching to become an argument.

4. **Pairing strategy.** *Cue:* "not appeared before" and an even arena. *Circuit:* exhibit a perfect matching of the unvisited arena along legal moves, then always reply with the partner. One invariant, one explicit involution (swap $1 \leftrightarrow 2$ in the first nonzero digit), a four-line proof. Ideal.

The ideal solution

Bob wins for every $n \geq 1$.

Let $S = \{0,1,2\}^n$, let $\mathbf{0}$ be the all-zero string, and let G be the graph on S in which two strings are adjacent when they differ by exactly 1 in exactly one position. A legal move is a step along an edge of G to a vertex not yet visited, where $\mathbf{0}$ counts as visited from the start.

Lemma 1.3.1. *Suppose $\tau\colon S \setminus \{\mathbf{0}\} \to S \setminus \{\mathbf{0}\}$ is an involution without fixed points such that v and $\tau(v)$ are adjacent in G for every v. Then Bob wins by always moving to $\tau(v)$, where v is the string Alice has just produced.*

Proof. Say a set $U \subseteq S \setminus \{\mathbf{0}\}$ is *paired* if $\tau(U) = U$, that is, U is a union of pairs $\{v, \tau(v)\}$. We claim that before each move of Alice the set of visited strings is $\{\mathbf{0}\} \cup U$ with U paired. This holds at the start with $U = \emptyset$. Suppose it holds and Alice moves to v. Then $v \notin \{\mathbf{0}\} \cup U$. Since U is paired and $v \notin U$, also $\tau(v) \notin U$; and $\tau(v) \neq \mathbf{0}$ by the definition of τ. Hence $\tau(v)$ is unvisited, and it is adjacent to v, so Bob's move to $\tau(v)$ is legal. After it the visited set is $\{\mathbf{0}\} \cup (U \cup \{v, \tau(v)\})$, and $U \cup \{v, \tau(v)\}$ is paired, so the claim persists. Thus Bob always has a legal reply. Every move visits a new string, so the game ends after at most $3^n - 1$ moves, and the player left without a move is Alice. □

It remains to construct τ. For $v \neq \mathbf{0}$ let $i(v)$ be the smallest index with $v_{i(v)} \neq 0$, so $v_{i(v)} \in \{1,2\}$, and let $\tau(v)$ be the string obtained from v by replacing $v_{i(v)}$ with $3 - v_{i(v)}$. Then $\tau(v)$ differs from v by exactly 1 in exactly one position, so $\tau(v) \neq v$ and $\tau(v)$ is adjacent to v; the digits before position $i(v)$ are still 0 and the digit at $i(v)$ is still nonzero, so $\tau(v) \neq \mathbf{0}$ and $i(\tau(v)) = i(v)$; hence $\tau(\tau(v)) = v$. So τ is a fixed-point-free involution along edges, and by the lemma Bob wins. In words: Bob's strategy is to change the first nonzero digit from 1 to 2 or from 2 to 1. ■

Layer 1: WHAT

Block 1: model the game as a no-revisit walk on the grid graph $\{0,1,2\}^n$ from $\mathbf{0}$. Block 2: count the arena, $3^n - 1$ even, and translate "Bob answers every move" into "a perfect matching of the nonzero strings along edges". Block 3: construct the matching as an explicit involution, swapping 1 and 2 in the first nonzero digit. Block 4: prove that the pairing strategy always has a legal reply, by the invariant "visited equals start plus complete pairs".

Juxtapose. The nominal route plays the game: $n = 1$, then $n = 2$ on a 3×3 grid, then an attempt to set up induction on n or to assign values to positions. All of it treats the current string as the state. The ideal route treats the visited set as the state, and because that set is huge, it looks for a strategy that never needs to know the set, only the last move. The bifurcation point is the sentence "the state of this game is the set of strings that have appeared". Once you write that sentence the pairing strategy is the only local strategy available, and the rest is construction.

Layer 2: HOW

Block 1. **Cue.** "Add or subtract 1 from one digit", "a new string that has not appeared before".

Why natural. Positions related by a single unit change in one coordinate are adjacent vertices of the grid graph; that is the definition of the Cartesian product of paths. "Not appeared before" is the no-revisit rule. Naming the graph is not decoration: it makes "legal move" mean "edge to an unvisited vertex", and "strategy" mean "a rule on vertices".

Link to the next block. A rule on vertices that never consults the visited set must be a pairing; so count whether a pairing of the whole arena is even possible.

Block 2. **Cue.** 3^n vertices in total, $3^n - 1$ after removing the start; even.

Why natural. If the nonzero strings can be split into disjoint adjacent pairs, then every Alice move enters a fresh pair and Bob completes it; the invariant "visited equals start plus complete pairs" is what makes the reply always legal. The parity of $3^n - 1$ is exactly the condition for such a split to be possible at all. Had the count been odd, the same reasoning would point to Alice taking the start's partner in a perfect matching of the whole graph.

Link to the next block. The pairing must be along edges and must be explicit; look for a canonical coordinate in which two adjacent values can be swapped.

Block 3. **Cue.** Three symbols, of which 1 and 2 are adjacent and 0 is the "empty" symbol; every nonzero string has a first nonzero digit.

Why natural. Swapping $1 \leftrightarrow 2$ in one fixed coordinate is an edge, and it is an involution, but it needs a coordinate that is nonzero; "the first nonzero coordinate" is canonical (it is unchanged by the swap), so the map is self-inverse and never hits $\mathbf{0}$. This is how you manufacture perfect matchings on product sets: a canonical position plus a transposition of two adjacent values.

Link to the next block. With τ in hand, the strategy is stated; what remains is to prove it never fails, and that is the invariant.

Block 4. **Cue.** A strategy described by a local rule must be shown to be always legal.

Why natural. The only way Bob's reply $\tau(v)$ could be illegal is if $\tau(v)$ had already been visited. The invariant that the visited set minus the start is τ-closed rules that out, because v itself is unvisited. Writing the invariant is what a grader wants to see; "Bob mirrors" without it is worth about half.

Link to the next block. None; termination is automatic because every move consumes a vertex.

Layer 3: WHY

The truth beneath the route is a theorem about undirected vertex geography (Fraenkel, Scheinerman and Ullman, 1993): on a finite graph with start vertex s, the first player wins if and only if every maximum matching covers s. Here $G - \mathbf{0}$ has a perfect matching, and since G has an odd number of vertices that matching is a maximum matching of G missing $\mathbf{0}$, so the second player wins. You do not need the theorem for the exam; you need its easy half, which is the pairing lemma. But knowing the theorem tells you what to look for in every no-revisit game: does the arena minus the start have a perfect matching?

Why does a pairing strategy work at all? Because it compresses an exponential state into a one-bit invariant, "the visited set is closed under τ", and the invariant is preserved by the pair of moves (Alice, Bob) regardless of what Alice does. This is the same mechanism as the mirror strategy on a symmetric board, where τ is a symmetry of the board; the grid here has plenty of symmetries, but the correct τ is not a symmetry, it is a coordinate swap, which is why you should think "involution along edges" rather than "symmetry".

The discernment mechanism has two questions. Is the state of the game the position or the history? If the history, forget values and look for pairings. Is the number of non-start positions even or odd? Even suggests a second-player pairing of the arena, odd suggests a first-player pairing of arena plus start. Train it by classifying the games you meet: fixed-length games (parity), impartial games with position as state (Grundy), no-revisit games (matchings), and by practising the construction of explicit involutions on product sets.

The examiners nudged you by choosing three symbols rather than two. With two symbols the arena $\{0,1\}^n \setminus \{\mathbf{0}\}$ has $2^n - 1$ vertices, odd, and Alice wins by a different pairing; with three, the values 1 and 2 form a natural adjacent pair leaving 0 as the start symbol. They also wrote "for each $n \geq 1$" so that you would waste time on small cases if you had not installed the circuit.

Revolving concepts

Grid graphs and product structure. The Cartesian product $G \times H$ has vertex set $V(G) \times V(H)$ with $(g,h) \sim (g',h')$ when $g = g'$ and $h \sim h'$, or $h = h'$ and $g \sim g'$. The game graph here is P_3^n; the hypercube is P_2^n. Adjacency in a product changes exactly one coordinate. See Book 3, field: Discrete structures and graphs, topic: product graphs.

Matchings. A matching is a set of disjoint edges; it is perfect if it covers every vertex and maximum if no matching has more edges. A fixed-point-free involution τ with $v \sim \tau(v)$ is the same thing as a perfect matching, and this is the standard way to write one down on a structured set. Existence in general is Tutte's theorem (or Hall's theorem for bipartite graphs); on the exam you almost always want an explicit involution instead. See Book 3, field: Discrete structures and graphs, topic: matchings, Hall and Tutte.

Pairing strategies. If the moves of a game consume elements of a set X and X can be partitioned into pairs such that whenever one element of a pair is playable so is the other immediately afterwards, the second player wins by completing pairs. If instead $X \cup \{s\}$ pairs up but X does not, the first player wins by taking the partner of s. Mirror strategies on symmetric boards are the special case where the pairing is a symmetry. See Book 3, field: Games and invariants, topic: pairing and symmetry strategies.

Undirected vertex geography. The theorem quoted in Layer 3. Its proof in the hard direction (if some maximum matching misses s, the second player wins by following that matching; if all maximum matchings cover s, the first player wins by moving along a maximum matching and using the alternating-path structure) is beyond what you need, but the statement should be installed as a decision rule. See Book 3, field: Games and invariants, topic: geography games.

Generalised recursion. The invariant argument is an induction on the number of moves: the statement "after Bob's t-th move the visited set is the start plus t complete pairs" is the inductive hypothesis, and the inductive step is the single observation that an unvisited v has an unvisited partner. Whenever a strategy is described by a local rule, its correctness proof is an induction on moves with an invariant about the history, and the invariant should be stated before the rule is verified.

Circuit Bank

- **WHEN** you see a game in which positions may not be revisited **DO** write "the state is the visited set" and look for a perfect matching of the unvisited arena along legal moves **BECAUSE** a pairing strategy is the only local strategy in a game with history, and its invariant is preserved by every Alice-Bob pair of moves.
- **WHEN** you count the non-start positions and get an even number **DO** expect a second-player pairing of the arena; if odd, expect the first player to take the start's partner in a pairing of arena plus start **BECAUSE** parity of the arena is exactly the condition for the respective perfect matching to exist.
- **WHEN** you need an explicit perfect matching on tuples or strings **DO** swap two adjacent values in the first coordinate where a canonical condition holds **BECAUSE** a canonical coordinate is preserved by the swap, so the map is a fixed-point-free involution along edges.
- **WHEN** you are tempted to play small cases of a game with memory **DO** stop after $n = 1$ and write the invariant instead **BECAUSE** the state space grows as 2^{3^n} and no pattern in small cases supplies a mechanism.

Backtesting

1. First useful cue: "a new string that has not appeared before", which makes the history the state; then the even count $3^n - 1$.

2. Method the expression suggested: a perfect matching of $\{0,1,2\}^n \setminus \{\mathbf{0}\}$ along edges, realised by swapping $1 \leftrightarrow 2$ in the first nonzero digit, and the invariant proof that Bob's reply is always legal.
3. Where you would hesitate, and the thought to reinforce: whether Bob's partner vertex could already have been visited. Reinforce: the visited set minus the start is always a union of complete pairs, so an unvisited vertex has an unvisited partner.
4. The trap the question sets: "for each n" inviting case analysis and an induction on n that cannot be set up; and the temptation to say "Bob mirrors" without stating the invariant.
5. What makes you recognise it faster next time: no-revisit rule plus even arena equals second-player pairing; three symbols with two adjacent nonzero values equals an obvious involution.
6. The reusable decision rule: classify the game by its state (position, history, or fixed length) before touching it; for history-state games, ask whether the arena minus the start has a perfect matching along moves.

Mirror drills

1. The same game on the path $\{0,1,\ldots,m\}$ starting at 0 (add or subtract 1, no revisits). Who wins? *Answer:* the walk is forced, $0 \to 1 \to \cdots \to m$, so Alice wins if and only if m is odd; in matching language, $\{1,\ldots,m\}$ has a perfect matching along edges if and only if m is even, and then Bob wins.
2. The same game on binary strings $\{0,1\}^n$ starting at 0^n (flip one bit, no revisits). Who wins? *Answer:* Alice. Pair every string v with v having its first bit flipped; this is a perfect matching of the whole cube. Alice first moves to the partner of 0^n and thereafter always moves to the partner of Bob's string; the invariant is that after each Alice move the visited set is a union of complete pairs.
3. A knight stands on a corner of an 8×8 board; players alternately move it to a square it has not visited; a player who cannot move loses. Who wins? *Answer:* the first player. A closed knight's tour exists, so the knight graph has a Hamiltonian cycle of even length and hence a perfect matching; the first player moves to the partner of the corner and then always to the partner of the opponent's square.

1.4 A4. Commuting exactly along a cycle

Find the minimal value of k such that there exist k-by-k real matrices $A_1, \ldots, A_{2025}$ with the property that $A_iA_j = A_jA_i$ if and only if $|i-j| \in \{0, 1, 2024\}$.

Read it out loud

This is a linear algebra question wearing a combinatorial coat. You are handed a graph, the cycle C_{2025} (vertex i adjacent to $i \pm 1$ modulo 2025), and asked for the smallest dimension in which it is the commutation graph of a family of real matrices: neighbours commute, non-neighbours do not. The fields wired in are the structure of commutants (who commutes with a given matrix), rank-one matrices, eigenvectors, and general position of vectors. What is really being tested is whether you know what the set of matrices commuting with a fixed matrix looks like, and whether you can build matrices whose commutation relations you control exactly, in both directions.

The first cue is "if and only if". Both directions must be delivered: the two cyclic neighbours must commute with A_i, and every one of the other 2022 matrices must fail to. That is a demand for exact control, and exact control over commutation comes from matrices whose products are governed by a few scalars, which is the signature of rank one. The second cue is the graph itself: every vertex has degree exactly 2. The third cue is "minimal k", which is always a two-part command: a lower bound proved in general, and a construction at the bound.

Within thirty seconds you should have killed $k = 1$ (scalars all commute, but A_1 and A_3 must not) and asked the only question that matters for $k = 2$: what is the commutant of a non-scalar 2×2 matrix? It is $\{pI + qA\}$, two-dimensional and commutative. So in dimension 2, any two matrices commuting with a common non-scalar matrix commute with each other, and a cycle of length at least 4 is impossible. You should then expect $k = 3$, and the reason is a dimension count: the kernel of a rank-one map in $\mathbb{R}^3$ is a plane, and a plane can be made to contain exactly two prescribed directions, which is exactly the degree of the cycle.

Approaches, ranked worst to best

1. **Guess 2×2 examples.** *Cue:* small matrices, explicit families. *Circuit:* try diagonal matrices, rotations, Jordan blocks, hope to close a cycle. Every attempt produces cliques (everything in one family commutes) or matchings, never a long cycle, and no amount of failure proves impossibility. Zombie maths.

2. **Eigenvalue case split for $k = 2$.** *Cue:* 2×2 matrices and "commute". *Circuit:* distinct eigenvalues means diagonalisable, and commuting diagonalisable matrices share an eigenbasis; a repeated eigenvalue means a shifted nilpotent. This is the official route to the lower bound. It works, but it splits into cases, has to handle complex eigenvalues, and needs the simultaneous diagonalisation theorem. Costs more ink than the next item and offers more places to slip.

3. **Commutant lemma via a cyclic vector.** *Cue:* "commutes with A", A non-scalar, dimension 2. *Circuit:* if v is not an eigenvector then v, Av is a basis and B is determined by Bv. One lemma, no cases, no eigenvalues: the commutant of a non-scalar 2×2 matrix is $\mathrm{span}(I, A)$, which is commutative, so commutation is transitive through non-scalar matrices. Ideal for the lower bound.

4. **Orthogonal projections onto an umbrella.** *Cue:* "commute" for symmetric rank-one matrices. *Circuit:* $u_iu_i^T$ and $u_ju_j^T$ commute if and only if $u_i \perp u_j$ or $u_i \parallel u_j$. You then need 2025 unit vectors in $\mathbb{R}^3$ that are orthogonal exactly along the cycle (the Lovász umbrella with ribs at angles $2\pi \cdot 1012\, i/2025$ does it). Explicit, but proving "no accidental orthogonality" is a trigonometric chore.

5. **Oblique rank-one projections, general position.** *Cue:* "commute if and only if", degree 2, dimension 3. *Circuit:* $A_i = v_i\phi_i$ with ϕ_i killing the two neighbours; commutation reduces to two scalar contractions. Any three of the v_i independent (moment curve, Vandermonde) makes both directions of "if and only if" one-line checks. Ideal for the construction.

The ideal solution

Write $N = 2025$ and read all indices modulo N, so the condition says that A_i and A_j commute exactly when $j \equiv i$ or $j \equiv i \pm 1 \pmod N$. The answer is $k = 3$.

Why $k \le 2$ fails. For $k = 1$ all matrices commute, but A_1 and A_3 must not (as $|1-3| = 2 \notin \{0, 1, 2024\}$). For $k = 2$ we use the following lemma.

Lemma 1.4.1. *Let A be a real 2×2 matrix that is not a scalar multiple of I. If B commutes with A then $B = pI + qA$ for some real p, q. Consequently any two matrices that commute with A commute with each other.*

Proof. Some nonzero vector $v \in \mathbb{R}^2$ is not an eigenvector of A: otherwise $e_1, e_2, e_1 + e_2$ would all be eigenvectors, and $Ae_1 = \lambda_1 e_1$, $Ae_2 = \lambda_2 e_2$, $A(e_1 + e_2) = \mu(e_1 + e_2)$ force $\lambda_1 = \mu = \lambda_2$, making A scalar. For such v the vectors v, Av are linearly independent, hence a basis of $\mathbb{R}^2$. Write $Bv = pv + qAv$. Then $B(Av) = A(Bv) = pAv + qA^2v$, so B and $pI + qA$ agree on the basis v, Av and are therefore equal. Finally, if $B = pI + qA$ and $C = p'I + q'A$ then $BC = CB$ because I and A commute with each other. □

Suppose 2×2 matrices $A_1, \dots, A_N$ have the required property. Then A_2 is not scalar, since it fails to commute with A_4. Both A_1 and A_3 commute with A_2, so by the lemma A_1 commutes with A_3; but $|1 - 3| = 2$, contradiction. Hence $k \ge 3$.

A construction with $k = 3$. Choose distinct real numbers $t_1 < t_2 < \cdots < t_N$ and put $v_i = (1, t_i, t_i^2)^T \in \mathbb{R}^3$. Any three distinct v_i are linearly independent, because the determinant of the matrix with columns v_a, v_b, v_c is the Vandermonde determinant $(t_b - t_a)(t_c - t_a)(t_c - t_b) \neq 0$. In particular no two of the v_i are parallel. For each i, the vectors v_{i-1}, v_i, v_{i+1} (three distinct indices, as $N \ge 3$) form a basis of $\mathbb{R}^3$, so there is a unique row vector ϕ_i with

$$\phi_i v_i = 1, \qquad \phi_i v_{i-1} = \phi_i v_{i+1} = 0,$$

and then $\ker \phi_i = \operatorname{span}(v_{i-1}, v_{i+1})$ (a plane containing two independent vectors). Define the 3×3 matrix $A_i := v_i\phi_i$, the projection onto $\mathbb{R}v_i$ along that plane.

Since the product of a column by a row is a matrix and the product of a row by a column is a scalar,

$$A_iA_j = v_i(\phi_i v_j)\phi_j = (\phi_i v_j)\, v_i\phi_j, \qquad A_jA_i = (\phi_j v_i)\, v_j\phi_i.$$

Claim 1.4.2. *For $i \neq j$, $A_iA_j = A_jA_i$ if and only if $\phi_i v_j = 0$ and $\phi_j v_i = 0$.*

Proof. If both scalars vanish, both products are the zero matrix. Conversely suppose $A_iA_j = A_jA_i$ but $\phi_i v_j \neq 0$. Since $v_i \neq 0$ and $\phi_j \neq 0$ (as $\phi_j v_j = 1$), the matrix $A_iA_j = (\phi_i v_j)v_i\phi_j$ is nonzero, so A_jA_i is nonzero too, and $\phi_j v_i \neq 0$. The column space of A_iA_j is $\mathbb{R}v_i$ and that of A_jA_i is $\mathbb{R}v_j$; equal matrices have equal column spaces, so v_i and v_j are parallel, contradicting the independence of the v's. Hence $\phi_i v_j = 0$, and by the same argument with the roles exchanged $\phi_j v_i = 0$. □

Now $\phi_i v_j = 0$ if and only if $v_j \in \ker \phi_i = \operatorname{span}(v_{i-1}, v_{i+1})$, which for $j \neq i$ happens exactly when $j \in \{i-1, i+1\}$: if $j \notin \{i-1, i, i+1\}$ then v_j, v_{i-1}, v_{i+1} are three distinct members of the family, hence independent, and v_j is not in the plane. Therefore, for $i \neq j$, A_i and A_j commute if and only if $j \equiv i \pm 1$ and $i \equiv j \pm 1 \pmod N$, that is, if and only if $j - i \equiv \pm 1 \pmod N$, which for $1 \le i, j \le N$ means $|i - j| \in \{1, 2024\}$. Together with the trivial case $i = j$, the family has exactly the required property, and

$$\boxed{k_{\min} = 3.}$$

■

Layer 1: WHAT

Block 1: read the condition as a graph, the cycle, and note both directions are demanded. Block 2: dispose of $k = 1$ and ask the commutant question for $k = 2$; prove the cyclic-vector lemma. Block 3: transitivity of commutation through a non-scalar matrix contradicts the existence of two non-adjacent neighbours of A_2. Block 4: design principle for $k = 3$: rank-one idempotents, whose products are controlled by scalar contractions, so that commutation becomes "each vector lies in the other's kernel". Block 5: choose the kernels as the planes through the two neighbours' vectors, guarantee no accidents with the moment curve, and verify both directions.

Juxtapose. The nominal route asks "which pairs of small matrices commute?" and experiments. The ideal route asks "what is the set of all matrices commuting with a given one?" and reads the answer off its structure: in dimension 2 that set is commutative, so the commutation graph of non-scalar 2×2 matrices is a disjoint union of cliques; in dimension 3 there are matrices, rank-one idempotents, whose commutant is not commutative and can be steered. The bifurcation point is the switch from pairs to commutants, and it happens before any matrix is written down.

Layer 2: HOW

Block 1. **Cue.** $|i - j| \in \{0, 1, 2024\}$ with $2024 = 2025 - 1$; "if and only if".

Why natural. The set $\{0, \pm 1\}$ modulo 2025 is the adjacency of a cycle; naming the graph exposes the invariant that matters, the degree 2, and the fact that non-adjacent pairs exist at all (for a cycle of length 3 everything would be adjacent and $k = 1$ would do). "If and only if" tells you that a construction must be checked in both directions, so you want building blocks for which non-commutation is as easy to prove as commutation.

Link to the next block. "Minimal k" means a lower bound first, and the lower bound is about what commutation can look like in dimension 2.

Block 2. **Cue.** "Commute", dimension 2, non-scalar.

Why natural. The centraliser of A is the set of B with $BA = AB$, a subspace; to describe it you need coordinates adapted to A, and the cheapest adapted coordinates are v, Av for a non-eigenvector v. In that basis B is determined by Bv alone, because $B(Av) = A(Bv)$ is forced by commutation. This is the general fact that the commutant of a matrix with a cyclic vector is the polynomials in it, in its smallest case.

Link to the next block. A commutative commutant means commutation is transitive through A, and transitivity is exactly what a cycle of length at least 4 violates.

Block 3. **Cue.** A_1 and A_3 both commute with A_2; A_2 is not scalar because it must fail to commute with A_4.

Why natural. The lemma converts a local hypothesis (two neighbours of one vertex) into a conclusion about the pair (they commute), which contradicts non-adjacency. Note the exact use of $2025 \geq 4$: you need a non-neighbour A_4 of A_2 to certify A_2 non-scalar, and a non-adjacent pair A_1, A_3 to contradict.

Link to the next block. With $k \geq 3$ established, the construction must exploit what dimension 3 has that dimension 2 lacks: a non-scalar matrix with a non-commutative commutant.

Block 4. **Cue.** Exact control over which pairs commute.

Why natural. The product of two rank-one matrices $v\phi$ and $w\psi$ is $(\phi w)\, v\psi$: a scalar times a rank-one matrix. So A_iA_j and A_jA_i are each either zero or a nonzero matrix whose column space is known, and they can only be equal if both are zero (column spaces differ otherwise). Commutation is thus the pair of linear conditions $v_j \in \ker \phi_i$ and $v_i \in \ker \phi_j$, and kernels of functionals are planes,

which you may place freely. This is why rank one is the natural building block: it turns a quadratic condition (commuting) into linear ones (membership in a plane).

Link to the next block. A plane in $\mathbb{R}^3$ through two prescribed directions is determined; you need it to contain no third member of the family, which is a general-position requirement.

Block 5. Cue. "No three of the v_i coplanar" needed 2025 times.

Why natural. The moment curve $t \mapsto (1, t, t^2)$ supplies arbitrarily many vectors any three of which are independent, certified by the Vandermonde determinant, with no genericity hand-waving. Then $\ker \phi_i = \operatorname{span}(v_{i-1}, v_{i+1})$ contains v_j only for $j \in \{i \pm 1\}$, and both directions of the claim follow from the same sentence.

Link to the next block. None; the answer is boxed.

Layer 3: WHY

The first truth: the commutant of a matrix with a cyclic vector is the algebra of polynomials in that matrix, which is commutative. In dimension 2 every non-scalar matrix has a cyclic vector, so commutation among non-scalar 2×2 matrices is an equivalence relation and the only commutation graphs are disjoint unions of cliques together with universal vertices (the scalars). In dimension 3 and above there are non-scalar matrices without a cyclic vector, the derogatory ones, and rank-one idempotents are the simplest: the commutant of $v\phi$ is the set of matrices preserving both $\mathbb{R}v$ and $\ker \phi$, a 5-dimensional non-commutative algebra in $\mathbb{R}^3$. That is where cycles live.

The second truth is the rank-one calculus $(v\phi)(w\psi) = (\phi w)\, v\psi$, which makes the commutation relation between members of a rank-one family a pair of incidence conditions between points and hyperplanes. The third truth is a dimension count: a hyperplane in $\mathbb{R}^k$ can contain exactly $k-1$ prescribed directions in general position, so this construction realises graphs of maximum degree $k-1$ in dimension k; the cycle has degree 2, so $k = 3$ is exactly enough, and the lower bound confirms it is exactly necessary.

The discernment mechanism is one question: "who commutes with this matrix?" before "do these two commute?". Train it by memorising the commutants of the basic types: a scalar (everything), a diagonal matrix with distinct entries (the diagonal matrices), a single Jordan block or any matrix with a cyclic vector (polynomials in it), a rank-one idempotent (block-triangular in an adapted basis). Once those are installed, "commute if and only if" problems are read as incidence problems.

The examiners nudged you with 2025, which is odd and large. Odd rules out the lazy construction "alternate between two commuting families" that would realise an even cycle; large makes trial and error hopeless and makes the general-position requirement visible. The number itself is otherwise decoration: any cycle of length at least 4 has the same answer.

Revolving concepts

Commutant (centraliser). $C(A) = \{B : AB = BA\}$ is a subalgebra containing $\mathbb{F}[A]$. If A has a cyclic vector v (that is, $v, Av, \ldots, A^{k-1}v$ is a basis; equivalently the minimal polynomial has degree k), then $C(A) = \mathbb{F}[A]$, of dimension k, by the argument in the lemma. Matrices with a cyclic vector are called non-derogatory. See Book 1, field: Linear algebra, topic: commutants and cyclic vectors.

Commuting matrices and eigenspaces. If $AB = BA$ then B maps each eigenspace of A into itself, since $Av = \lambda v$ implies $A(Bv) = \lambda Bv$. Commuting diagonalisable matrices are simultaneously diagonalisable. Either fact gives an alternative non-commutation proof in the construction: v_j spans an eigenspace of A_j and is not an eigenvector of A_i. See Book 1, field: Linear algebra, topic: simultaneous diagonalisation.

Rank-one matrices and idempotents. Every rank-one matrix is $v\phi$ (column times row); $(v\phi)(w\psi) = (\phi w)v\psi$; $v\phi$ is idempotent if and only if $\phi v = 1$, and then it is the projection onto $\mathbb{R}v$

along $\ker \phi$. Two rank-one matrices $v\phi$, $w\psi$ with $v \not\parallel w$ commute if and only if $\phi w = 0 = \psi v$. See Book 1, field: Matrices and determinants, topic: rank-one matrices and projections.

General position and the moment curve. The vectors $(1, t, t^2, \ldots, t^{k-1})$ for distinct t have every k of them independent, by Vandermonde. This is the standard explicit source of "general position" and it removes every genericity argument. See Book 1, field: Matrices and determinants, topic: Vandermonde.

Commutation graphs and orthogonality representations. An orthogonality representation of a graph assigns vectors so that non-adjacent vertices are orthogonal (or, in the strict version used here, adjacency equals orthogonality). The Lovász umbrella for C_5 and its odd-cycle relatives are the classical examples; the symmetric version $A_i = u_i u_i^T$ of the construction is a strict orthogonality representation of C_{2025} in $\mathbb{R}^3$. See Book 3, field: Discrete structures and graphs, topic: vector representations of graphs.

Generalised construction (no recursion present). For any finite graph of maximum degree d, take v_i on the moment curve in $\mathbb{R}^{d+1}$ and let ϕ_i vanish on the neighbours' vectors and on $d - \deg(i)$ further generic vectors, with $\phi_i v_i = 1$; the same claim shows the commutation graph of the $A_i = v_i \phi_i$ is exactly the given graph. Dimension $d + 1$ therefore always suffices for graphs of maximum degree d.

Circuit Bank

- **WHEN** you see "commute if and only if" with a prescribed pattern **DO** ask "who commutes with A?" and write the commutant of each candidate type before writing any matrix **BECAUSE** the structure of commutants decides which graphs are possible in each dimension.
- **WHEN** you see 2×2 matrices and a commutation condition **DO** write the lemma "commutant of non-scalar A is $\operatorname{span}(I, A)$" via a non-eigenvector v and the basis v, Av **BECAUSE** commutation is then transitive through non-scalar matrices, which kills every graph that is not a union of cliques.
- **WHEN** you must construct matrices with controlled commutation **DO** use rank-one idempotents $v\phi$ and compute $(v\phi)(w\psi) = (\phi w)v\psi$ **BECAUSE** commuting becomes two linear incidence conditions, $w \in \ker \phi$ and $v \in \ker \psi$, and both directions of "if and only if" are one line.
- **WHEN** you need many vectors with no k dependent **DO** take $(1, t, \ldots, t^{k-1})$ for distinct t **BECAUSE** the Vandermonde determinant certifies independence with no genericity appeal.
- **WHEN** you see $AB = BA$ and need to prove non-commutation **DO** write "then B preserves each eigenspace of A" and exhibit an eigenvector of A that B moves off the eigenspace **BECAUSE** commuting operators preserve each other's eigenspaces.

Backtesting

1. First useful cue: $|i - j| \in \{0, 1, 2024\}$, the cycle, with "if and only if" demanding both directions.
2. Method the expression suggested: commutant structure for the lower bound (dimension 2 forces transitivity) and rank-one idempotents on the moment curve for the construction (dimension 3 lets a kernel plane hold exactly the two neighbours).
3. Where you would hesitate, and the thought to reinforce: proving that non-neighbours do not commute. Reinforce: for rank-one matrices the products are scalar multiples of $v_i \phi_j$ and $v_j \phi_i$, whose column spaces differ, so commuting forces both scalars to vanish.
4. The trap the question sets: believing $k = 2$ might work with rotations or Jordan blocks and spending twenty minutes on examples; or producing 3×3 matrices for which the "only if" direction is never checked.

5. What makes you recognise it faster next time: "commutation graph with a vertex of degree 2 and non-adjacent neighbours" equals "$k \geq 3$ by transitivity in dimension 2"; "degree d" equals "dimension $d+1$ suffices by rank-one projections".
6. The reusable decision rule: convert commutation into incidence by choosing rank-one building blocks, and convert impossibility into a structural statement about commutants.

Mirror drills

1. Let A be a real 2×2 matrix that is not scalar. Prove that the matrices commuting with A form a 2-dimensional space, namely $\mathrm{span}(I, A)$. *Answer:* pick v that is not an eigenvector; v, Av is a basis; $Bv = pv + qAv$ determines $B = pI + qA$; and I, A are independent because A is not scalar.
2. Let $u, w \in \mathbb{R}^k$ be non-parallel columns and ϕ, ψ nonzero rows. Show that $u\phi$ and $w\psi$ commute if and only if $\phi w = 0$ and $\psi u = 0$. *Answer:* $(u\phi)(w\psi) = (\phi w)u\psi$ and $(w\psi)(u\phi) = (\psi u)w\phi$ have column spaces $\mathbb{R}u$ and $\mathbb{R}w$ when nonzero, so equality forces both to vanish.
3. Find the minimal k for which there are $k \times k$ real matrices A_1, A_2, A_3, A_4 with $A_i A_j = A_j A_i$ if and only if $|i - j| \leq 1$. *Answer:* $k = 3$. In dimension 2, A_1 and A_3 both commute with the non-scalar A_2 and so with each other. In $\mathbb{R}^3$ take v_i on the moment curve and ϕ_i vanishing on the neighbours' vectors, padded with one generic vector for the endpoints $i = 1, 4$.

1.5 A5. Zigzag patterns beat every other pattern

Let n be an integer with $n \geq 2$. For a sequence $s = (s_1, \ldots, s_{n-1})$ where each $s_i = \pm 1$, let $f(s)$ be the number of permutations $(a_1, \ldots, a_n)$ of $\{1, 2, \ldots, n\}$ such that $s_i(a_{i+1} - a_i) > 0$ for all i. For each n, determine the sequences s for which $f(s)$ is maximal.

Read it out loud

This is enumerative combinatorics: $f(s)$ counts the permutations whose up-down pattern (the signs of the consecutive differences) is s. The map from permutations to patterns is onto $\{\pm 1\}^{n-1}$, so the numbers $f(s)$ sum to $n!$, and the question asks for the mode of that distribution. The fields wired in are permutation enumeration, the "position of the maximum" decomposition, induction on n, and the Euler zigzag numbers $1, 1, 1, 2, 5, 16, 61, 272, \ldots$ which count alternating permutations. What is really being tested is whether you can set up a recursion for pattern counts that is uniform in the pattern, and then compare a general pattern against the alternating one inside that recursion. A formula for $f(s)$ exists (MacMahon, by inclusion and exclusion over descent sets) and is useless here; the exam wants a comparison mechanism, not a closed form.

The first cue is $s_i(a_{i+1} - a_i) > 0$, which is the definition of the pattern, and its immediate consequence: alternating patterns are the zigzag permutations, the most famous pattern-counting object there is. The second cue is "determine the sequences for which $f(s)$ is maximal": an extremal statement over 2^{n-1} objects, so the answer must come from an inequality proved for every s, not from computing each $f(s)$. Within thirty seconds you should have guessed the two alternating sequences, on the heuristic that a run of r equal signs forces $r + 1$ entries to be monotone and costs a factor $1/(r+1)!$ instead of $1/2^r$, so long runs are expensive and alternation keeps every run at length one, and you should have checked $n = 3$ (patterns $(+, -)$ and $(-, +)$ give 2, the others give 1) and $n = 4$ (alternating gives 5).

The third cue is structural and it is the one that produces the proof: in any permutation the value n sits at a peak of the pattern and the value 1 sits at a valley, and removing n splits the permutation into two independent blocks. That decomposition is exactly how the recursion $2E_n = \sum_i \binom{n-1}{i-1} E_{i-1} E_{n-i}$ for the zigzag numbers is derived, so the target's own recursion is the comparison tool. Read this way, the proof is: general s satisfies the zigzag recursion with some terms missing, and missing terms are positive.

Approaches, ranked worst to best

1. **Closed formula.** *Cue:* a count over permutations with prescribed descents. *Circuit:* inclusion and exclusion over subsets of the descent set, or MacMahon's determinant. You can write $f(s)$ as an alternating sum of multinomial coefficients. Comparing such sums for different s is hopeless; the formula answers "how many" and not "which is largest". Worst.

2. **Compute small cases and guess.** *Cue:* "for each n, determine". *Circuit:* tabulate $n \leq 5$. Correctly suggests the two alternating sequences and the zigzag numbers, which you need to know what to prove, and is worth nothing on its own.

3. **Tail flip by prefix and suffix sums.** *Cue:* the last entry a_n determines how the pattern extends. *Circuit:* let $f(s, j)$ count pattern-s permutations ending in j; appending $+1$ replaces the vector $(f(s, j))_j$ by its prefix sums, appending -1 by its suffix sums. With this recursion one proves that if $s_{j-1} = s_j$ then negating s from position j onward strictly increases f, by propagating a componentwise inequality through the sums. Correct and instructive (this is de Bruijn's proof and the boustrophedon algorithm), but it is a page of index bookkeeping and the propagation step is where marks leak.

4. **Position of the maximum, then induction.** *Cue:* the value n must sit at a peak, the value 1 at a valley. *Circuit:* split at the maximum, count the two blocks independently, add the peak and valley identities, relax to all positions, induct against the zigzag recursion. Four short lemmas and a six-line induction with the strictness built in. Ideal.

The ideal solution

Throughout, for $m \geq 1$ and $s \in \{\pm 1\}^{m-1}$, $f(s)$ denotes the number of permutations of $[m] = \{1, \ldots, m\}$ with pattern s; for $m = 1$ the only pattern is the empty sequence and $f(\emptyset) = 1$. Since a pattern depends only on the relative order of the entries, $f(s)$ also counts the arrangements of any fixed set of m distinct reals with pattern s. Let $t_n \in \{\pm 1\}^{n-1}$ be the alternating sequence $(+1, -1, +1, \ldots)$, put $E_n := f(t_n)$ for $n \geq 1$, and $E_0 := 1$. The answer is that $f(s)$ is maximal exactly for $s = t_n$ and $s = -t_n$, the two alternating sequences.

Lemma 1.5.1 (every pattern occurs)**.** *$f(s) \geq 1$ for every s.*

Proof. Induction on m; the case $m = 1$ is the permutation (1). For $m \geq 2$, take a permutation $(a_1, \ldots, a_{m-1})$ of $[m-1]$ with pattern $(s_1, \ldots, s_{m-2})$. If $s_{m-1} = +1$ append m; if $s_{m-1} = -1$ replace each a_j by $a_j + 1$ and append 1. The first $m-2$ signs are unchanged and the last sign is s_{m-1}. □

Lemma 1.5.2 (complement)**.** *$f(s) = f(-s)$, where $-s = (-s_1, \ldots, -s_{m-1})$.*

Proof. $(a_1, \ldots, a_m) \mapsto (m + 1 - a_1, \ldots, m + 1 - a_m)$ is a bijection of the permutations of $[m]$ that reverses every sign of the pattern. □

Now fix $n \geq 2$ and $s \in \{\pm 1\}^{n-1}$. Call $i \in [n]$ a *peak* of s if ($i = 1$ or $s_{i-1} = +1$) and ($i = n$ or $s_i = -1$), and a *valley* of s if ($i = 1$ or $s_{i-1} = -1$) and ($i = n$ or $s_i = +1$). Write $P(s)$ and $V(s)$ for the sets of peaks and valleys. For $i \in [n]$ let $\ell_i(s)$ be the number of arrangements of a fixed $(i-1)$-element set with pattern $(s_1, \ldots, s_{i-2})$, so $\ell_1(s) = 1$ (the empty arrangement) and $\ell_i(s) = f(s_1, \ldots, s_{i-2})$ for $i \geq 2$; similarly let $r_i(s)$ be the number of arrangements of a fixed $(n-i)$-element set with pattern $(s_{i+1}, \ldots, s_{n-1})$, so $r_n(s) = 1$ and $r_i(s) = f(s_{i+1}, \ldots, s_{n-1})$ for $i \leq n-1$.

Lemma 1.5.3 (split at the maximum and at the minimum)**.**

$$f(s) = \sum_{i \in P(s)} \binom{n-1}{i-1} \ell_i(s)\, r_i(s) = \sum_{i \in V(s)} \binom{n-1}{i-1} \ell_i(s)\, r_i(s).$$

Proof. Classify the permutations with pattern s by the position i of the value n. Since n is the largest entry, $a_{i-1} < a_i$ when $i > 1$ and $a_i > a_{i+1}$ when $i < n$, so $s_{i-1} = +1$ and $s_i = -1$ where these are defined: i is a peak. Conversely, for a peak i, a permutation with pattern s and $a_i = n$ is the same thing as a choice of the set $L \subseteq [n-1]$ of the $i-1$ values to the left of n, an arrangement of L with pattern $(s_1, \ldots, s_{i-2})$, and an arrangement of $[n-1] \setminus L$ with pattern $(s_{i+1}, \ldots, s_{n-1})$; the signs at positions $i-1$ and i are then automatically $+1$ and -1, which agree with s because i is a peak. Counting gives $\binom{n-1}{i-1}\ell_i(s)r_i(s)$ permutations for each peak i and none for other i. The second identity is the same argument for the value 1, which must sit at a valley. □

Lemma 1.5.4 (peaks and valleys)**.** *$P(s) \cap V(s) = \emptyset$, and $P(s) \cup V(s) = [n]$ if and only if s is alternating, that is, $s_{i-1} \neq s_i$ for $1 < i < n$.*

Proof. Position 1 is a peak if $s_1 = -1$ and a valley if $s_1 = +1$; position n is a peak if $s_{n-1} = +1$ and a valley if $s_{n-1} = -1$; so each of 1 and n lies in exactly one of the two sets. For $1 < i < n$, i is a peak if $(s_{i-1}, s_i) = (+1, -1)$ and a valley if $(s_{i-1}, s_i) = (-1, +1)$, so i is in exactly one of the sets when $s_{i-1} \neq s_i$ and in neither when $s_{i-1} = s_i$. □

Theorem 1.5.5. *For $n \geq 1$ and $s \in \{\pm 1\}^{n-1}$, $f(s) \leq E_n$, with equality if and only if $s \in \{t_n, -t_n\}$.*

Proof. Strong induction on n. For $n \in \{1,2\}$ every pattern is alternating and every $f(s)$ equals $1 = E_n$. Let $n \geq 3$ and assume the statement for all lengths below n. For any s and any $i \in [n]$, the blocks have sizes $i-1 \leq n-1$ and $n-i \leq n-1$, so by the induction hypothesis (and $E_0 = 1$ for an empty block) $\ell_i(s) \leq E_{i-1}$ and $r_i(s) \leq E_{n-i}$. Adding the two identities of the splitting lemma and using that peaks and valleys are disjoint,

$$2f(s) = \sum_{i \in P(s) \cup V(s)} \binom{n-1}{i-1} \ell_i(s) r_i(s) \;\leq\; \sum_{i=1}^{n} \binom{n-1}{i-1} \ell_i(s) r_i(s) \;\leq\; \sum_{i=1}^{n} \binom{n-1}{i-1} E_{i-1} E_{n-i}. \qquad (*)$$

Apply $(*)$ to $s = t_n$. Every position of an alternating sequence is a peak or a valley, so the first inequality is an equality; and every block $(s_1, \ldots, s_{i-2})$, $(s_{i+1}, \ldots, s_{n-1})$ of an alternating sequence is alternating, hence equal to $\pm t_{i-1}$ or $\pm t_{n-i}$, so by the complement lemma $\ell_i(t_n) = E_{i-1}$ and $r_i(t_n) = E_{n-i}$ and the second inequality is an equality. Therefore

$$2E_n = \sum_{i=1}^{n} \binom{n-1}{i-1} E_{i-1} E_{n-i},$$

and $(*)$ says $2f(s) \leq 2E_n$ for every s. If s is not alternating, some $i_0 \in [n]$ is neither a peak nor a valley, and the omitted term $\binom{n-1}{i_0-1} \ell_{i_0}(s) r_{i_0}(s)$ is at least 1 by the first lemma, so the first inequality in $(*)$ is strict and $f(s) < E_n$. If s is alternating then $s = t_n$ or $s = -t_n$, and $f(s) = E_n$ by the complement lemma. □

Hence, for every $n \geq 2$, the sequences maximising f are exactly the two alternating sequences

$$\boxed{s_i = (-1)^{i+1} \ (i = 1, \ldots, n-1) \qquad \text{and} \qquad s_i = (-1)^{i} \ (i = 1, \ldots, n-1),}$$

and the maximum is the zigzag number E_n. ■

Layer 1: WHAT

Block 1: name the object (the up-down pattern), record the two symmetries (complement; also reversal) and guess the alternating sequences from small cases and the run-length heuristic. Block 2: the universal decomposition: the value n sits at a peak; removing it leaves two independent blocks with a binomial choice of values. Block 3: the same for the value 1 at a valley, and the observation that peaks and valleys are disjoint and exhaust $[n]$ exactly for alternating sequences. Block 4: add the two identities and relax the sum to all positions, which is the zigzag recursion. Block 5: strong induction, with strictness supplied by the omitted term and the fact that every pattern occurs at least once.

Juxtapose. The nominal route computes $f(s)$ for small n, notices the zigzag numbers, and then either hunts for a formula for $f(s)$ or tries to set up an induction on n by inserting the new element n somewhere, which gets tangled because inserting n changes the pattern in a position-dependent way. The ideal route removes n rather than inserting it, because removal is a clean split. The bifurcation point is the choice between "build a permutation of $[n]$ from one of $[n-1]$" and "split a permutation of $[n]$ at its maximum into two smaller ones"; the second gives independence and the binomial coefficient, the first does not.

Layer 2: HOW

Block 1. **Cue.** $s_i(a_{i+1} - a_i) > 0$; "determine the sequences for which $f(s)$ is maximal".

Why natural. The condition is the sign of each step, so s is the up-down pattern, and the alternating patterns are the classical zigzag permutations. An extremal question over patterns needs a candidate before a proof; the complement symmetry $f(s) = f(-s)$ says the candidates come in pairs, and $n = 3, 4$ single out the alternating pair. The run heuristic (a run of r equal signs forces

a monotone block of length $r+1$, which only $1/(r+1)!$ of arrangements satisfy) explains why alternation should win before any proof exists.

Link to the next block. To compare $f(s)$ with $f(t_n)$ you need a recursion valid for all s at once; the zigzag numbers' own recursion comes from the position of the maximum.

Block 2. **Cue.** A pattern condition on consecutive entries; the largest value n.

Why natural. The maximum is larger than both neighbours, so its position is a peak whatever s is, and the two sides of it are arrangements of disjoint value sets whose patterns are the two pieces of s. Independence of the two sides is what makes the count a product, and the freedom to choose which values go left is the binomial coefficient. This is the standard "remove the maximum" decomposition; it is natural because it is the only removal that satisfies the two adjacent constraints automatically.

Link to the next block. The minimum gives a second identity of the same shape, and two identities over complementary index sets are begging to be added.

Block 3. **Cue.** Two sums over $P(s)$ and over $V(s)$ with identical summands.

Why natural. A position cannot be both a peak and a valley, and an interior position is one of the two exactly when the adjacent signs differ. So $P \cup V$ is a disjoint union that fills $[n]$ precisely for alternating s. This is the definitional reason why alternation is extremal: the alternating pattern is the one where every position is available to the maximum or to the minimum.

Link to the next block. The sum over $P \cup V$ is bounded by the sum over all of $[n]$, and that sum, with the summands bounded by induction, is the zigzag recursion.

Block 4. **Cue.** $2f(s) = \sum_{P\cup V} \le \sum_{[n]}$; the summands involve f of shorter patterns.

Why natural. Relaxing a sum over a subset to the full set is the simplest inequality there is, and it is tight exactly for alternating s. Bounding the summands by $E_{i-1}E_{n-i}$ is the induction hypothesis. The full sum is then $2E_n$, and you know it is $2E_n$ not from memory but by running the same chain on $s = t_n$, where both inequalities are equalities. Nothing external is needed: the recursion for E_n is derived inside the proof.

Link to the next block. Strictness for non-alternating s must be argued, and it comes from the omitted term.

Block 5. **Cue.** "Determine the sequences", which demands uniqueness of the maximisers.

Why natural. A non-alternating s omits at least one position from $P \cup V$, and the omitted summand is a product of a binomial coefficient and two counts, each at least 1 because every pattern is realised by some permutation. So the relaxation loses at least 1 and the inequality is strict. The base cases $n = 1, 2$ are trivial because every short pattern is alternating, and strong induction is needed because the blocks have arbitrary sizes below n.

Link to the next block. None; the answer is the alternating pair, and the maximum is E_n.

Layer 3: WHY

The first truth is that the maximum of a permutation is a universal splitter: it sits at a peak of any pattern, it separates the permutation into independent halves, and the values on each side are chosen freely. Every statistic on permutations that is determined by consecutive comparisons has a recursion of the form $\sum_i \binom{n-1}{i-1}(\text{left})(\text{right})$, and in exponential generating functions such a recursion becomes a product; for the zigzag numbers it becomes $2E'(x) = 1 + E(x)^2$ and $E(x) = \sec x + \tan x$, André's theorem. The second truth is that alternating patterns are exactly the patterns in which every position is a peak or a valley, so the alternating recursion is the "full" recursion and every

other pattern's recursion is a sub-sum of it. The third truth is positivity: sub-sums of positive terms are strictly smaller, so the comparison is strict as soon as one term is missing.

The discernment mechanism: when asked to compare a family of counts against a distinguished member, ask what recursion the distinguished member satisfies and whether the general member satisfies a truncated version of it. Train it on the classical examples where a known sequence is the extreme case: alternating permutations among patterns (this problem), and more generally any "which configuration maximises the count" question where the extremal object's recursion has the most terms. Train the decomposition itself by deriving the zigzag recursion from scratch until the peak condition is automatic.

The examiners nudged you by defining f through the condition $s_i(a_{i+1} - a_i) > 0$ rather than through descent sets; the sign language makes the complement symmetry and the peak-valley dichotomy visible. They also asked "for each n", which signals a uniform answer and an induction on n; and they chose an answer, the zigzag pair, whose recursion is the most famous in the subject. The result is Niven's theorem (1968), also proved by de Bruijn (1970) by the prefix-sum route.

Revolving concepts

Up-down patterns and descent sets. The pattern of $(a_1, \dots, a_n)$ is the sign vector of consecutive differences; equivalently its descent set $D = \{i : a_i > a_{i+1}\}$. The number of permutations with descent set contained in $D = \{d_1 < \cdots < d_k\}$ is the multinomial coefficient $\binom{n}{d_1, d_2 - d_1, \dots, n - d_k}$, and inclusion and exclusion gives the number with descent set exactly D (MacMahon). See Book 3, field: Combinatorics, topic: permutation statistics and descent sets.

Zigzag (Euler) numbers. E_n counts alternating permutations of $[n]$ starting with an ascent: $1, 1, 1, 2, 5, 16, 61, 272, 1385, \dots$ (OEIS A000111). Recursion $2E_n = \sum_{i=1}^{n} \binom{n-1}{i-1} E_{i-1} E_{n-i}$ for $n \geq 2$, with $E_0 = E_1 = 1$; exponential generating function $\sum E_n x^n / n! = \sec x + \tan x$; the even-indexed ones are the secant numbers and the odd-indexed ones the tangent numbers. See Book 3, field: Combinatorics, topic: alternating permutations.

Splitting at the maximum. For any property of permutations determined by consecutive comparisons, classify by the position of n; the two sides are independent and the values on each side are a free choice. In exponential generating functions this reads $F' = (\text{left}) \cdot (\text{right})$ after accounting for the constraints at the splitting point. See Book 3, field: Generating functions, topic: exponential generating functions and the product rule.

Symmetries of patterns. Complement $a \mapsto n + 1 - a$ negates the pattern; reversal $(a_1, \dots, a_n) \mapsto (a_n, \dots, a_1)$ negates and reverses it. So $f(s) = f(-s) = f(\bar{s})$ where $\bar{s}$ is the reversed negated pattern, and pattern counts are constant on orbits of a group of order 4. See Book 3, field: Combinatorics, topic: symmetry reductions.

Generalised recursion (the boustrophedon). Let $F(s) = (f(s, 1), \dots, f(s, m))$ where $f(s, j)$ counts pattern-s permutations ending in j. Appending $+1$ to s replaces F by its vector of prefix sums $(0, f(s, 1), f(s, 1) + f(s, 2), \dots)$; appending -1 replaces it by its suffix sums. Starting from $F(\varnothing) = (1)$ this computes $f(s) = \sum_j f(s, j)$ for any pattern in $O(n^2)$ additions; for alternating patterns it is the Seidel-Entringer triangle, and its rows are the Entringer numbers. The general solution method for such vector recursions is to identify the linear operator (prefix or suffix sum) and to propagate componentwise inequalities through it; that is the engine of the tail-flip proof. See Book 3, field: Sequences and recurrences, topic: linear recursions on vectors.

Circuit Bank

- **WHEN** you count permutations with constraints on consecutive entries **DO** condition on the position of the maximum (or the minimum) and write $\sum_i \binom{n-1}{i-1} (\text{left})(\text{right})$ **BECAUSE** the maximum satisfies both adjacent constraints automatically and the two sides are independent.

- **WHEN** you must show a distinguished configuration maximises a count **DO** write the distinguished object's recursion and show the general object satisfies the same recursion with terms omitted **BECAUSE** omitted positive terms give a strict inequality and induction closes the argument.
- **WHEN** you have two identities over complementary index sets with equal summands **DO** add them and relax to the full index set **BECAUSE** the union is easier to compare with "all indices", and the relaxation is tight exactly for the extremal object.
- **WHEN** you see $s_i(a_{i+1} - a_i) > 0$ or a descent condition **DO** name the pattern, record $f(s) = f(-s)$ and the reversal symmetry, and check $n = 3, 4$ **BECAUSE** symmetries halve the work and small cases identify the candidate before any proof.
- **WHEN** you need "every pattern is realised" **DO** append m for a final $+1$, or shift by one and append 1 for a final -1 **BECAUSE** this extends any realisation by one sign without disturbing the earlier signs.

Backtesting

1. First useful cue: the sign condition $s_i(a_{i+1} - a_i) > 0$, which names the up-down pattern and points at the zigzag permutations.
2. Method the expression suggested: split at the maximum and at the minimum, add, relax to all positions, and induct against the zigzag recursion.
3. Where you would hesitate, and the thought to reinforce: whether to insert n into a permutation of $[n-1]$ or to remove it. Reinforce: removal splits, insertion tangles; always split at an extreme value.
4. The trap the question sets: chasing a formula for $f(s)$, or proving $f(s) \leq E_n$ and forgetting the uniqueness, which needs the positivity of the omitted term and hence the lemma that every pattern occurs.
5. What makes you recognise it faster next time: "maximal over patterns" equals "the pattern where every position is a peak or a valley", and that is the alternating pattern by definition.
6. The reusable decision rule: to compare counts across a family, find the universal decomposition (here the maximum), express every member's count in it, and identify the member for which no term is missing.

Mirror drills

1. Prove that every $s \in \{\pm 1\}^{n-1}$ is the pattern of at least one permutation of $[n]$. *Answer:* induct on n; append n if the last sign is $+1$, otherwise add 1 to every entry and append 1.
2. Compute $f(+1, +1, -1)$ by the prefix and suffix sum recursion, and list the permutations. *Answer:* $F(\emptyset) = (1)$, $F(+) = (0, 1)$, $F(+, +) = (0, 0, 1)$, $F(+, +, -) = (1, 1, 1, 0)$, so $f = 3$: the permutations are 1243, 1342, 2341.
3. Show that $f(+1, \ldots, +1, -1)$ (with $n-2$ plus signs) equals $n-1$ using the splitting lemma. *Answer:* the only peak is position $n-1$, so $f = \binom{n-1}{n-2} f(+1, \ldots, +1) f(\emptyset) = (n-1) \cdot 1 \cdot 1$.

1.6 A6. Iterate the polynomial and expand at zero

Let $b_0 = 0$ and, for $n \geq 0$, define $b_{n+1} = 2b_n^2 + b_n + 1$. For each $k \geq 1$, show that $b_{2^{k+1}} - 2b_{2^k}$ is divisible by 2^{2k+2} but not by 2^{2k+3}.

Read it out loud

This is 2-adic number theory on a polynomial dynamical system. The sequence is the orbit of 0 under the map $f(x) = 2x^2 + x + 1$, so $b_n = f^{\circ n}(0)$, and the claim is an exact 2-adic valuation: $v_2(b_{2^{k+1}} - 2b_{2^k}) = 2k + 2$. The fields wired in are valuations and congruences, the algebra of polynomial composition, the Taylor expansion of an integer polynomial at a point, and induction where the modulus grows with the index. What is really being tested is whether you can stop iterating the recurrence and start iterating the polynomial: the sequence is unmanageable (b_5 already has eight digits), but the 2^k-fold iterate of f, as a polynomial, has a constant term and a linear coefficient whose valuations you can control exactly.

The first cue is the pair of indices 2^k and 2^{k+1}. Doubling an index is composing the iterate with itself: if $g_k := f^{\circ 2^k}$ then $g_{k+1} = g_k \circ g_k$, $b_{2^k} = g_k(0)$ and $b_{2^{k+1}} = g_k(g_k(0))$. The second cue is the exponent $2k + 2$, which is $(k + 1) + (k + 1)$; the examiners are telling you that the quantity is a product of two factors each of valuation $k + 1$, plus junk of higher valuation. Numerically, $b_1 = 1$, $b_2 = 4$, $b_4 = 2776 = 8 \cdot 347$, and $b_8 \equiv 16 \pmod{32}$: so $v_2(b_{2^k}) = k + 1$ is one of the factors. The third cue is the shape $b_{2^{k+1}} - 2b_{2^k} = g_k(A) - g_k(0) - A$ with $A = g_k(0)$, the deviation of g_k from a translation. For an integer polynomial, $g(A) - g(0) = g'(0)A + A^2(\cdots)$, so the quantity is $(g_k'(0) - 1)A + A^2(\cdots)$ and the other factor of valuation $k + 1$ must be $g_k'(0) - 1$. Within thirty seconds you should have written $g_k(x) = A_k + B_k x + x^2 Q_k(x)$, the target $(B_k - 1)A_k + A_k^2 Q_k(A_k)$, and the conjecture $v_2(A_k) = v_2(B_k - 1) = k + 1$, checked at $k = 1$ on $g_1(x) = 8x^4 + 8x^3 + 12x^2 + 5x + 4$.

A caveat worth clarifying: the number 2 in $2b_n^2$ is not decoration. It makes $f'(x) = 4x + 1 \equiv 1 \pmod 4$ and makes $f \circ f \equiv x \pmod 4$ as a polynomial, which is the coarse structure that renders every higher-order term harmless. Read the coefficients of a recursion as design decisions by the examiners.

Approaches, ranked worst to best

1. **Compute modulo 2^{2k+3}.** *Cue:* a concrete recursion and a concrete modulus. *Circuit:* reduce every term modulo 2^{2k+3} and iterate. For a fixed k this is a finite computation; for all k it proves nothing, and the modulus grows with the index you are computing to. Zombie maths.

2. **Track the orbit modulo 2^j.** *Cue:* b_n modulo small powers of 2 looks periodic. *Circuit:* find the period of the orbit modulo 2^j and use it to compare b_{2^k+i} with b_i. The period modulo 2^j is 2^{j-1} for $j \geq 2$, which is true and useful, but to turn it into the exact valuation you still need a mechanism for the quantity itself.

3. **Difference factorisation.** *Cue:* b_{n+1} is a polynomial in b_n. *Circuit:* $f(x) - f(y) = (x - y)(2x + 2y + 1)$, so $b_{m+n+1} - b_{n+1} = (b_{m+n} - b_n)(2(b_{m+n} + b_n) + 1)$ telescopes. This gives $b_{2^{k+1}} - b_{2^k} = b_{2^k} \prod_{i<2^k}(2(b_{2^k+i} + b_i) + 1)$, hence $b_{2^{k+1}} - 2b_{2^k} = b_{2^k}(\Pi - 1)$, and reduces the problem to $v_2(b_{2^k}) = k + 1$ and $v_2(\Pi - 1) = k + 1$. Both need their own induction and the second needs the periodicity from the previous item to replace Π by $\prod(4b_i + 1)$. This is the official first solution: correct, but two interlocking inductions and a page and a half of congruences. It costs more ink because it works with the orbit rather than with the map.

4. **Iterate the polynomial and expand at zero.** *Cue:* indices 2^k and 2^{k+1}, and $b_0 = 0$. *Circuit:* $g_{k+1} = g_k \circ g_k$; write $g_k = A_k + B_k x + x^2 Q_k$; $g_k \equiv x \pmod 4$; induct on $(v_2(A_k), v_2(B_k - 1))$. One coarse lemma (mod 4), one induction on the pair (constant term, derivative at 0), and the target falls out as $(B_k - 1)A_k$ plus a negligible tail. Ideal.

The ideal solution

Let $f(x) = 2x^2 + x + 1 \in \mathbb{Z}[x]$, so that $b_{n+1} = f(b_n)$ and $b_n = f^{\circ n}(0)$, where $f^{\circ n}$ is the n-fold composition. For $k \geq 0$ put $g_k := f^{\circ 2^k}$. Then $g_0 = f$, $g_{k+1} = g_k \circ g_k$ (because $2^{k+1} = 2^k + 2^k$), $b_{2^k} = g_k(0)$, and $b_{2^{k+1}} = g_k(g_k(0))$. A direct expansion gives

$$g_1(x) = f(f(x)) = 2(2x^2 + x + 1)^2 + (2x^2 + x + 1) + 1 = 8x^4 + 8x^3 + 12x^2 + 5x + 4.$$

Lemma 1.6.1. *For every $k \geq 1$, $g_k(x) \equiv x \pmod 4$ coefficientwise; that is, $g_k(x) = x + 4h_k(x)$ with $h_k \in \mathbb{Z}[x]$.*

Proof. For $k = 1$, $g_1(x) - x = 8x^4 + 8x^3 + 12x^2 + 4x + 4$. If $g_k = x + 4h_k$ then

$$g_{k+1}(x) = g_k(g_k(x)) = g_k(x) + 4h_k(g_k(x)) = x + 4\big(h_k(x) + h_k(g_k(x))\big),$$

and $h_k(g_k(x)) \in \mathbb{Z}[x]$. □

For $k \geq 1$ write

$$g_k(x) = A_k + B_k x + x^2 Q_k(x), \qquad A_k, B_k \in \mathbb{Z},\ Q_k \in \mathbb{Z}[x],$$

so that $A_k = g_k(0) = b_{2^k}$ and $B_k = g_k'(0)$. By the lemma, $4 \mid A_k$, $4 \mid B_k - 1$, and every coefficient of Q_k is divisible by 4; consequently $4 \mid Q_k(a)$ and $4 \mid Q_k'(a)$ for every integer a.

Lemma 1.6.2. *For every $k \geq 1$, $v_2(A_k) = k + 1$ and $v_2(B_k - 1) = k + 1$.*

Proof. Induction on k. For $k = 1$, $A_1 = 4$ and $B_1 = 5$. Suppose the claim holds for some $k \geq 1$ and abbreviate $A = A_k$, $B = B_k$, $Q = Q_k$.

Constant term. $A_{k+1} = g_{k+1}(0) = g_k(g_k(0)) = g_k(A) = A + BA + A^2 Q(A) = A(1 + B) + A^2 Q(A)$. Since $v_2(B - 1) = k + 1 \geq 2$, we have $1 + B = 2 + (B - 1)$ with $v_2(1 + B) = 1$, so $v_2(A(1 + B)) = k + 2$; and $v_2(A^2 Q(A)) \geq 2(k + 1) + 2 > k + 2$. Hence $v_2(A_{k+1}) = k + 2$.

Linear coefficient. By the chain rule, $B_{k+1} = g_{k+1}'(0) = g_k'(g_k(0))\, g_k'(0) = g_k'(A)\, B$. Since $g_k'(x) = B + 2xQ(x) + x^2 Q'(x)$,

$$g_k'(A) = B + A\big(2Q(A) + AQ'(A)\big) =: B + R, \qquad v_2(R) \geq (k + 1) + 3 = k + 4,$$

because $v_2(2Q(A)) \geq 3$ and $v_2(AQ'(A)) \geq (k + 1) + 2$. Therefore $B_{k+1} - 1 = (B^2 - 1) + BR$. Now $B^2 - 1 = (B - 1)(B + 1)$ with $v_2(B - 1) = k + 1$ and $v_2(B + 1) = 1$, so $v_2(B^2 - 1) = k + 2$, while $v_2(BR) = v_2(R) \geq k + 4$ as B is odd. Hence $v_2(B_{k+1} - 1) = k + 2$. □

Now fix $k \geq 1$. Using $b_{2^{k+1}} = g_k(A_k)$ and $b_{2^k} = A_k$,

$$b_{2^{k+1}} - 2b_{2^k} = \big(A_k + B_k A_k + A_k^2 Q_k(A_k)\big) - 2A_k = (B_k - 1)A_k + A_k^2 Q_k(A_k).$$

By the second lemma, $v_2\big((B_k - 1)A_k\big) = (k + 1) + (k + 1) = 2k + 2$, while $v_2\big(A_k^2 Q_k(A_k)\big) \geq 2(k + 1) + 2 = 2k + 4$. A sum of two integers with different valuations has the smaller valuation, so

$$v_2\big(b_{2^{k+1}} - 2b_{2^k}\big) = 2k + 2 :$$

the number is divisible by 2^{2k+2} and not by 2^{2k+3}. ■

Layer 1: WHAT

Block 1: rewrite the sequence as the orbit of 0 under f, and the doubling of the index as self-composition of the iterate g_k. Block 2: expand g_k at 0, so that the target becomes $(B_k-1)A_k + A_k^2 Q_k(A_k)$, and read $2k+2 = (k+1)+(k+1)$ as the conjecture $v_2(A_k) = v_2(B_k-1) = k+1$. Block 3: the coarse lemma $g_k \equiv x \pmod 4$, which makes the tail Q_k carry an extra 4 everywhere. Block 4: the induction on the pair (A_k, B_k) through $g_{k+1} = g_k \circ g_k$: the constant term evolves as $A(1+B)$ and the derivative as B^2, to leading order. Block 5: assemble the valuations.

Juxtapose. The nominal route works with the orbit: it reduces b_n modulo powers of 2, discovers the period doubling, finds the difference factorisation $f(x)-f(y) = (x-y)(2x+2y+1)$, telescopes it into a product over half the orbit, and then needs a second induction to control that product. The ideal route works with the map: one polynomial g_k, two numbers A_k, B_k, one induction. The bifurcation point is the sentence "$b_{2^{k+1}} = g_k(b_{2^k})$ is a polynomial evaluated at a 2-adically small number": the zombie iterates the recurrence, the analyst Taylor-expands the iterate.

Layer 2: HOW

Block 1. **Cue.** $b_{n+1} = f(b_n)$ with a fixed polynomial f; indices 2^k and 2^{k+1}; $b_0 = 0$.

Why natural. A first-order recursion $b_{n+1} = f(b_n)$ is the same thing as iterating f, so $b_n = f^{\circ n}(0)$, and the only index arithmetic available for iterates is addition of exponents: $f^{\circ(m+n)} = f^{\circ m} \circ f^{\circ n}$. Powers of 2 are the indices for which the whole orbit is generated by repeated self-composition, $g_{k+1} = g_k \circ g_k$. The hypothesis $b_0 = 0$ makes b_{2^k} the constant term of g_k, which is why expanding at 0 is the natural coordinate.

Link to the next block. Once $b_{2^{k+1}} = g_k(b_{2^k})$ is written, the question is how a polynomial behaves at a point close to 0 in the 2-adic sense.

Block 2. **Cue.** A polynomial with integer coefficients evaluated at an integer A that is divisible by a high power of 2; the target $g_k(A) - 2A$.

Why natural. For $g \in \mathbb{Z}[x]$, $g(A) = g(0) + g'(0)A + A^2(\text{integer})$: this is Taylor's expansion, which over $\mathbb{Z}$ is a congruence modulo A^2 and is the algebraic core of Hensel's lemma. With $g(0) = A$ the target is $(g'(0)-1)A + A^2 Q(A)$, and the exponent $2k+2$ decomposes as the sum of two valuations $k+1$; the numerics $v_2(b_{2^k}) = k+1$ fix one factor, so the other must be $v_2(g_k'(0)-1) = k+1$.

Link to the next block. The tail $A^2Q(A)$ must be shown negligible, which needs a uniform statement about the coefficients of Q_k, that is, a coarse congruence for the whole polynomial g_k.

Block 3. **Cue.** $f'(x) = 4x+1 \equiv 1 \pmod 4$; the computed $g_1 = 8x^4+8x^3+12x^2+5x+4$ has every coefficient of $g_1 - x$ divisible by 4.

Why natural. Compositions preserve coefficientwise congruences: if $g \equiv x \pmod 4$ then $g \circ g \equiv x \pmod 4$ because substituting an integer polynomial into a polynomial with coefficients in $4\mathbb{Z}$ keeps the coefficients in $4\mathbb{Z}$. So the base case $k=1$ propagates to all k with no further computation. This is the only place where the coefficient 2 of the recursion is used, and it is used to guarantee that the nonlinear tail always carries an extra factor 4.

Link to the next block. With the tail controlled, the induction only has to follow the two leading coefficients through one composition.

Block 4. **Cue.** $g_{k+1} = g_k \circ g_k$; the constant term and derivative of a composition.

Why natural. The constant term of $g_k \circ g_k$ is $g_k(A)$, which by Block 2 is $A(1+B)$ plus a tail; the derivative at 0 is $g_k'(A)B$ by the chain rule, which is B^2 plus a tail. So to leading order the pair evolves as $(A,B) \mapsto (A(1+B), B^2)$. Both steps gain exactly one factor of 2: $1+B \equiv 2 \pmod 4$ because $B \equiv 1 \pmod 4$, and $B^2-1 = (B-1)(B+1)$ with $B+1 \equiv 2 \pmod 4$. The tails have

valuation at least $k+3$, comfortably above the $k+2$ you are proving, and their bounds come from Block 3.

Link to the next block. Both valuations are now exact for all k, and the target from Block 2 is a sum of a term of valuation $2k+2$ and a term of valuation at least $2k+4$.

Block 5. Cue. A sum of two integers with different 2-adic valuations.

Why natural. The ultrametric rule: $v_2(x+y) = \min(v_2(x), v_2(y))$ when the valuations differ. This is why "divisible by 2^{2k+2} but not 2^{2k+3}" can be read off from the leading term alone.

Link to the next block. None; the proof is complete.

Layer 3: WHY

The first truth is the Taylor congruence for integer polynomials: $g(a+h) \equiv g(a) + g'(a)h \pmod{h^2}$. It is the reason 2-adic questions about iterates reduce to two numbers, the value and the derivative, and it is the same mechanism that makes Newton's method converge 2-adically (Hensel's lemma). The second truth is that composition transports these two numbers by explicit rules: value of $g \circ g$ at 0 is $g(g(0))$, derivative is $g'(g(0))g'(0)$, so the linearisation of g_k at 0, the affine map $x \mapsto A_k + B_k x$, is squared at each step, up to a tail controlled by a coarse congruence. The third truth is the one-step lifting of the exponent: for odd B with $v_2(B-1) \geq 2$, $v_2(B^2-1) = v_2(B-1)+1$. This is why the valuations grow by exactly one per doubling, and hence linearly in k, which is what the problem asserts.

The coarse structure deserves its own sentence. Because $f'(x) \equiv 1 \pmod 4$ and f acts on $\mathbb{Z}/4$ as an involution ($0 \leftrightarrow 1$, $2 \leftrightarrow 3$), $f \circ f$ is the identity modulo 4 as a polynomial, and any polynomial $g \equiv x \pmod{2^e}$ with $e \geq 2$ satisfies $g \circ g \equiv x \pmod{2^{e+1}}$. Thus $g_k \equiv x \pmod{2^{k+1}}$ coefficientwise for all $k \geq 1$, which already gives the "at least" halves of both valuations for free; the exact induction is only needed for the "not divisible by 2^{2k+3}" half. This is also why the orbit of 0 has period exactly 2^{j-1} modulo 2^j for $j \geq 2$, the phenomenon the orbit-based route discovers empirically and the map-based route explains.

The discernment mechanism: when a recursion is $b_{n+1} = f(b_n)$ and the indices in the claim are powers of 2 (or multiples of some m), pass from the orbit to the iterate and from the iterate to its linearisation at the base point. When the exponent in the claim is a sum of two equal pieces, look for a product of two factors with equal valuations. Train it by computing $f \circ f$ by hand once, by proving the Taylor congruence and the chain rule for polynomials over $\mathbb{Z}$ yourself, and by drilling the lifting-the-exponent step until $v_2(B^2-1) = v_2(B-1)+1$ is a reflex.

The examiners nudged in four places: $b_0 = 0$ (so the iterate's constant term is the sequence), the coefficient 2 (so the derivative is 1 modulo 4), the subtraction of $2b_{2^k}$ rather than b_{2^k} (which removes the leading part $2A$ of $A(1+B)$ and leaves the product $(B-1)A$), and the exact exponent $2k+2$ against $2k+3$ (which forces you to find both factors rather than a crude bound).

There is a theory behind the linear growth of the valuation, and you should know where this problem lives even though the exam never asks for it. A theorem of Bell, sharpened by Poonen, says that if g is a polynomial (or p-adic analytic map) with $g(x) \equiv x \pmod{p^c}$ for some $c > 1/(p-1)$, so $c \geq 2$ when $p = 2$, then the orbit map $n \mapsto g^{\circ n}(x)$ extends to a p-adic analytic function of $n \in \mathbb{Z}_p$. Here $g = f \circ f \equiv x \pmod 4$ qualifies, so $n \mapsto b_{2n}$ is a 2-adic analytic function $F(n)$ with $F(0) = 0$, and $b_{2^{k+1}} - 2b_{2^k} = F(2^k) - 2F(2^{k-1})$ is a second-order difference: it kills the linear term of F and is dominated by the quadratic term, which is why the valuation grows like $2k$. In other words the problem is a finite-difference statement about a 2-adic analytic function, and the pair (A_k, B_k) in the proof is the elementary shadow of that function's first two Taylor coefficients. Context only: the elementary induction is the whole proof, and reaching for the theorem in the arena would cost time and marks.

The knowledge that must be installed before this problem is even approachable, stated bluntly, as a protocol:

1. The 2-adic valuation with its multiplicativity and its ultrametric rule, until "different valuations, take the minimum" is automatic.
2. The lifting-the-exponent lemma for $p = 2$, at least in the one-step form $v_2(B^2 - 1) = v_2(B - 1) + 1$ for $B \equiv 1 \pmod 4$, with the reason ($B + 1 \equiv 2 \pmod 4$) attached, never as a bare formula.
3. The Taylor expansion of an integer polynomial as a congruence, $g(a + h) \equiv g(a) + g'(a)h \pmod{h^2}$, and its role in Hensel's lemma.
4. The formal chain rule $(g \circ h)' = (g' \circ h)\, h'$ over $\mathbb{Z}[x]$, and its consequence that the derivative of an iterate along an orbit is the product of f' along the orbit.
5. The habit of treating a first-order recursion as an iterated map, and of computing $f \circ f$ by hand when the claim involves even or power-of-two indices.

None of this is in A-level Further Mathematics beyond the chain rule. Items 1 to 3 are the same three facts that carry every "exact power of p dividing a sequence" problem on the Putnam, so they are not installed for this problem alone; they are installed once and reused for a decade.

Revolving concepts

2-adic valuation. $v_2(n)$ is the exponent of 2 in n, with $v_2(0) = \infty$; $v_2(xy) = v_2(x) + v_2(y)$ and $v_2(x + y) \geq \min(v_2(x), v_2(y))$ with equality when $v_2(x) \neq v_2(y)$. "Divisible by 2^a but not 2^{a+1}" means $v_2 = a$ exactly. See Book 1, field: Number theory, topic: p-adic valuation.

Lifting the exponent for $p = 2$. If B is odd and $v_2(B - 1) \geq 2$ then $v_2(B^{2^j} - 1) = v_2(B - 1) + j$; more generally for odd x, y and even n, $v_2(x^n - y^n) = v_2(x - y) + v_2(x + y) + v_2(n) - 1$. The one-step form $B^2 - 1 = (B - 1)(B + 1)$ with $v_2(B + 1) = 1$ is what the induction uses. See Book 1, field: Number theory, topic: lifting the exponent.

Taylor expansion of integer polynomials. For $g \in \mathbb{Z}[x]$ and integers a, h: $g(a + h) = g(a) + g'(a)h + h^2 r$ with $r \in \mathbb{Z}$; in particular $g(a + h) \equiv g(a) + g'(a)h \pmod{h^2}$. This is the algebraic form of Hensel's lemma and the reason p-adic questions localise to values and derivatives. See Book 1, field: Polynomials, topic: Taylor expansion over $\mathbb{Z}$ and Hensel's lemma.

Composition and the chain rule. $(g \circ h)(0) = g(h(0))$ and $(g \circ h)'(0) = g'(h(0))h'(0)$ hold formally in $\mathbb{Z}[x]$; for the n-fold iterate, $(f^{\circ n})'(x_0) = \prod_{i<n} f'(x_i)$ along the orbit $x_i = f^{\circ i}(x_0)$, which is the official first solution's product $\prod(4b_i + 1)$. See Book 1, field: Polynomials, topic: formal derivatives and composition.

Coefficientwise congruences under composition. If $g \equiv x \pmod m$ coefficientwise then $g \circ g \equiv x \pmod m$; and if $g = x + p^e h$ with $e \geq 1$ then $g^{\circ p} \equiv x \pmod{p^{e+1}}$, because $g^{\circ j} \equiv x + jp^e h \pmod{p^{2e}}$. Iterating p times gains a power of p: the source of "period 2^{j-1} modulo 2^j". See Book 1, field: Number theory, topic: periodicity of recursions modulo m.

Divided differences. $f(x) - f(y) = (x - y)\,\frac{f(x)-f(y)}{x-y}$ with the quotient a polynomial in x, y; for $f = 2x^2 + x + 1$ it is $2x + 2y + 1$. Along two orbits this telescopes into products, and as $y \to x$ the quotient becomes $f'(x)$: the orbit route and the map route are the same computation in different coordinates. See Book 1, field: Polynomials, topic: divided differences and telescoping.

Generalised recursion. For $b_{n+1} = f(b_n)$ with $f \in \mathbb{Z}[x]$, $b_0 = 0$, and $f^{\circ m} \equiv x \pmod{p^e}$ coefficientwise ($e \geq 1$, and $e \geq 2$ when $p = 2$), write $g = f^{\circ m}$, $g_k = g^{\circ p^k}$, and $g_k = A_k + B_k x + x^2 Q_k$. Then to leading order $A_{k+1} = A_k(1 + B_k + \cdots + B_k^{p-1})$ and $B_{k+1} = B_k^p$, so $v_p(A_k)$ and $v_p(B_k - 1)$ each grow by one per step once they are positive, and $b_{mp^{k+1}} - p\, b_{mp^k} = A_k \sum_{j=0}^{p-1}(B_k^j - 1) + \text{tail}$, whose valuation is computed from $v_p(A_k)$ and $v_p(B_k - 1)$ (for $p = 2$ the sum is just $B_k - 1$). The solution method is always: pass to the iterate, linearise at the base point, prove exact valuations of the two linear data by induction, and bound the tail by a coarse coefficientwise congruence. The

same scheme proves the official remark that $v_2(b_{m+n} - b_n) = v_2(m) + 1$ for even m. See Book 3, field: Sequences and recurrences, topic: iterated polynomial maps and p-adic orbits.

Circuit Bank

- **WHEN** you see $b_{n+1} = f(b_n)$ with indices 2^k, 2^{k+1} (or mp^k) in the claim **DO** write $g_k = f^{\circ 2^k}$, $g_{k+1} = g_k \circ g_k$, and express the claim through $g_k(0)$ and $g_k(g_k(0))$ **BECAUSE** doubling an index is self-composition, and the orbit is unmanageable while the iterate is a single polynomial.
- **WHEN** you evaluate an integer polynomial at a point divisible by a high power of p **DO** write $g(A) = g(0) + g'(0)A + A^2(\cdots)$ and track only $g(0)$ and $g'(0)$ **BECAUSE** the Taylor congruence modulo A^2 localises p-adic information to the value and the derivative.
- **WHEN** a claimed exponent decomposes as a sum, such as $2k + 2 = (k + 1) + (k + 1)$ **DO** look for a product of two factors with those valuations and a tail of strictly larger valuation **BECAUSE** the ultrametric rule reads the valuation of a sum off its unique smallest term.
- **WHEN** you need $v_2(B^2 - 1)$ for $B \equiv 1 \pmod 4$ **DO** write $(B - 1)(B + 1)$ and add exactly 1 **BECAUSE** $B + 1 \equiv 2 \pmod 4$, the one-step lifting of the exponent.
- **WHEN** you must bound every higher-order term of an iterate at once **DO** prove a coefficientwise congruence $g_k \equiv x \pmod{p^e}$ and propagate it through composition **BECAUSE** substituting an integer polynomial into one with coefficients in $p^e\mathbb{Z}$ keeps the coefficients in $p^e\mathbb{Z}$.

Backtesting

1. First useful cue: the indices 2^k and 2^{k+1} with $b_0 = 0$, which say "self-compose the iterate and expand at 0".
2. Method the expression suggested: $g_k = A_k + B_k x + x^2 Q_k$, the target $(B_k - 1)A_k + A_k^2 Q_k(A_k)$, a coarse lemma $g_k \equiv x \pmod 4$, and an induction giving $v_2(A_k) = v_2(B_k - 1) = k + 1$.
3. Where you would hesitate, and the thought to reinforce: whether the nonlinear tail could spoil the exact valuation. Reinforce: the tail is A^2 times something divisible by 4, so its valuation is at least $2k + 4$, two above the leading term; the coefficient 2 of the recursion was chosen to make this true.
4. The trap the question sets: reducing the recurrence modulo 2^{2k+3} and iterating, or telescoping the orbit differences and drowning in two coupled inductions; also forgetting the "not divisible by 2^{2k+3}" half, which needs exact valuations, not bounds.
5. What makes you recognise it faster next time: "power-of-two indices in an iterated polynomial" equals "linearise the 2^k-th iterate at the base point"; "exponent equal to a sum of two equal pieces" equals "product of two factors with equal valuation".
6. The reusable decision rule: work with the map, not the orbit; track the value and the derivative of the iterate; control everything else by one coefficientwise congruence.

Mirror drills

1. For $f(x) = 2x^2 + x + 1$, verify $f(f(x)) = 8x^4 + 8x^3 + 12x^2 + 5x + 4$ and deduce that $b_{n+2} \equiv b_n \pmod 4$ for all n. *Answer:* expand $2(2x^2 + x + 1)^2 + (2x^2 + x + 1) + 1$; then $f \circ f \equiv x \pmod 4$ coefficientwise, so $b_{n+2} = (f \circ f)(b_n) \equiv b_n$.

2. Let B be an integer with $v_2(B-1) = e \geq 2$. Prove $v_2(B^{2^j}-1) = e + j$ for all $j \geq 0$. *Answer:* $B^2 - 1 = (B-1)(B+1)$ and $B+1 \equiv 2 \pmod 4$ gives one step; induct, noting the hypothesis $v_2 \geq 2$ is preserved.

3. Let $g \in \mathbb{Z}[x]$ and let a be an integer. Prove $g(a) \equiv g(0) + g'(0)a \pmod{a^2}$, and check it for $g(x) = x^3 + 5x + 7$, $a = 6$. *Answer:* each monomial cx^j with $j \geq 2$ contributes $ca^j \equiv 0 \pmod{a^2}$; numerically $g(6) - g(0) - 6g'(0) = 253 - 7 - 30 = 216 = 6 \cdot 36$.

1.7 B1. Two-colour plane closed under circumcentres

Suppose that each point in the plane is coloured either red or green, subject to the following condition: for every three noncollinear points A, B, C of the same colour, the centre of the circle passing through A, B and C is also this colour. Prove that all points of the plane are the same colour.

Read it out loud

A two-colouring of the plane with one closure rule: a monochromatic noncollinear triple hands its colour to its circumcentre, and you must show only the trivial colourings survive. The fields wired in are elementary circle geometry (circumcentres, when two circles meet), a drop of logic (the contrapositive of a closure rule) and combinatorics (double counting). No continuity is given, so none may be used.

The first useful cue is "the centre of the circle passing through A, B and C". A circle has one centre and infinitely many points, so the rule says something weak about the centre and, read backwards, something strong about the circle. Within thirty seconds you should have written the contrapositive as a number: every circle centred at a red point has at most two green points. The instant a closure rule becomes a number, counting becomes available, and counting is what kills "two colours coexist". That conversion, made before you draw anything, is what is being tested.

Approaches, ranked worst to best

1. **Orbit generation.** *Cue:* a closure condition, so generate the closure. *Circuit:* take three same-coloured points, keep adding circumcentres, hope the orbit reaches a point of the other colour. (Stalls at once: nothing controls where circumcentres land and the orbit cannot be steered onto a prescribed point.)
2. **Forced-colour chase.** *Cue:* equal distances produce centres for free. *Circuit:* build a rigid configuration (equilateral triangles on PQ, then reflections) in which each new point's colour is forced by an earlier centre, until a monochromatic triple has a centre of the wrong colour. (The official first solution; eight points. It ranks below the ideal because it is a search with no invariant: each step needs its own noncollinearity check.)
3. **Budget and double count.** *Cue:* the contrapositive of the rule is a cap of two per circle. *Circuit:* with P red and Q green, draw three circles about P and three about Q; each P-circle carries at most two green points, each Q-circle at most two red, and the eighteen intersection points cannot all be coloured. (Ideal: one lemma, one configuration built from P, Q, $|PQ|$ alone, one inequality $18 > 12$.)

The ideal solution

Suppose, for contradiction, that both colours occur: let P be red and Q green, and put $d = |PQ| > 0$.

Lemma 1.7.1. *Every circle centred at a red point contains at most two green points, and every circle centred at a green point contains at most two red points.*

Proof. Let O be red and Γ a circle centred at O. If Γ contained three distinct green points A, B, C, they would be noncollinear, because a line meets a circle in at most two points. The unique circle through three noncollinear points is then Γ itself, so its centre O would be green by hypothesis, a contradiction. The other statement is the same with the colours exchanged. □

Choose distinct radii ρ_1, ρ_2, ρ_3 and distinct radii $\sigma_1, \sigma_2, \sigma_3$, all in the open interval $(d, \frac{3}{2}d)$. Let Γ_i be the circle centred at P of radius ρ_i and Δ_j the circle centred at Q of radius σ_j. Two circles with centres

at distance d and radii ρ, σ meet in exactly two points precisely when $|\rho - \sigma| < d < \rho + \sigma$; here $|\rho_i - \sigma_j| < \frac{1}{2}d < d$ and $\rho_i + \sigma_j > 2d > d$, so each pair (Γ_i, Δ_j) meets in exactly two points. A point X of $\Gamma_i \cap \Delta_j$ satisfies $|XP| = \rho_i$ and $|XQ| = \sigma_j$, so X determines (i, j); hence the nine intersections are pairwise disjoint and their union T has exactly 18 points.

Every point of T lies on some Γ_i, and each Γ_i carries at most two green points, so T has at most 6 green points. Every point of T lies on some Δ_j, so T has at most 6 red points. Every point of T is red or green, so $18 \leq 12$, which is false. Hence both colours cannot occur. □

(Two circles about P and three about Q already suffice: 12 points, at most 4 green and 6 red.)

Layer 1: WHAT

Block 1: assume both colours occur; fix red P, green Q and $d = |PQ|$. Block 2: the budget lemma, the contrapositive of the hypothesis plus "cocircular implies noncollinear". Block 3: a grid of three concentric circles about P and three about Q, radii chosen so every pair meets twice and the 18 points are distinct. Block 4: count the grid against the two budgets.

Juxtapose with the nominal route. The zombie starts drawing: an equilateral triangle on PQ, a reflection, another, each time asking "what colour is this forced to be?" Nothing tells it where to go next. The bifurcation point is the first sentence after "suppose P is red and Q is green". The zombie writes "consider the point P_3 such that …"; you write "every circle centred at P has at most two green points". One sentence turns a rule into a number, and after it the problem is a count, not a search.

Layer 2: HOW

Block 1. **Cue.** "Prove that all points of the plane are the same colour": a universal conclusion about an unstructured colouring. **Why natural.** Contradiction from the minimal failure, one point of each colour, is the only handle. The hypothesis mentions only circles and centres, so the complete data of the failure is P, Q and d. **Link to the next block.** Before building anything, ask what the hypothesis forbids near P and near Q.

Block 2. **Cue.** The closure rule "three same-coloured points on a circle force the centre's colour". **Why natural.** Forwards, the rule needs monochromatic triples on demand, which you cannot produce; backwards it is a cap. Predicated on O red, three green points on a circle about O would make O green. The check graders want, noncollinearity, is free: a line cuts a circle at most twice, and uniqueness of the circumcircle identifies the circle through the three points with the one you drew. The lemma is nothing but the definition of a circle and the definition of circumcentre. **Link to the next block.** Two budgets, linear in the number of circles. You need a set of points that grows faster than linearly.

Block 3. **Cue.** Two families of concentric circles, one about P, one about Q. **Why natural.** Concentric circles are pairwise disjoint, so a point lies on exactly one circle of each family, while a P-circle and a Q-circle meet twice when the radii are compatible with d. So a and b circles give $2ab$ distinct points against budgets of $2a$ green and $2b$ red; quadratic beats linear once $(a-1)(b-1) > 1$. Radii in $(d, \frac{3}{2}d)$ make the meeting condition automatic; distinctness is the statement that a point knows its distances to P and Q. **Link to the next block.** The grid is finite and each point lies on one circle of each family: count.

Block 4. **Cue.** A finite set with independent caps on its two colour classes. **Why natural.** Every point is red or green, so $|T| \leq 6 + 6 < 18$. The contradiction is arithmetic. **Link to the next block.** None. Re-check the two places a grader probes: the circles meet (radius condition) and the points are distinct (distances identify the pair).

Layer 3: WHY

The truth underneath is an incidence bound. Two pencils of concentric circles are transversal: a member of one meets a member of the other in at most two points, and no point lies on two members of one pencil. So $a + b$ objects generate $2ab$ points, and any hypothesis capping "bad" points per object is defeated once a, b are moderate. The second official solution is exactly this for k colours and ℓ points: $2m^2 > 2m(k-1)\ell$ for large m.

The discernment mechanism is one early question: does this hypothesis produce objects or restrict them? "If these are all colour c then that is colour c" produces weakly and restricts strongly; when the output is a single point and the inputs are several, the restriction is a small cap, and the cap is what you write. Train it by taking every closure hypothesis you meet (closed under midpoints, sums, circumcentres, reflections) and writing "at most ... per ..." before doing anything else.

The examiners nudged by choosing a centre as the produced object: a centre carries the concentric circles, the one family of plane curves whose members are pairwise disjoint, so each point counts exactly once against each budget. Compare the midpoint analogue: "the midpoint of two same-coloured points has that colour" is satisfied by "red if $x > 0$, green otherwise", since each class is convex. The circumcentre rule is strong because circumcentres escape half-planes, and the budget lemma is where that strength is cashed.

Revolving concepts

Circumcentre. The point equidistant from three noncollinear points, the meet of the perpendicular bisectors; unique for every noncollinear triple; three distinct points on one circle are noncollinear, and their circumcentre is that circle's centre. That is the entire content of the budget lemma. See Book 1, field: Geometry, topic: circumcircle and perpendicular bisectors.

Circle intersection. Centres at distance d, radii ρ, σ: two points if $|\rho - \sigma| < d < \rho + \sigma$, one at either equality, none otherwise; a point is determined up to reflection in the line of centres by its distances to two fixed points. See Book 1, field: Geometry, topic: circles and radical axis.

Closure rules. "S is closed under ω" is equivalent to "no output of ω on inputs from S lies outside S"; when ω takes several inputs to one output, the contrapositive caps how many inputs from S can lie on a fibre of ω. See Book 1, field: Logic and set theory, topic: contrapositive and closure.

Double counting against budgets. Finite T, two families covering T with each point in exactly one member of each, per-member caps: $|T| \le a \cdot \mathrm{cap}_1 + b \cdot \mathrm{cap}_2$ while transversality gives $|T| = 2ab$; with cap $(k-1)(\ell-1)$ per circle you need $ab > (a+b)(k-1)(\ell-1)/2$. See Book 1, field: Combinatorics, topic: double counting and incidences; for the chase route, topic: Euclidean Ramsey problems.

Circuit Bank

- **WHEN** you see a closure rule ("if these are all colour c then so is that") **DO** write its contrapositive as a numerical cap: "an object centred at a c-point carries at most m points of any other colour" **BECAUSE** a cap is countable and a closure rule is not; caps feed double counting
- **WHEN** you have two special points of different colours and the only shapes in the problem are circles **DO** draw families of concentric circles about each and study the grid of intersection points **BECAUSE** concentric circles are pairwise disjoint, so each grid point counts once against each budget, and $2ab$ points beat linear budgets
- **WHEN** you place three points on one circle **DO** state that they are noncollinear because a line meets a circle at most twice **BECAUSE** this is the hypothesis's precondition and graders look for it

Backtesting

1. First useful cue: "the centre of the circle passing through A, B and C is also this colour": a closure rule whose output is a centre.
2. Method the expression suggested: contrapositive cap, then two pencils of concentric circles and a count.
3. Where you would hesitate, and the thought to reinforce: whether the circles meet and whether the intersection points are distinct. Reinforce: radii in $(d, \frac{3}{2}d)$ make the meeting condition automatic, and a point knows its distances to P and Q.
4. The trap the question sets: using the rule forwards in a chase with no invariant, or silently assuming continuity of the colouring.
5. What makes you recognise it faster next time: the word "centre" attached to a closure rule. Centres bring concentric circles, and concentric circles are disjoint.
6. The reusable decision rule: closure rule, therefore cap; cap, therefore grid; grid, therefore count.

Mirror drills

1. (drill) The plane is coloured with k colours so that whenever ℓ distinct points of one colour lie on a circle, the centre has that colour. Show all points have one colour. *Answer:* a circle about a c-point carries at most $(k-1)(\ell-1)$ non-c points; with a circles about P and a about Q, the $2a^2$ grid points include at most $2a(k-1)(\ell-1)$ that are not red and as many that are not green; take $a > 2(k-1)(\ell-1)$.
2. (drill) Show that "red if $x > 0$, green otherwise" violates the hypothesis although each class is convex. *Answer:* three points with $x > 0$ on the circle of radius 2 centred at $(-1, 0)$ are red and their circumcentre is green.
3. (drill) The plane is two-coloured and not monochromatic. Show there are two points of the same colour at distance 1 and two of different colours at distance 1. *Answer:* a unit equilateral triangle gives the first pair by pigeonhole; for the second, join a red point to a green point by a zigzag chain of unit steps and take the first step where the colour changes.

1.8 B2. Lamina centroid against solid of revolution centroid

Let $f\colon [0,1] \to [0,\infty)$ be strictly increasing and continuous. Let R be the region bounded by $x = 0$, $x = 1$, $y = 0$ and $y = f(x)$. Let x_1 be the x-coordinate of the centroid of R. Let x_2 be the x-coordinate of the centroid of the solid generated by rotating R around the x-axis. Prove that $x_1 < x_2$.

Read it out loud

Two centroids of two objects built from one graph, and a strict inequality between their x-coordinates. Say what a centroid is: first moment divided by total mass. Slicing the lamina into vertical strips gives $x_1 = \int_0^1 xf \,/\, \int_0^1 f$; slicing the solid into discs of area $\pi f(x)^2$ gives $x_2 = \int_0^1 xf^2 \,/\, \int_0^1 f^2$, the π cancelling. So the sentence you should have written within thirty seconds is: x_1 is the mean of x under the weight f, x_2 is the mean of x under the weight f^2, and the claim is that multiplying the weight by the increasing factor f pushes the mean to the right.

The fields wired in are integral calculus (centroids by slicing), inequalities (Chebyshev's integral inequality, rearrangement) and probability (weighted means, covariance). What is tested is whether you see a ratio of integrals as a weighted mean and whether you know that two weighted means whose weights differ by a monotone factor compare in the direction of that factor. The hypothesis "strictly increasing" is the whole engine: it is the comonotonicity of x and $f(x)$, and "strictly" is what buys the strict inequality. "Continuous" is there so the integrals exist and so that a positive continuous integrand has a positive integral.

Approaches, ranked worst to best

1. **Formula grinding.** *Cue:* two explicit centroid formulas. *Circuit:* write x_1 and x_2 out, cross-multiply, try integration by parts on the four single integrals. (Stalls: there is no single-variable identity relating $\int xf^2 \int f$ to $\int xf \int f^2$. Testing $f(x) = x$ gives $2/3 < 3/4$, which is reassurance, not proof.)

2. **Geometric mass transfer.** *Cue:* a lamina and a solid over the same base. *Circuit:* stand a prism of height $f(x_1)$ on R (its centroid projects to x_1), carve away the part left of $x = x_1$ above the surface $z = f(x)$ and add the part right of it below that surface; the result has square cross-sections of area $f(x)^2$, whose x-centroid equals that of the solid of revolution. (The official second solution; correct and pretty. It costs three-dimensional bookkeeping and two lemmas a grader will want: removing mass left of the centroid moves the centroid right, and a solid's x-centroid depends only on its cross-sectional area function.)

3. **Single crossing.** *Cue:* compare two weighted means in one variable. *Circuit:* let $c = \int f^2 / \int f$, so $\int f(f - c) = 0$; $f - c$ changes sign once, at x_0, so $(x - x_0)f(f - c) \geq 0$ pointwise; integrate. (Complete in six lines and worth knowing: it is the one-variable proof of the same inequality. It ranks second only because it needs the crossing point and a small continuity argument for strictness, whereas the symmetrisation is one identity.)

4. **Symmetrise the double integral.** *Cue:* a product of two integrals is a double integral over the square. *Circuit:* write the cross-multiplied difference as $\iint f(x)f(y)^2(y - x)$, swap the names of the variables, add, and read off the sign from $(y - x)(f(y) - f(x)) \geq 0$. (Ideal: Chebyshev's integral inequality proved on the spot, in a form that generalises to any weight and any pair of comonotone functions.)

The ideal solution

Since f is strictly increasing and $f(0) \geq 0$, we have $f(x) > f(0) \geq 0$ for $x \in (0,1]$; as f is continuous, $\int_0^1 f > 0$ and $\int_0^1 f^2 > 0$.

The centroid of a plane region is its first moment divided by its area. Slicing R into vertical strips of width dx and height $f(x)$,

$$x_1 = \frac{\int_0^1 xf(x)\,dx}{\int_0^1 f(x)\,dx}.$$

The solid of revolution has, at abscissa x, a cross-section which is a disc of area $\pi f(x)^2$; its volume is $\int_0^1 \pi f(x)^2\,dx$ and its first moment about the plane $x = 0$ is $\int_0^1 x \cdot \pi f(x)^2\,dx$, so

$$x_2 = \frac{\int_0^1 xf(x)^2\,dx}{\int_0^1 f(x)^2\,dx}.$$

Both denominators are positive, so $x_1 < x_2$ is equivalent to $D > 0$, where

$$D := \Big(\int_0^1 f(x)\,dx\Big)\Big(\int_0^1 yf(y)^2\,dy\Big) - \Big(\int_0^1 xf(x)\,dx\Big)\Big(\int_0^1 f(y)^2\,dy\Big).$$

Each product of two integrals of continuous functions is a double integral over the square $Q = [0,1]^2$ (Fubini for continuous integrands), so

$$D = \iint_Q f(x)f(y)^2(y-x)\,dx\,dy.$$

The names of the variables are immaterial; renaming $x \leftrightarrow y$ gives $D = \iint_Q f(y)f(x)^2(x-y)\,dx\,dy$. Adding the two expressions,

$$2D = \iint_Q \left[f(x)f(y)^2(y-x) + f(y)f(x)^2(x-y)\right]dx\,dy = \iint_Q f(x)f(y)\,(y-x)\big(f(y)-f(x)\big)\,dx\,dy.$$

Let $g(x,y) = f(x)f(y)(y-x)(f(y)-f(x))$. Because f is increasing, $(y-x)$ and $(f(y)-f(x))$ have the same sign, so $g \geq 0$ on Q. At the interior point $(\frac{1}{4}, \frac{3}{4})$ we have $f(\frac{1}{4}) > 0$, $f(\frac{3}{4}) > 0$, $\frac{3}{4} - \frac{1}{4} > 0$ and $f(\frac{3}{4}) - f(\frac{1}{4}) > 0$, so $g(\frac{1}{4}, \frac{3}{4}) > 0$; since g is continuous, $g > 0$ on a small disc about $(\frac{1}{4}, \frac{3}{4})$ contained in Q. A continuous nonnegative function that is positive on an open set has positive integral, so $2D > 0$. Therefore $x_2 - x_1 = D/\big(\int_0^1 f \int_0^1 f^2\big) > 0$. □

Layer 1: WHAT

Block 1: write both centroids as moment over mass by slicing, and check the denominators are positive. Block 2: clear denominators; the claim becomes $D > 0$ for a difference of two products of integrals. Block 3: convert each product into a double integral over the square, rename the variables, add, and obtain an integrand that is a product of nonnegative factors. Block 4: strictness from one interior point of positivity plus continuity.

Juxtapose. The nominal route reaches Block 2 and then attacks the four single integrals: integration by parts, substitution, a test function or two. The bifurcation point is the treatment of a product of two integrals. The zombie sees two numbers multiplied; you see one double integral over a square, because that is what a product of integrals is, and the only symmetry a square has (swap the axes) is then applied at once. Everything after that is reading off signs.

Layer 2: HOW

Block 1. **Cue.** "Centroid" twice, of a lamina and of a solid of revolution. **Why natural.** A centroid is defined as first moment over total mass; the only computational content is choosing slices. Vertical strips are forced for R (the boundary is a graph over x), and discs perpendicular to the axis are forced for the solid. Writing x_2 with πf^2 and cancelling π is the moment you notice that rotation merely squares the weight. Positivity of the denominators is not decoration: $f(0)$ may be 0, so you must say $f > 0$ on $(0, 1]$. **Link to the next block.** Two ratios with positive denominators; a strict inequality between ratios is a strict inequality between cross products.

Block 2. **Cue.** Two weighted means of the same variable with weights f and f^2. **Why natural.** Cross-multiplying is the only move that removes fractions, and it produces D, a difference of two products of integrals. Nothing about f has been used yet; this block is pure bookkeeping. **Link to the next block.** D is built from four integrals in two different variables' worth of information; to see its sign you need them under one integral sign.

Block 3. **Cue.** A product of two integrals. **Why natural.** $\int a \cdot \int b = \iint a(x)b(y)$ is not a technique, it is the definition of the product written on the square. Once D is one double integral, the integrand $f(x)f(y)^2(y-x)$ has no sign, but the square is symmetric under $x \leftrightarrow y$ and the integral is unchanged by renaming. Adding the two names is the standard way to make a symmetric integrand out of an asymmetric one; the factor $(y-x)$ then forces its partner to be $f(y) - f(x)$, and comonotonicity of y and $f(y)$ makes the product nonnegative. This is exactly how Chebyshev's inequality is proved; you are reproving it because it is a two-line lemma and the grader wants to see it. **Link to the next block.** The integrand is nonnegative; the problem says strictly.

Block 4. **Cue.** "Strictly increasing" in the hypothesis and "$<$" in the conclusion. **Why natural.** $g \geq 0$ with equality on the diagonal is not yet $\iint g > 0$; you need a positive value on an open set, and continuity supplies it from a single point. The point $(\frac{1}{4}, \frac{3}{4})$ is chosen in the interior of the square, off the diagonal, so that both f factors and both differences are visibly positive and a whole disc about it lies inside Q; a boundary point such as $(\frac{1}{2}, 1)$ would need a half-disc and an extra sentence. **Link to the next block.** None; the proof is closed.

Layer 3: WHY

The truth beneath the route is Chebyshev's integral inequality: for a weight $w \geq 0$ and two functions u, v that are monotone in the same direction,

$$\int w \int wuv - \int wu \int wv = \frac{1}{2} \iint w(x)w(y)\,\big(u(x) - u(y)\big)\big(v(x) - v(y)\big)\,dx\,dy \geq 0.$$

Here $w = f$, $u = x$, $v = f$. In the language of probability, put the density $f / \int f$ on $[0, 1]$ and let X be the random abscissa; then $x_1 = \mathrm{E}[X]$, $x_2 = \mathrm{E}[Xf(X)] / \mathrm{E}[f(X)]$, and

$$x_2 - x_1 = \frac{\mathrm{Cov}(X, f(X))}{\mathrm{E}\, f(X)},$$

which is positive because a random variable and an increasing function of it are positively correlated. That single sentence is the entire problem, and it is why the answer could never have gone the other way.

The discernment mechanism: every ratio of integrals with the same variable upstairs is a weighted mean, and every comparison of two weighted means is a covariance in disguise. When the two weights differ by a factor h, the sign of $\mathrm{E}_w[Xh] - \mathrm{E}_w[X]\,\mathrm{E}_w[h]$ is the sign of the monotonicity of h. Train it by refusing to compute centroids numerically: rewrite every centroid, centre of mass,

expectation and average as $\mathrm{E}_w[\cdot]$, name the weight, and ask what changed between the two weights. The examiners nudged by the phrase "strictly increasing" (there is no other property of f in play) and by rotating about the x-axis rather than the y-axis, which squares the weight without changing the variable being averaged.

The single-crossing proof is the same fact seen in one variable: $f - c$ with $c = \mathrm{E}_w f$ crosses zero once, and $(x - x_0)(f(x) - c) \geq 0$ is the one-dimensional shadow of $(x - y)(f(x) - f(y)) \geq 0$. Knowing both forms means you can choose the cheaper one in the arena: symmetrisation when the weight is arbitrary, single crossing when you want to avoid double integrals altogether.

Revolving concepts

Centroid. Definition: $\bar{x} = \int x\,dm / \int dm$ for a mass distribution; for a lamina under a graph, $dm = f(x)\,dx$; for a solid with cross-sectional area $A(x)$, $dm = A(x)\,dx$, so the x-centroid depends only on the area function A, not on the shape of the sections (this is what makes the square-section solid and the solid of revolution interchangeable in the geometric route). Pappus's theorems sit next door. See Book 1, field: Calculus and integrals, topic: moments and centroids by slicing.

Chebyshev's integral inequality. Statement and the symmetrisation identity above; equality iff one of u, v is constant on the support of w. Discrete form: if $a_1 \leq \cdots \leq a_n$ and $b_1 \leq \cdots \leq b_n$ then $n \sum a_i b_i \geq \sum a_i \sum b_i$, proved by $\sum_{i,j}(a_i - a_j)(b_i - b_j) \geq 0$. Rearrangement inequality is the ancestor. See Book 1, field: Inequalities, topic: Chebyshev and rearrangement.

Covariance of comonotone variables. $\mathrm{Cov}(X, h(X)) \geq 0$ for h increasing, with the same symmetrisation proof on the product space; more generally $\mathrm{Cov}(u(X), v(X)) \geq 0$ for u, v similarly monotone (the FKG inequality in one dimension). See Book 1, field: Probability, topic: covariance and monotone coupling.

The one-parameter family. Generalised statement: for $p > 0$ let $x_p = \int x f^p / \int f^p$; then $p \mapsto x_p$ is strictly increasing when f is strictly increasing and positive. Proof identical with $w = f^p$ and $v = f^{q-p}$. This is the recursion-flavoured generalisation: each extra factor of f moves the mean right by $\mathrm{Cov}_w(X, f) / \mathrm{E}_w f$. Neighbouring fact: $p \mapsto \log \int f^p$ is convex (Cauchy's inequality). See Book 1, field: Inequalities, topic: power means and log-convexity.

Positivity of integrals. A continuous $g \geq 0$ on a rectangle with $g(P) > 0$ at one point has $\iint g > 0$: continuity gives a disc where $g > g(P)/2$. See Book 1, field: Real analysis, topic: integrals of continuous functions.

Circuit Bank

- **WHEN** you see a centroid, centre of mass, average or expectation **DO** write it as $\int x\,w / \int w$ and name the weight **BECAUSE** comparisons of centroids are comparisons of weighted means, and the weight is where the hypothesis lives
- **WHEN** you must compare $\int a \int b$ with $\int c \int d$ **DO** write each product as a double integral over the square, rename $x \leftrightarrow y$, and add **BECAUSE** a product of integrals is a double integral, and the swap is the only symmetry the square has; symmetrising produces a factor $(x - y)$ paired with a difference
- **WHEN** two weights differ by a monotone factor h **DO** expect the mean to move in the direction of h and prove it by $\mathrm{Cov}(X, h(X)) \geq 0$ **BECAUSE** a variable and an increasing function of it are positively correlated
- **WHEN** you need a strict inequality from a nonnegative integrand **DO** exhibit one point of strict positivity and cite continuity **BECAUSE** "equality only on the diagonal" is not a proof; an open set of positivity is

Backtesting

1. First useful cue: "centroid" of a region and of its solid of revolution: the weights are f and f^2, the averaged variable is x in both.
2. Method the expression suggested: weighted means, cross-multiply, write products as double integrals, symmetrise.
3. Where you would hesitate, and the thought to reinforce: whether π matters (it cancels), whether a denominator can vanish ($f(0)$ may be 0 but $f > 0$ on $(0,1]$), and how to get strictness (one interior point plus continuity).
4. The trap the question sets: three-dimensional visualisation that feels like insight but needs unproved lemmas about moving mass, or grinding four single integrals that never talk to each other.
5. What makes you recognise it faster next time: "strictly increasing" next to a ratio of integrals. Monotone plus mean equals covariance.
6. The reusable decision rule: ratio of integrals, therefore weighted mean; two weighted means, therefore a covariance; covariance of comonotone functions, therefore symmetrise and read the sign.

Mirror drills

1. (drill) For the same f, show that $x_p = \int_0^1 x f^p / \int_0^1 f^p$ is strictly increasing in $p > 0$. *Answer:* for $q > p$, $\int f^p \int x f^q - \int x f^p \int f^q = \frac{1}{2} \iint f(x)^p f(y)^p (y-x)\big(f(y)^{q-p} - f(x)^{q-p}\big) > 0$ since f^{q-p} is strictly increasing.
2. (drill) If $u, v\colon [0,1] \to \mathbb{R}$ are continuous and both increasing, prove $\int_0^1 uv \geq \int_0^1 u \int_0^1 v$. *Answer:* $\int uv - \int u \int v = \frac{1}{2} \iint (u(x) - u(y))(v(x) - v(y)) \geq 0$.
3. (drill) Compute x_1 and x_2 for $f(x) = x$, and state what happens to the inequality if f is strictly decreasing. *Answer:* $x_1 = \frac{1/3}{1/2} = \frac{2}{3}$, $x_2 = \frac{1/4}{1/3} = \frac{3}{4}$; for decreasing f the same identity gives $x_1 > x_2$, since $(y-x)(f(y) - f(x)) \leq 0$.

1.9 B3. Divisor-closed set forced to contain every integer

Suppose S is a nonempty set of positive integers with the property that if n is in S, then every positive divisor of $2025^n - 15^n$ is in S. Must S contain all positive integers?

Read it out loud

A closure condition on a set of positive integers: membership of n forces membership of every divisor of $F(n) = 2025^n - 15^n$, and you are asked whether the closure of any nonempty seed is the whole of $\mathbb{N}$. The answer is yes, and the structure that makes it yes is in the numbers: $2025 = 45^2 = 3^4 \cdot 5^2$ and $15 = 3 \cdot 5$ have the same prime support, so $2025 = 15 \cdot 135$ and

$$F(n) = 15^n\big(135^n - 1\big).$$

That factorisation is the sentence to write in the first thirty seconds. It splits every modulus into two kinds of prime: 3 and 5, which are swallowed by 15^n once n is large enough, and everything else, which is coprime to 135 and is therefore handled by Euler's theorem on $135^n - 1$.

The fields wired in are elementary number theory (Euler's theorem, orders, coprime factors of a common multiple) and the logic of strong induction with a constructed witness. What is really tested is the design of the witness: the induction hands you every $k \le n - 1$, and you must find one k in that range with $n \mid F(k)$. The witness must be large enough for the powers of 3 and 5, a multiple of $\phi(d)$ for the coprime part d, and below n. The slack that makes all three compatible is $\phi(d) < d \le n$, which is why Euler's theorem, not Fermat's, is the right tool: Euler always hands you an exponent smaller than the modulus.

Approaches, ranked worst to best

1. **Numerical exploration.** *Cue:* a concrete base, so compute. *Circuit:* $F(1) = 2010 = 2 \cdot 3 \cdot 5 \cdot 67$ puts $1, 2, 3, 5, 6, 10, 15, 30, 67, \ldots$ into S; then factor $F(2)$, $F(3)$, and hope everything appears. (Cannot conclude for all n; a finite computation never proves a universal statement. Useful only to guess the answer, which the factorisation already told you.)
2. **Fermat reflex.** *Cue:* $n \mid c^{n-1} - 1$ for prime n. *Circuit:* try the witness $k = n - 1$ and Fermat's little theorem. (Fails for composite n: $4 \nmid 135^3 - 1$ since $135 \equiv -1 \pmod 4$. The right exponent is a multiple of $\phi(d)$, and it must also be at least the 3-adic and 5-adic exponents of n.)
3. **Tower of iterates.** *Cue:* iterate the closure from the seed. *Circuit:* let $a_0 = 1$, $a_{i+1} = F(a_i)$; show $a_i \mid a_{i+1}$ via $x^m - y^m \mid x^{md} - y^{md}$, then show every n divides some a_i by minimal counterexample, reducing to prime powers coprime to 15 and applying Euler. (The official second solution; correct and conceptually clean, since the divisor sets of the tower are nested. It costs three lemmas where the ideal route costs one inequality.)
4. **Strong induction with a designed witness.** *Cue:* the hypothesis gives you all $k < n$. *Circuit:* write $n = 3^a 5^b d$, $\gcd(d, 15) = 1$, $c = \max(a, b)$, and take $k = \max(c, 1)\,\phi(d)$; check $1 \le k \le n - 1$ and $n \mid 15^k(135^k - 1)$. (Ideal: one induction, one explicit witness, one inequality $c\,\phi(d) \le n - 1$.)

The ideal solution

Yes: S must contain every positive integer.

Write $F(k) = 2025^k - 15^k$. Since $2025 = 15 \cdot 135$,

$$F(k) = 15^k\big(135^k - 1\big).$$

We prove $n \in S$ by strong induction on n.

Base. S is nonempty; pick $n_0 \in S$. Then 1 divides $F(n_0)$, so $1 \in S$.

Step. Let $n \geq 2$ and assume $1, 2, \ldots, n-1 \in S$. Write $n = 3^a 5^b d$ with $a, b \geq 0$ and $\gcd(d, 15) = 1$, and put $c = \max(a, b)$ and

$$k = \max(c, 1) \cdot \phi(d),$$

where ϕ is Euler's totient function.

First, $1 \leq k \leq n-1$. Clearly $k \geq 1$. If $c = 0$ then $n = d \geq 2$ and $k = \phi(n) \leq n-1$, since n itself is not coprime to n. If $c \geq 1$ then, using $\phi(d) \leq d$, the inequality $c \leq 3^c - 1$ (valid for $c \geq 1$, as $3^c = (1+2)^c \geq 1 + 2c$), $d \geq 1$, and $3^c \leq 3^a 5^b$,

$$k = c\,\phi(d) \leq c\,d \leq (3^c - 1)\,d = 3^c d - d \leq 3^a 5^b d - 1 = n - 1.$$

Hence $k \in S$ by the induction hypothesis, and so every positive divisor of $F(k)$ lies in S.

Second, $n \mid F(k)$. Since $k \geq c \geq a$ and $k \geq c \geq b$, we have $3^a 5^b \mid 3^k 5^k = 15^k$. Since $\gcd(d, 135) = 1$, Euler's theorem gives $135^{\phi(d)} \equiv 1 \pmod{d}$, and $\phi(d) \mid k$, so $135^k \equiv 1 \pmod{d}$; that is, $d \mid 135^k - 1$. (For $d = 1$ this is trivial.) The integers $3^a 5^b$ and d are coprime and both divide $F(k) = 15^k(135^k - 1)$, so their product n divides $F(k)$.

Therefore n is a positive divisor of $F(k)$ with $k \in S$, and $n \in S$. By strong induction, $S = \mathbb{N}$. □

Layer 1: WHAT

Block 1: answer yes; factor $F(k) = 15^k(135^k - 1)$; note $1 \in S$ from nonemptiness. Block 2: strong induction, and split the target n into its $\{3, 5\}$-part $3^a 5^b$ and its coprime part d, because the two factors of $F(k)$ serve the two parts. Block 3: design the witness: k must lie in $\{1, \ldots, n-1\}$, be at least $\max(a, b)$, and be a multiple of $\phi(d)$; the slack $\phi(d) \leq d$ and $3^c d \leq n$ makes $k = \max(c, 1)\phi(d)$ work. Block 4: verify $n \mid F(k)$ by checking the two coprime factors separately and multiplying.

Juxtapose. The nominal route either computes examples or iterates the closure from 1 and studies the tower. The bifurcation point is the question "which k do I use?" The zombie reaches for $k = n - 1$ (the Fermat reflex) and dies on $n = 4$; you list the three constraints on k, notice that Euler's exponent $\phi(d)$ is strictly smaller than $d \leq n$, and pick the smallest multiple of $\phi(d)$ that clears c.

Layer 2: HOW

Block 1. **Cue.** "$2025^n - 15^n$" with $2025 = 45^2$ and $15 = 3 \cdot 5$: the two bases share their primes. **Why natural.** A difference of powers with a common factor is $g^n(A'^n - B'^n)$; here $g = 15$, $A' = 135$, $B' = 1$, so the second factor is of Euler type. The question "must S contain all positive integers" is a universal claim, and $1 \in S$ is immediate, so strong induction is the natural frame: the closure gives you all divisors of $F(k)$ for each k already admitted. **Link to the next block.** To admit n, some already-admitted k must satisfy $n \mid F(k)$; the two factors of $F(k)$ tell you how to split n.

Block 2. **Cue.** $F(k) = 15^k \cdot (135^k - 1)$, a prime-power factor times a "$c^k - 1$" factor. **Why natural.** A prime $p \mid n$ is either in $\{3, 5\}$, and then p-adically only 15^k can help (as $135^k - 1 \equiv -1 \pmod{p}$), or coprime to 135, and then only $135^k - 1$ can help. So $n = 3^a 5^b d$ is not a choice but the shape the modulus is forced into, and $\gcd(3^a 5^b, d) = 1$ lets you verify divisibility one factor at a time. **Link to the next block.** Each factor imposes a condition on k; collect them.

Block 3. **Cue.** Three constraints on one integer k: $k \geq \max(a, b)$, $\phi(d) \mid k$, $k \leq n - 1$. **Why natural.** Existence of a witness is an inequality, not a search. Multiples of $\phi(d)$ that clear c start at $c\,\phi(d)$ (or $\phi(d)$ when $c = 0$), so the only question is whether $c\,\phi(d) \leq n - 1$. It is, with room: $\phi(d) \leq d$ and $c \leq 3^c - 1$ give $c\,\phi(d) \leq 3^c d - d \leq n - 1$. The case $c = 0$ is Euler's $\phi(n) < n$. This is where the induction hypothesis is cashed: the witness is below n. **Link to the next block.** With k fixed and admitted, verification is mechanical.

Block 4. **Cue.** Two coprime factors of n, two factors of $F(k)$. **Why natural.** $3^a5^b \mid 15^k$ needs only $k \geq a$ and $k \geq b$ (not $k \geq a+b$, a common overshoot). $d \mid 135^k - 1$ is Euler's theorem plus $\phi(d) \mid k$. Coprime divisors of a common multiple multiply: $n \mid F(k)$. **Link to the next block.** None; the induction closes.

Layer 3: WHY

The truth underneath is a statement about differences of powers with equal radicals. If $A \neq B$ are positive integers with the same set of prime divisors, write $g = \gcd(A, B)$, $A = gA'$, $B = gB'$. Every prime dividing $A'B'$ divides g, so for any modulus n the primes of n split into those dividing g (absorbed by g^k for k at least the largest exponent in n) and those coprime to $A'B'$ (handled by $A'^k \equiv B'^k \pmod{d}$ for $\phi(d) \mid k$, after multiplying by the inverse of B'). So every n divides $A^k - B^k$ for some $k < n$, and the closure under "divisors of $A^n - B^n$" of any nonempty seed is $\mathbb{N}$. Without equal radicals the statement fails: with $A = 2$, $B = 1$, the set $S = \{1\}$ is closed, because $2^1 - 1 = 1$, and no even number ever divides $2^n - 1$. The examiners chose 2025 and 15 precisely to satisfy $\mathrm{rad}(2025) = \mathrm{rad}(15)$ while looking arbitrary.

The discernment mechanism has two parts. First, for a difference of powers, always ask "which primes are absorbed and which are Euler": it is the p-adic reading of $x^n - y^n$. Second, whenever an induction gives you "all smaller values", write down exactly what the step needs from a witness and turn its existence into an inequality; the standard slack in multiplicative number theory is $\phi(m) < m$ (or better, $\mathrm{ord}_m(c) \mid \phi(m)$), which is what makes "an exponent below the modulus" always available. You train both by refusing to test small cases before you have factored, and by never writing "by Fermat" for a modulus that is not prime.

The nudge in the question is the word "must". A yes-or-no phrasing invites you to look for a counterexample; the factorisation shows there is none, and the same factorisation is the proof. Consumption of examples costs ink; analysis of the expression costs one line.

Revolving concepts

Euler's theorem and ϕ. If $\gcd(c, m) = 1$ then $c^{\phi(m)} \equiv 1 \pmod{m}$; ϕ is multiplicative, $\phi(p^e) = p^{e-1}(p-1)$, and $\phi(m) \leq m - 1$ for $m \geq 2$ with equality iff m is prime. Sharper: the order $\mathrm{ord}_m(c)$ divides $\phi(m)$ and divides Carmichael's $\lambda(m)$; any multiple of the order works as the exponent. This is beyond the A-level syllabus (Fermat is not enough here) and must be installed. See Book 1, field: Number theory, topic: Euler's theorem, orders and the totient.

Differences of powers. $x - y \mid x^k - y^k$; more generally $x^m - y^m \mid x^{md} - y^{md}$ by the factorisation $x^{md} - y^{md} = (x^m - y^m)\left(x^{m(d-1)} + x^{m(d-2)}y^m + \cdots + y^{m(d-1)}\right)$. This is the lemma behind the tower route and behind lifting-the-exponent arguments. See Book 1, field: Number theory, topic: divisibility of $a^n - b^n$.

Coprime divisors multiply. If $u \mid m$, $v \mid m$ and $\gcd(u, v) = 1$ then $uv \mid m$; equivalently $\mathrm{lcm}(u, v) = uv$. Checking divisibility one prime power at a time is the working form of the Chinese remainder theorem. See Book 1, field: Number theory, topic: lcm, gcd and the Chinese remainder theorem.

Radical and p-adic splitting. $\mathrm{rad}(A)$ is the product of the distinct primes of A; the general theorem above holds exactly when $\mathrm{rad}(A) = \mathrm{rad}(B)$. See Book 1, field: Number theory, topic: p-adic valuation of $a^n - b^n$.

The recursion. The closure of a seed under "divisors of $F(\cdot)$" is the union of the divisor sets of the tower $a_0 = \text{seed}$, $a_{i+1} = F(a_i)$, and when $a_i \mid a_{i+1}$ the divisor sets are nested, so "is the closure everything" becomes "does every n divide some a_i". Generalised: for any F with $u \mid v \Rightarrow F(u) \mid F(v)$ the same reduction applies, and minimal-counterexample arguments reduce to prime powers. The strong induction of the ideal route is the same recursion read one step at a time: to reach n you need

one earlier level k with $n \mid F(k)$. See Book 1, field: Logic and set theory, topic: closure operators and strong induction.

Circuit Bank

- **WHEN** you see $A^n - B^n$ with $\gcd(A, B) > 1$ **DO** factor out $\gcd(A, B)^n$ and separate the primes of the gcd (absorbed by the power) from the primes coprime to it (handled by Euler) **BECAUSE** the p-adic behaviour of $x^n - y^n$ splits along $p \mid \gcd$ versus p coprime
- **WHEN** you need an exponent k with $m \mid c^k - 1$ and $\gcd(c, m) = 1$ **DO** take a multiple of $\phi(m)$, or of $\mathrm{ord}_m(c)$, and note it can be chosen below m **BECAUSE** Euler's theorem, and $\phi(m) < m$ for $m \geq 2$
- **WHEN** a closure condition "$n \in S \Rightarrow$ divisors of $F(n) \in S$" asks whether S is everything **DO** strong induction: to admit n, exhibit $k < n$ with $n \mid F(k)$ **BECAUSE** the hypothesis makes every $k < n$ available, so the only problem is the design of k
- **WHEN** a witness must satisfy several constraints at once **DO** write each constraint as an inequality or a divisibility and locate the slack **BECAUSE** existence is an inequality, not a search; here the slack is $\phi(d) \leq d$ and $c \leq 3^c - 1$

Backtesting

1. First useful cue: $2025 = 45^2$ and $15 = 3 \cdot 5$ share their primes, so $F(n) = 15^n(135^n - 1)$.
2. Method the expression suggested: strong induction; witness k a multiple of $\phi(d)$ that is at least $\max(a, b)$ and below n.
3. Where you would hesitate, and the thought to reinforce: whether $k \leq n - 1$ really holds (it does, with the slack $c\,\phi(d) \leq 3^c d - d$), and whether $3^a 5^b \mid 15^k$ needs $k \geq a + b$ (it needs only $k \geq \max(a, b)$).
4. The trap the question sets: answering "no" by analogy with $2^n - 1$, or using Fermat with $k = n - 1$, which fails at $n = 4$.
5. What makes you recognise it faster next time: "every divisor of" next to a difference of powers whose bases share primes.
6. The reusable decision rule: shared primes are absorbed by the power, coprime primes are handled by Euler with an exponent below the modulus, and strong induction supplies the exponent.

Mirror drills

1. (drill) Same question with $2^n - 1$ in place of $2025^n - 15^n$. *Answer:* No: $S = \{1\}$ is closed since $2^1 - 1 = 1$, and no even number divides $2^n - 1$; the radicals of 2 and 1 differ.
2. (drill) Show that every positive integer coprime to 10 divides a repunit $11 \cdots 1$. *Answer:* for n coprime to 10, Euler on the modulus $9n$ gives $9n \mid 10^{\phi(9n)} - 1$, so $n \mid (10^{\phi(9n)} - 1)/9$, a repunit.
3. (drill) With $a_0 = 1$ and $a_{i+1} = 2025^{a_i} - 15^{a_i}$, prove $a_i \mid a_{i+1}$ for all i. *Answer:* induction; if $a_i \mid a_{i+1}$ then $2025^{a_i} - 15^{a_i} \mid 2025^{a_{i+1}} - 15^{a_{i+1}}$ by $x^m - y^m \mid x^{md} - y^{md}$.

1.10 B4. Sum versus support of a staircase matrix

For $n \geq 2$, let $A = [a_{i,j}]_{i,j=1}^{n}$ be an n-by-n matrix of nonnegative integers such that

(a) $a_{i,j} = 0$ *when* $i + j \leq n$;

(b) $a_{i+1,j} \in \{a_{i,j}, a_{i,j} + 1\}$ *when* $1 \leq i \leq n - 1$ *and* $1 \leq j \leq n$; *and*

(c) $a_{i,j+1} \in \{a_{i,j}, a_{i,j} + 1\}$ *when* $1 \leq i \leq n$ *and* $1 \leq j \leq n - 1$.

Let S be the sum of the entries of A, and let N be the number of nonzero entries of A. Prove that

$$S \leq \frac{(n+2)N}{3}.$$

Read it out loud

A square array of nonnegative integers, zero on and above the anti-diagonal, and each step to the right or downward raises the entry by 0 or 1. So the entries are nondecreasing in both directions and grow at most one unit per step away from the zero band. S/N is the average nonzero entry, and the claim is that this average never exceeds $(n+2)/3$. The fields wired in are the combinatorics of monotone arrays (the zero set is an order ideal), Lipschitz bounds (an entry is at most its distance from a zero), averaging arguments, and the discipline of computing the extremal example before proving anything.

The first thing to do, within thirty seconds, is to build the matrix that should be extremal: fill the triangle $i + j > n$ with the distance to the anti-diagonal band, $a_{i,j} = i + j - n$. It satisfies (a), (b), (c), the entries equal to k number $n + 1 - k$, so

$$N = \frac{n(n+1)}{2}, \qquad S = \sum_{k=1}^{n} k(n+1-k) = \frac{n(n+1)(n+2)}{6}, \qquad \frac{S}{N} = \frac{n+2}{3}.$$

The constant is therefore the average of $i + j - n$ over the full triangle, and the bound is tight. What is really tested is the next question: why can a matrix with a bigger zero region, or with slower growth, not beat this average? A bigger zero region shrinks N, but it also forces small entries near its boundary, and the proof has to quantify that second effect. The fraction $\frac{1}{3}$ in the target is a cue in itself: an average of three bounds.

Approaches, ranked worst to best

1. **Extremal guessing.** *Cue:* a maximisation of S/N over a finite family. *Circuit:* argue that filling the whole triangle with the fastest growth is "obviously" best. (Not a proof. The admissible family is enormous: any down-set of zeros, any pattern of 0/1 increments. Removing entries changes N and S at once and the ratio can move either way.)

2. **One bound.** *Cue:* entries grow at most 1 per step from the band $i + j \leq n$. *Circuit:* prove $a_{i,j} \leq i + j - n$ and sum. (Correct but insufficient: it gives $S \leq \sum_{\text{nonzero}} (i + j - n)$, which equals $(n+2)N/3$ for the full triangle and exceeds it otherwise; for $n = 2$ and A with the single nonzero entry $a_{2,2} = 1$, it yields $S \leq 2$ against the target $4/3$. The bound ignores where the zeros end.)

3. **Taxicab reduction and induction on n.** *Cue:* a 0/1-growth array dominated by distances to the zero set. *Circuit:* replace each entry by its taxicab distance to the zero set (this keeps N, does not decrease S, and preserves the conditions), then peel: subtract 1 from the nonzero entries and delete the first row and column; prove the level counts c_k strictly decrease and close the induction. (The official first solution. It works, but the strict decrease of the level counts needs an injection with four verifications, and the base case is a five-matrix check. Far more ink than the ideal.)

4. **Three bounds that average to a constant.** *Cue:* the target is $\frac{1}{3}(n+2)$ per nonzero entry. *Circuit:* bound each nonzero entry three ways, by its distance to the band ($i+j-n$), by its position among the nonzero entries of its row ($j - Z_i$) and of its column ($i - W_j$); sum the row bound along each row and re-index it as $n+1-j$, likewise columns; the three bounds add to $n+2$ at every nonzero position. (Ideal. Two short lemmas and one addition.)

The ideal solution

By (b) and (c), $a_{i,j} \le a_{i+1,j}$ and $a_{i,j} \le a_{i,j+1}$: entries are nondecreasing downward and to the right. Hence if $a_{i,j} = 0$ then $a_{i',j'} = 0$ for all $i' \le i$, $j' \le j$. In particular the zeros of row i occupy an initial block of columns $1, \dots, Z_i$ and the nonzero entries occupy columns $Z_i + 1, \dots, n$ (with $Z_i = n$ if the row is zero); similarly the zeros of column j occupy rows $1, \dots, W_j$.

Lemma 1.10.1. *For every (i,j), $a_{i,j} \le \max(0, i+j-n)$. In particular every nonzero entry satisfies $a_{i,j} \le i+j-n$.*

Proof. Induction on i. For $i = 1$: if $j \le n-1$ then $a_{1,j} = 0$ by (a); and $a_{1,n} \le a_{1,n-1} + 1 = 1 = 1 + n - n$ by (c) and (a). For $i \ge 2$: if $i + j \le n$ the entry is 0 by (a); if $i + j \ge n+1$ then $(i-1) + j \ge n$, so by (b) and the induction hypothesis $a_{i,j} \le a_{i-1,j} + 1 \le \max(0, i-1+j-n) + 1 = i+j-n$. □

Lemma 1.10.2. *Every nonzero entry satisfies $a_{i,j} \le j - Z_i$ and $a_{i,j} \le i - W_j$.*

Proof. Consider row i with $Z_i < n$. Its first nonzero entry a_{i,Z_i+1} is at most 1: if $Z_i \ge 1$ then by (c) it is at most $a_{i,Z_i} + 1 = 1$; if $Z_i = 0$ then $a_{i,1} \ne 0$ forces $i + 1 > n$, so $i = n$, and by (b) and (a) (note $(n-1)+1 \le n$) we get $a_{n,1} \le a_{n-1,1} + 1 = 1$. Moving right along the row adds at most 1 per step by (c), so for $j \ge Z_i + 1$, $a_{i,j} \le 1 + (j - Z_i - 1) = j - Z_i$. The column statement is identical with (b) in place of (c) and the roles of i, j exchanged. □

Now sum. Let P be the set of positions of the nonzero entries, $|P| = N$. In row i the nonzero positions are $j = Z_i + 1, \dots, n$, so by the second lemma

$$\sum_{j=Z_i+1}^{n} a_{i,j} \;\le\; \sum_{j=Z_i+1}^{n} (j - Z_i) \;=\; 1 + 2 + \cdots + (n - Z_i) \;=\; \sum_{j=Z_i+1}^{n} (n+1-j),$$

the last equality because both sides list the integers $1, \dots, n - Z_i$, in opposite orders. Summing over rows,

$$S \le \sum_{(i,j)\in P} (n+1-j).$$

The same argument along columns gives $S \le \sum_{(i,j)\in P}(n+1-i)$, and the first lemma gives $S \le \sum_{(i,j)\in P}(i+j-n)$. Adding the three inequalities,

$$3S \;\le\; \sum_{(i,j)\in P} \big[(i+j-n) + (n+1-j) + (n+1-i)\big] \;=\; \sum_{(i,j)\in P} (n+2) \;=\; (n+2)N,$$

which is the claim. □

Equality holds for the full taxicab triangle $a_{i,j} = \max(0, i+j-n)$, where all three bounds are tight at every nonzero position, and for the zero matrix.

Layer 1: WHAT

Block 1: read (b), (c) as monotonicity plus growth at most 1 per step; deduce that the zero set is a down-set, so each row's zeros form a prefix of length Z_i and each column's a prefix of length W_j. Block 2: three upper bounds for a nonzero entry, one per route to a zero: up-left to the band ($i+j-n$), left to the row's last zero ($j - Z_i$), up to the column's last zero ($i - W_j$). Block 3: sum

each bound over P; the row bound sums, row by row, to a triangular number that re-indexes as $\sum(n+1-j)$, and likewise for columns. Block 4: add the three sums; the position-dependent parts cancel to the constant $n+2$.

Juxtapose. The nominal route proves the band bound $a_{i,j} \le i+j-n$, sees it is not enough, and either tries to sharpen it or drops into the induction on n. The bifurcation point is what you do with an insufficient bound. The zombie sharpens; you add. The reason is in the equality case: in the full triangle the three distances coincide ($Z_i = n-i$, $W_j = n-j$), so all three bounds are tight there, and the target constant $(n+2)/3$ is announcing that three quantities are being averaged.

Layer 2: HOW

Block 1. **Cue.** "$a_{i+1,j} \in \{a_{i,j}, a_{i,j}+1\}$" and the same to the right: monotone, and Lipschitz with constant 1. **Why natural.** Monotonicity in both directions makes the zero set closed under moving up or left, which is the only way to describe where the nonzero entries live: a suffix of each row and of each column. Without this you cannot even name the row sums you are about to bound. Lipschitz 1 from a zero is the only quantitative content the conditions have, so every bound you will ever prove is "at most the number of steps to some zero". **Link to the next block.** Choose the zeros to measure from. There are three natural ones for each entry.

Block 2. **Cue.** The band $i+j \le n$ is a zero region you know; the row and column prefixes are zero regions you have just found. **Why natural.** Three routes from (i,j) to a zero, each a straight path in the grid, each giving a bound equal to its length: diagonally up-left to the band in $i+j-n$ steps, left in $j-Z_i$ steps, up in $i-W_j$ steps. The band bound needs an induction because the band is not adjacent to most entries; the row and column bounds need only that the first nonzero entry in a line is 1, which is one step from a zero (with the single exception $a_{n,1}$, handled by the column). These are the tightest bounds available from single straight paths, and in the extremal matrix all three are exact. **Link to the next block.** Each bound is pointwise; the target is a sum. Sum them.

Block 3. **Cue.** A per-row bound $j-Z_i$ whose values along the row are $1, 2, \ldots, n-Z_i$. **Why natural.** The sum of the row bound over the row is a triangular number determined by the row's count of nonzero entries alone, not by Z_i's position, and the multiset $\{1, \ldots, m\}$ reads the same from either end. So you may charge the value $n+1-j$ to position (i,j) instead of $j-Z_i$: the total is unchanged and the new label depends on j only, not on the row. This is the whole content of the "reverse the nonzero entries in each row" device of the second official solution, without constructing the reversed matrices. The column bound re-indexes to $n+1-i$ the same way. **Link to the next block.** Three sums over the same index set P, with summands $i+j-n$, $n+1-j$, $n+1-i$.

Block 4. **Cue.** Three summands whose i and j dependence cancels. **Why natural.** $(i+j-n)+(n+1-j)+(n+1-i) = n+2$ at every position. Adding the three inequalities gives $3S \le (n+2)N$; there is nothing left to estimate. **Link to the next block.** None. Record the equality case as a check that no inequality was wasted.

Layer 3: WHY

The truth beneath the route is that an entry is at most its taxicab distance to the zero set, and that three specific paths to zero give three bounds whose sum, after a legal re-indexing within rows and within columns, is a constant. The re-indexing is a rearrangement: the row bound summed over a row depends only on how many nonzero entries the row has, so the labels may be assigned from the right end instead of the left. Averaging then does the rest. In the extremal matrix every path is a geodesic to the zero set and every bound is an equality; in any other admissible matrix at least one

bound is slack somewhere, and the same three inequalities absorb the slack automatically. That is why no case analysis on the shape of the zero region is needed.

The discernment mechanism: when a target reads "$S \le cN/m$" for an integer m, look for m per-object bounds summing to c. Compute the extremal configuration first; it tells you what "tight" looks like, and the bounds you need are exactly the ones that are tight there. When one bound sums to a row-dependent triangular number, re-index it from the other end so that it becomes pointwise comparable with the others. Train this by refusing to sharpen a single bound that is tight in the extremal case (it cannot be sharpened; the extremal case is a witness) and instead asking what other bound is also tight there.

The examiners nudged twice. The anti-diagonal band makes $i + j - n$ a coordinate you cannot avoid, and the denominator 3 tells you how many bounds to find. The same device, with k axis bounds and one diagonal bound, gives for k-dimensional arrays with the analogous conditions the bound $S \le (n + k)N/(k + 1)$, the average of the extremal simplex.

Revolving concepts

Monotone arrays and down-sets. If a is nondecreasing in each coordinate on a grid, the set where $a \le t$ is an order ideal (closed under decreasing coordinates) for every t; its rows and columns are prefixes. Neighbouring objects: plane partitions, Young diagrams, the Ferrers shape of the zero set. See Book 1, field: Discrete structures and graphs, topic: partial orders, order ideals and Young diagrams.

Lipschitz bounds from a boundary. If $|a(u) - a(v)| \le 1$ for adjacent u, v and $a = 0$ on a set Z, then $a(u) \le d(u, Z)$ in the graph (taxicab) metric; each monotone path to Z gives a bound equal to its length. Replacing a by $d(\cdot, Z)$ is the official reduction to "taxicab matrices". See Book 1, field: Inequalities, topic: Lipschitz functions and distance to a set.

Averaging arguments. To prove $\sum_{u \in P} a(u) \le c|P|$, it suffices to find bounds $b_1, \dots, b_m$ with $a \le b_t$ on P and $\sum_t b_t(u) \le mc$ pointwise, or with $\sum_t \sum_u b_t(u) \le mc|P|$ after re-indexing. This is the same mechanism as bounding an average by the average of several majorants. See Book 1, field: Combinatorics, topic: double counting and averaging.

Triangular numbers and re-indexing. $\sum_{j=Z+1}^{n} (j - Z) = \sum_{j=Z+1}^{n} (n + 1 - j) = \binom{n-Z+1}{2}$; more generally any sum of a function of the rank within a line can be re-indexed from either end. See Book 1, field: Combinatorics, topic: sums over ranks and rearrangement.

The extremal example and its recursion. For $a_{i,j} = \max(0, i + j - n)$, the entries equal to k number $n + 1 - k$, so $S = \sum k(n + 1 - k) = \binom{n+2}{3}$ and $N = \binom{n+1}{2}$. The official induction peels one layer: subtracting 1 from the nonzero entries and deleting the first row and column maps $(S, N, n) \mapsto (S - N, N - c_1, n - 1)$, where c_1 counts entries equal to 1; generalised, any array built from nested level sets satisfies $S = \sum_{k \ge 1} N_k$ with N_k the number of entries at least k, which is the layer-by-layer recursion for sums of nonnegative integers. See Book 1, field: Sequences and recurrences, topic: layer-cake sums and peeling inductions.

Circuit Bank

- **WHEN** entries change by at most 1 per step and vanish on a known region **DO** write "entry $\le$ length of a monotone path to a zero" and list the straight paths available (row, column, diagonal band) **BECAUSE** Lipschitz 1 from zero is the only quantitative content of such conditions
- **WHEN** the target is $S \le cN/m$ with a visible denominator m **DO** look for m per-entry bounds that sum to c and add them **BECAUSE** averaging is the mechanism that produces a fraction with denominator m

- **WHEN** a per-line bound sums, over the line, to a quantity depending only on the line's count **DO** re-index it from the other end of the line so that it becomes pointwise comparable with the remaining bounds **BECAUSE** the multiset $\{1, \ldots, k\}$ is symmetric; this is the reversal device
- **WHEN** an inequality has an unexplained constant **DO** construct the extremal example first and compute the constant from it **BECAUSE** it identifies the equality case and tells you which bounds must be tight

Backtesting

1. First useful cue: the denominator 3 in $(n+2)/3$, and the anti-diagonal zero band that makes $i+j-n$ a coordinate.
2. Method the expression suggested: three per-entry bounds (band, row, column) averaged.
3. Where you would hesitate, and the thought to reinforce: the row bound is $j - Z_i$, not $n+1-j$ pointwise (for $n=2$, $a_{2,2}=2$ exceeds $n+1-j=1$); the switch to $n+1-j$ is legal only after summing over the whole row. Also the first nonzero entry of row n can sit in column 1 and needs the column condition to be at most 1.
4. The trap the question sets: proving $a_{i,j} \le i+j-n$, summing, and believing you are done; or launching the peeling induction with its level-count lemma.
5. What makes you recognise it faster next time: "sum at most constant times count" is an average bound; average bounds come from several majorants that are simultaneously tight in the extremal case.
6. The reusable decision rule: compute the extremal case, extract every bound that is tight there, re-index the line bounds from the far end, and add.

Mirror drills

1. (drill) For $a_{i,j} = \max(0, i+j-n)$ compute S and N and check $S = (n+2)N/3$. *Answer:* entries equal to k number $n+1-k$, so $N = n(n+1)/2$ and $S = \sum_{k=1}^{n} k(n+1-k) = n(n+1)(n+2)/6$.
2. (drill) Show that any matrix satisfying (a), (b), (c) has $a_{i,j} \le d_{i,j}$, the taxicab distance from (i,j) to the set of zero positions. *Answer:* along a shortest lattice path to a zero the entry changes by at most 1 per step, and it ends at 0.
3. (drill) Prove that in each row the nonzero entries form a block ending at column n whose first entry is 1. *Answer:* monotonicity along the row makes the zeros a prefix; the first nonzero entry is at most its left neighbour plus one, which is 1, except in row n, column 1, where the entry above is $a_{n-1,1} = 0$ by (a).

1.11 B5. Descents in the sequence of modular inverses

Let p be a prime number greater than 3. For each $k \in \{1, \dots, p-1\}$, let $I(k) \in \{1, 2, \dots, p-1\}$ be such that $k \cdot I(k) \equiv 1 \pmod{p}$. Prove that the number of integers $k \in \{1, \dots, p-2\}$ such that $I(k+1) < I(k)$ is greater than $p/4 - 1$.

Read it out loud

The sequence $I(1), I(2), \dots, I(p-1)$ is the permutation "inverse modulo p" of $\{1, \dots, p-1\}$, and you are counting its descents: positions k where the next value is smaller. The claim is that there are more than $p/4 - 1$ of them, roughly a quarter of the $p-2$ positions. A random permutation has about half its positions as descents, so the target is loose, and that looseness is itself information: the setters want a robust argument, not a delicate count. The proof below gives almost exactly half, $\frac{p-1}{2}$ minus at most three.

The fields wired in are arithmetic in the field $\mathbb{F}_p$ (inverses, the involution $k \mapsto I(k)$, quadratic equations having at most two roots), the lifting of a congruence to an integer equation by a size bound, and counting by an involution. The first useful cue is the comparison of I at consecutive arguments, $I(k+1)$ against $I(k)$. In $\mathbb{F}_p$, with $x = 1/k$,

$$\frac{1}{k+1} = \frac{1}{1/x+1} = \frac{x}{x+1} = 1 - \frac{1}{x+1}.$$

That is the line to write within thirty seconds: the inverse of the next integer is one minus the inverse of the shifted current inverse. Read as integers in $\{1, \dots, p-1\}$, it says $I(k+1) + I(I(k)+1) = p+1$, and the descent condition becomes a statement about the single quantity $m + I(m)$ for $m = I(k)+1$. From there an involution does the counting. What is tested is whether you conjugate the shift $k \mapsto k+1$ by the inversion, rather than subtracting inverses.

Approaches, ranked worst to best

1. **Small primes and heuristics.** *Cue:* a concrete permutation for each p. *Circuit:* tabulate I for $p = 5, 7, 11, 13$, count descents, observe "about half". (Not a proof, but it fixes the target: $f(5) = f(7) = 1$, $f(11) = 5$, $f(13) = 3$, which already tells you the count is near $\frac{p-1}{2}$ with small corrections depending on p modulo 3 and 4.)
2. **Difference identity.** *Cue:* compare $1/k$ and $1/(k+1)$. *Circuit:* write $\frac{1}{k} - \frac{1}{k+1} = \frac{1}{k(k+1)}$, so $I(k) - I(k+1) \equiv I(k^2+k)$, and a descent means this difference is the least positive residue. (Looks natural and stalls: $k \mapsto k^2 + k$ is not a bijection and the residue of $I(k^2+k)$ carries no usable order information.)
3. **Reflection symmetry alone.** *Cue:* $I(p-k) = p - I(k)$. *Circuit:* note that descents are symmetric under $k \mapsto p-1-k$. (True, and it only gives parity information about the count; no lower bound emerges.)
4. **Conjugate the shift, then pair.** *Cue:* $I(k+1)$ expressed through $I(k)$. *Circuit:* prove $I(k+1) = p+1-I(I(k)+1)$, reparametrise by $m = I(k)+1$ so that descents are $\{m : m + I(m) \geq p+2\}$, pair m with $p-m$ to halve the count, and bound the unpaired set by "a quadratic has at most two roots in $\mathbb{F}_p$". (Ideal. Every step is a bijection or a degree count, and the final inequality is arithmetic. The exact count via quadratic residues is available as a remark, not a requirement.)

The ideal solution

Write $f(p)$ for the number of $k \in \{1, \dots, p-2\}$ with $I(k+1) < I(k)$. All congruences are modulo p.

Preliminaries. I is a bijection of $\{1,\dots,p-1\}$ with $I(I(k))=k$, $I(1)=1$ and $I(p-1)=p-1$ (as $(p-1)^2\equiv 1$). Since $I(k)=p-1$ only for $k=p-1$, I maps $\{1,\dots,p-2\}$ bijectively onto itself. For $m\in\{1,\dots,p-1\}$ we have $(p-m)(p-I(m))\equiv m\,I(m)\equiv 1$ and $p-I(m)\in\{1,\dots,p-1\}$, so

$$I(p-m)=p-I(m).$$

Step 1: the identity. Let $k\in\{1,\dots,p-2\}$ and $x=I(k)$, so $x\in\{1,\dots,p-2\}$ and $x+1\in\{2,\dots,p-1\}$ is invertible. From $kx\equiv 1$ we get $(k+1)x\equiv x+1$; multiplying by $I(k+1)$ gives $x\equiv(x+1)I(k+1)$, and multiplying by $I(x+1)$ gives $I(k+1)\equiv x\,I(x+1)=(x+1-1)I(x+1)\equiv 1-I(x+1)$. Hence

$$I(k+1)+I\big(I(k)+1\big)\equiv 1 \pmod p.$$

Both summands lie in $\{1,\dots,p-1\}$, so the sum is an integer in $\{2,\dots,2p-2\}$; the only such integer congruent to 1 is $p+1$. Therefore

$$I(k+1)=p+1-I\big(I(k)+1\big)\qquad(1\le k\le p-2).$$

Step 2: reparametrise. For $m\in\{1,\dots,p-1\}$ put $T(m)=m+I(m)$. Fix $k\in\{1,\dots,p-2\}$ and set $m=I(k)+1\in\{2,\dots,p-1\}$. Since I is injective, $I(k+1)\neq I(k)$, so

$$I(k+1)<I(k)\iff I(k+1)\le I(k)\iff p+1-I(m)\le m-1\iff T(m)\ge p+2.$$

As k runs over $\{1,\dots,p-2\}$, $I(k)$ runs over $\{1,\dots,p-2\}$ bijectively, so m runs over $\{2,\dots,p-1\}$ bijectively. Since $T(1)=2<p+2$, we conclude

$$f(p)=\#\{m\in\{1,\dots,p-1\}:T(m)\ge p+2\}.$$

Step 3: the involution. By the preliminaries, $T(p-m)=(p-m)+(p-I(m))=2p-T(m)$. Hence $T(m)\ge p+2$ if and only if $T(p-m)\le p-2$, and $m\mapsto p-m$ is a bijection of $\{1,\dots,p-1\}$ exchanging the sets $U=\{m:T(m)\ge p+2\}$ and $L=\{m:T(m)\le p-2\}$. So $|U|=|L|$, and with $E=\{m:T(m)\in\{p-1,p,p+1\}\}$,

$$p-1=|U|+|L|+|E|=2f(p)+|E|,\qquad\text{that is,}\qquad f(p)=\frac{p-1-|E|}{2}.$$

Step 4: bound the exceptions. Let $\varepsilon\in\{-1,0,1\}$. Since $T(m)\in\{2,\dots,2p-2\}$, the only value of $T(m)$ congruent to ε modulo p is $p+\varepsilon$. Multiplying $m+I(m)\equiv\varepsilon$ by m,

$$T(m)=p+\varepsilon\iff m^2-\varepsilon m+1\equiv 0 \pmod p.$$

A polynomial of degree 2 over the field $\mathbb{F}_p$ has at most 2 roots, so each ε contributes at most 2 elements to E, and $|E|\le 6$.

Step 5: conclude. $f(p)\ge\frac{p-7}{2}$, and $\frac{p-7}{2}>\frac{p}{4}-1$ is equivalent to $p>10$, so the claim holds for all primes $p\ge 11$. For $p=5$ the sequence I is $1,3,2,4$ with the single descent at $k=2$, so $f(5)=1>\frac14$. For $p=7$ the sequence is $1,4,5,2,3,6$ with the single descent at $k=3$, so $f(7)=1>\frac34$. □

Remark 1.11.1. The count is exact once E is: the roots of m^2+m+1 and m^2-m+1 exist (two each) iff -3 is a square modulo p, that is iff $p\equiv 1 \pmod 3$; the roots of m^2+1 exist (two) iff $p\equiv 1 \pmod 4$. Hence $f(p)=\frac{p-1}{2}-2[p\equiv 1\ (3)]-[p\equiv 1\ (4)]$, matching $f(11)=5$ and $f(13)=3$.

Layer 1: WHAT

Block 1: record the structure of I: an involution of $\{1,\dots,p-1\}$ fixing 1 and $p-1$, hence a bijection of $\{1,\dots,p-2\}$, with the reflection law $I(p-m)=p-I(m)$. Block 2: express $I(k+1)$ through $I(k)$: the identity $I(k+1)=p+1-I(I(k)+1)$, obtained by conjugating the shift by the inversion and lifting the congruence by a size bound. Block 3: reparametrise by $m=I(k)+1$ so that a descent

is $T(m) \geq p+2$, the count being over $m \in \{1, \ldots, p-1\}$. Block 4: the involution $m \mapsto p-m$ sends T to $2p-T$, so it pairs large with small and leaves only the window $\{p-1, p, p+1\}$ unpaired. Block 5: the window is the root set of three quadratics, at most six elements; finish with arithmetic for $p \geq 11$ and two hand checks.

Juxtapose. The nominal route tabulates, sees "about half", and tries to prove half by the symmetry $k \mapsto p-1-k$, which only shows the descents come in mirror pairs. The bifurcation point is the question "how do I relate $I(k+1)$ to $I(k)$?" The zombie subtracts, $\frac{1}{k} - \frac{1}{k+1} = \frac{1}{k(k+1)}$, and gets a product that reparametrises nothing. You substitute, $\frac{1}{k+1} = \frac{x}{1+x} = 1 - \frac{1}{1+x}$ with $x = \frac{1}{k}$, and get inverses of a shift, which reparametrise by a bijection.

Layer 2: HOW

Block 1. **Cue.** "$k \cdot I(k) \equiv 1 \pmod{p}$" with p prime: I is inversion in the field $\mathbb{F}_p$. **Why natural.** Everything about I follows from inversion being an involutive automorphism of the abelian group $\mathbb{F}_p^*$: $I \circ I = \mathrm{id}$, the fixed points ± 1 (the solutions of $m^2 = 1$), and compatibility with negation, $I(-m) = -I(m)$, which as integers reads $I(p-m) = p - I(m)$. You write these before doing anything because every later bijection is one of them. The restriction to $\{1, \ldots, p-2\}$ is bijective only because $p-1$ is a fixed point; that detail is what makes the reparametrisation in Block 3 legal. **Link to the next block.** The condition compares I at k and $k+1$; you need $I(k+1)$ in terms of $I(k)$.

Block 2. **Cue.** "$I(k+1)$" against "$I(k)$": the shift $k \mapsto k+1$ seen through inversion. **Why natural.** Conjugating a shift by inversion is the Möbius map $x \mapsto x/(1+x)$, and every Möbius map is a composition of shifts, scalings and one inversion: $x/(1+x) = 1 - 1/(1+x)$. So $I(k+1)$ is $1 - I(I(k)+1)$ in $\mathbb{F}_p$, an inverse of a shift of $I(k)$. The lift to integers is forced: two numbers in $\{1, \ldots, p-1\}$ sum to something in $\{2, \ldots, 2p-2\}$, and only $p+1$ there is $\equiv 1$. The precondition $I(k)+1 \neq p$, that is $k \neq p-1$, is exactly the range of k in the problem, which is a sign you are on the intended road. **Link to the next block.** Descent is now an inequality between $p+1-I(m)$ and $m-1$, a condition on m alone.

Block 3. **Cue.** A condition on $m = I(k)+1$ with k ranging over a set that I preserves. **Why natural.** Counting over k or over m is the same count because $k \mapsto I(k)+1$ is a bijection from $\{1, \ldots, p-2\}$ to $\{2, \ldots, p-1\}$. The inequality $p+1-I(m) \leq m-1$ is $T(m) \geq p+2$ with $T(m) = m + I(m)$; replacing "$<$" by "$\leq$" first is harmless since I is injective, and it keeps the boundary clean. Extending the range to include $m = 1$ costs nothing since $T(1) = 2$. **Link to the next block.** T is the sum of a number and its inverse; it has a symmetry you already recorded.

Block 4. **Cue.** $T(m) = m + I(m)$ and the reflection law $I(p-m) = p - I(m)$. **Why natural.** $T(p-m) = 2p - T(m)$ is antisymmetry about the centre p. Any antisymmetric statistic under an involution pairs the values above the centre with the values below it, so the count above equals the count below, and the total $p-1$ splits as twice the count plus the width of the unpaired window. The window is $\{p-1, p, p+1\}$ because "$\geq p+2$" and its mirror "$\leq p-2$" leave exactly three values. **Link to the next block.** You need only an upper bound on the window's population.

Block 5. **Cue.** "$T(m) = p + \varepsilon$", a congruence in one variable after multiplying by m. **Why natural.** $m^2 - \varepsilon m + 1 \equiv 0$ is a quadratic over a field; the arena answer is "at most two roots", not "exactly two iff $p \equiv 1$ modulo something". Be lazy: $|E| \leq 6$ gives $f(p) \geq (p-7)/2$, which beats $p/4 - 1$ for $p > 10$. The primes 5 and 7 fall outside and are checked by writing down four and six numbers. The exact count by quadratic residues is a remark you may add for $+\alpha$, never a step you owe. **Link to the next block.** None; the inequality is arithmetic.

Layer 3: WHY

The truth underneath is that the descent statistic of the inversion permutation is governed by the single function $T(m) = m + 1/m$ on $\mathbb{F}_p^*$. T is invariant under $m \mapsto 1/m$ and antisymmetric under $m \mapsto -m$; the second symmetry pairs the set where T is large with the set where it is small, and the fixed structure of the pairing is the set where $T \in \{-1, 0, 1\}$, which is the set of elements of multiplicative order 3, 6 or 4 (the roots of $m^2 + m + 1$, $m^2 - m + 1$, $m^2 + 1$). So $f(p) = \frac{p-1}{2} - \frac{1}{2} \cdot \#\{\text{elements of order } 3, 4, 6 \text{ in } \mathbb{F}_p^*\}$. The answer is "almost half" because $\mathbb{F}_p^*$ is cyclic and has at most two elements of each of those orders. The looseness of the target $p/4 - 1$ is the setters telling you that the degree bound suffices.

The discernment mechanism has three parts. First, when a condition compares a permutation at consecutive arguments, conjugate the shift by the permutation and express the next value through the current one; for inversion this is a Möbius map and always reduces to shifts and one inversion, never to products. Second, a congruence between quantities living in a window shorter than $2p$ lifts to an equality with at most two candidates; write the candidates and eliminate. Third, an antisymmetric statistic under an involution is counted by halving the complement of the window, and the window is bounded by degree. You train the first by rewriting $1/(x + a)$ in terms of $1/x$ until $x/(1 + x) = 1 - 1/(1 + x)$ is a reflex; the third by recognising "$T(\sigma m) = c - T(m)$" as the signal to pair.

The examiners nudged by choosing $p/4 - 1$: weak enough that an exact count is unnecessary, strong enough that parity from $k \mapsto p - 1 - k$ is useless. They also fixed $p > 3$ so that the quadratics have nonzero discriminant -3 and the argument needs no exceptional case; you should notice that $p = 3$ would make $m^2 \pm m + 1$ collapse to $(m \mp 1)^2$.

Revolving concepts

Inversion in $\mathbb{F}_p$. For prime p, every nonzero residue has a unique inverse; I is an involution of $\{1, \ldots, p-1\}$ with fixed points exactly ± 1, and $I(-m) = -I(m)$. Existence of inverses for a prime modulus is A-level (Fermat or the Euclidean algorithm); the field language and the involution bookkeeping are the part to install. See Book 1, field: Number theory, topic: the field $\mathbb{F}_p$ and its multiplicative group.

Möbius transformations. $x \mapsto (ax + b)/(cx + d)$ over $\mathbb{F}_p$; the group they form; decomposition into shifts, scalings and $x \mapsto 1/x$; here $x \mapsto x/(1 + x)$ is the conjugate of the shift by inversion. See Book 1, field: Number theory, topic: fractional linear maps over finite fields.

Lifting congruences. If $a \equiv b \pmod{p}$ and a lies in an interval of length less than p, then a is determined; in an interval of length less than $2p$ there are at most two candidates. Used here to turn $\equiv 1$ into $= p + 1$. See Book 1, field: Number theory, topic: from congruence to equality by size.

Roots of polynomials over a field. A nonzero polynomial of degree d over a field has at most d roots (Lagrange's theorem on congruences for $\mathbb{F}_p$). Sharper, for the exact count: -1 is a square modulo p iff $p \equiv 1 \pmod 4$; -3 is a square modulo $p > 3$ iff $p \equiv 1 \pmod 3$; equivalently $\mathbb{F}_p^*$, being cyclic of order $p - 1$, contains elements of order 4 iff $4 \mid p - 1$ and of order 3 or 6 iff $3 \mid p - 1$. Beyond A-level and priority to install. See Book 1, field: Number theory, topic: quadratic residues and roots of unity in $\mathbb{F}_p$.

Counting by involutions. If σ is an involution of a finite set X and $T\colon X \to \mathbb{R}$ satisfies $T(\sigma x) = c - T(x)$, then $\#\{T > c/2 + w\} = \#\{T < c/2 - w\}$ for every w, so $\#\{T > c/2 + w\} = \frac{1}{2}\big(|X| - \#\{|T - c/2| \le w\}\big)$. This is the recursion-free generalisation of Step 3, and it is the same device as pairing k with $p - k$ in sums over $\mathbb{F}_p$. See Book 1, field: Combinatorics, topic: involutions and sign-reversing pairings.

Descents of permutations. The descent set and the Eulerian numbers are the combinatorial neighbours; the mean number of descents of a random permutation of n letters is $(n - 1)/2$, which is why "about half" was the right expectation. See Book 1, field: Combinatorics, topic: descents and

Eulerian numbers.

Circuit Bank

- **WHEN** a condition compares a permutation's values at consecutive arguments, such as $I(k+1)$ against $I(k)$ **DO** express the value at $k+1$ through the value at k by conjugating the shift **BECAUSE** the comparison becomes a condition on a single variable, which is what counting needs
- **WHEN** you see $1/(k+1)$ and already have $x = 1/k$ **DO** write $x/(1+x) = 1 - 1/(1+x)$ **BECAUSE** a Möbius map is shifts plus one inversion, so it sends inverses to inverses of shifts, never to products
- **WHEN** a congruence modulo p relates quantities in a window shorter than $2p$ **DO** list the at most two integers in the window with the right residue and eliminate **BECAUSE** congruences carry no order; equalities do
- **WHEN** a statistic satisfies $T(\sigma m) = c - T(m)$ for an involution σ **DO** pair m with σm and count only the central window **BECAUSE** the count above the centre is half the complement of the window
- **WHEN** you must bound the number of solutions of a polynomial congruence modulo p **DO** cite "degree d, at most d roots" and stop **BECAUSE** the degree bound costs one line; the residue-class count costs ten and the problem did not ask for it

Backtesting

1. First useful cue: "$I(k+1) < I(k)$", the inverse map evaluated at consecutive arguments.
2. Method the expression suggested: conjugate the shift by inversion ($x/(1+x) = 1-1/(1+x)$), lift to $I(k+1) + I(I(k)+1) = p+1$, reparametrise by $m = I(k)+1$, pair by $m \mapsto p-m$, bound the window by degree.
3. Where you would hesitate, and the thought to reinforce: whether $I(k)+1$ is in range (yes, $k \neq p-1$); whether "$<$" and "$\leq$" differ (no, I is injective); whether $p = 5, 7$ need separate treatment (yes, $(p-7)/2 \leq 0$ there).
4. The trap the question sets: the difference identity $1/k - 1/(k+1) = 1/(k(k+1))$, which looks like the obvious move and leads nowhere; and the mirror symmetry $k \mapsto p-1-k$, which gives parity, not a bound.
5. What makes you recognise it faster next time: any comparison of $I(k)$ with $I(k+a)$ is the Möbius map $x \mapsto x/(1+ax)$; any statistic antisymmetric under $m \mapsto -m$ is counted by pairing.
6. The reusable decision rule: conjugate the shift, lift by size, reparametrise by a bijection, pair by the negation involution, degree-count the exceptions, hand-check the primes below the threshold.

Mirror drills

1. (drill) Prove $I(p-m) = p - I(m)$ for $1 \leq m \leq p-1$. *Answer:* $(p-m)(p-I(m)) \equiv m\,I(m) \equiv 1$ and $p - I(m) \in \{1, \ldots, p-1\}$.
2. (drill) How many $m \in \{1, \ldots, p-1\}$ satisfy $m + I(m) \equiv 0 \pmod{p}$? *Answer:* $m^2 \equiv -1$, so two if $p \equiv 1 \pmod 4$ and none if $p \equiv 3 \pmod 4$.

3. (drill) Show that the number of ascents, $k \in \{1, \ldots, p-2\}$ with $I(k+1) > I(k)$, also exceeds $p/4 - 1$. *Answer:* ascents number $p - 2 - f(p) = \frac{p-3+|E|}{2} \geq \frac{p-3}{2} > \frac{p}{4} - 1$ for $p > 2$.

1.12 B6. Largest exponent in a self-referential growth inequality

Let $\mathbb{N} = \{1, 2, 3, \dots\}$. *Find the largest real constant* r *such that there exists a function* $g\colon \mathbb{N} \to \mathbb{N}$ *such that*

$$g(n+1) - g(n) \geq \big(g(g(n))\big)^r$$

for all $n \in \mathbb{N}$.

Read it out loud

A functional inequality on the positive integers with a self-referential term $g(g(n))$ and a free exponent r; you must find the supremum of the r for which a solution exists and show it is attained. The shape is two-sided. The left side is an increment, which is small when g grows slowly. The right side is a power of the composite $g \circ g$, which is enormous when g grows fast, because composition amplifies growth far more than differencing shrinks it. So there is a sweet spot in the growth rate, and r measures how much the composite is allowed to weigh.

The sentence to write within thirty seconds is the power-law ansatz. If $g(n) \approx n^s$ then $g(g(n)) \approx n^{s^2}$ and $g(n+1) - g(n) \approx sn^{s-1}$, so the inequality asks for $s - 1 \geq rs^2$, that is $r \leq (s-1)/s^2$. The right side is maximised at $s = 2$ with value $\frac{1}{4}$. That fixes the target: the answer is $r = \frac{1}{4}$, the extremal function should be $g(n) = n^2$, and indeed $2n + 1 \geq n = (n^4)^{1/4}$. Everything after this is proof of impossibility for $r > \frac{1}{4}$, and the ansatz tells you the mechanism: the exponent map $s \mapsto rs^2 + 1$ has a fixed point iff $1 - 4r \geq 0$; when $r > \frac{1}{4}$ every polynomial rate is pushed to a higher one, so a solution would have to grow faster than every polynomial, and the same inequality read backwards forbids that.

The fields wired in are growth rates of sequences (bootstrapping, telescoping), real analysis of "for all sufficiently large n" statements and how they compose, the dynamics of a quadratic map on exponents, and the discipline of reading one inequality in both directions. What is tested is the passage from heuristic to proof: a clean bootstrap lemma with named thresholds, and the observation that a lower bound on increments in terms of $g \circ g$ is also an upper bound on $g \circ g$ in terms of g.

Approaches, ranked worst to best

1. **Polynomial-only analysis.** *Cue:* a power law fits the inequality. *Circuit:* show that $g(n) = cn^s$ works iff $r \leq (s-1)/s^2$ and conclude $r = \frac{1}{4}$. (Only half a proof. It produces the example and the target but says nothing about functions that are not polynomial, and the problem quantifies over all g.)

2. **Ansatz gallery.** *Cue:* does faster growth help?. *Circuit:* test $g(n) = a^n$: increments $\approx a^n$, composite $\approx a^{a^n}$, fails for every $r > 0$; test slower than quadratic: increments too small. (Confirms that the sweet spot is quadratic, and that growth beyond it is punished by the composite. Still a heuristic, but it tells you the two directions of the real proof.)

3. **Bootstrap without organisation.** *Cue:* the inequality feeds a bound on g back into itself. *Circuit:* from $g(n) \geq n$ get increments $\geq n^r$, so $g \gtrsim n^{r+1}$, then increments $\gtrsim n^{r(r+1)^2}$, and so on, tracking constants by hand. (The right idea drowning in constants. Every round produces a new c and a new threshold, and without a lemma that states the round once and for all, the argument is unwritable in the arena.)

4. **Bootstrap lemma, exponent dynamics, reverse reading.** *Cue:* $g \circ g$ on the right, a difference on the left. *Circuit:* prove a lemma "$g \geq n^s$ eventually implies $g \geq n^t$ eventually for every $t < rs^2 + 1$"; use $rs^2 + 1 - s \geq 1 - \frac{1}{4r} > 0$ to climb through all polynomial rates; then read the inequality as $g(g(n-1))^r < g(n)$, obtain $g(n^4) < g(n)^4$ for large n, iterate along n^{4^j}, and contradict the superpolynomial growth. (Ideal. The lemma is stated once with an "eventually"

quantifier so no constant is ever tracked twice; the exponent dynamics is one line of completing the square; the ending is an induction along a geometric subsequence.)

The ideal solution

The answer is $\boxed{r = \frac{1}{4}}$.

Existence for $r = \frac{1}{4}$. Take $g(n) = n^2$. Then $g(g(n)) = n^4$ and

$$g(n+1) - g(n) = 2n + 1 \geq n = (n^4)^{1/4} = g(g(n))^{1/4}.$$

(The same g works for every $r \leq \frac{1}{4}$, since then $g(g(n))^r = n^{4r} \leq n$.)

Impossibility for $r > \frac{1}{4}$. Suppose $r > \frac{1}{4}$ and $g\colon \mathbb{N} \to \mathbb{N}$ satisfies the inequality for all n. We derive a contradiction.

Step 0: monotonicity. Since $g(g(n)) \geq 1$, we have $g(n+1) - g(n) \geq 1$, so g is strictly increasing, and as $g(1) \geq 1$, induction gives $g(n) \geq n$ for all n. In particular $g(u) \leq g(v)$ whenever $u \leq v$.

Lemma 1.12.1 (bootstrap)**.** *Let $s \geq 0$ and suppose $g(n) \geq n^s$ for all $n \geq n_0$. Then for every real $t < rs^2 + 1$ there exists n_1 such that $g(n) \geq n^t$ for all $n \geq n_1$.*

Proof. Let $m \geq n_0$. Then $g(m) \geq m \geq n_0$, so the hypothesis applies at the integer $g(m)$: $g(g(m)) \geq g(m)^s \geq (m^s)^s = m^{s^2}$, using $s \geq 0$. Hence $g(m+1) - g(m) \geq m^{rs^2}$ for all $m \geq n_0$.

Now let $n \geq 2n_0$ and put $a = \lceil n/2 \rceil \geq n_0$. The integers m with $a \leq m \leq n-1$ number $n - a = \lfloor n/2 \rfloor \geq (n-1)/2 \geq n/4$ (as $n \geq 2$), and each satisfies $m \geq n/2$. Telescoping,

$$g(n) \geq g(n) - g(a) = \sum_{m=a}^{n-1} \big(g(m+1) - g(m)\big) \geq \frac{n}{4}\Big(\frac{n}{2}\Big)^{rs^2} = C\, n^{rs^2+1}, \qquad C = 2^{-(rs^2+2)}.$$

Since $t < rs^2 + 1$, we have $Cn^{rs^2+1} \geq n^t$ whenever $n^{rs^2+1-t} \geq 1/C$. So the threshold

$$n_1 = \max\Big(2n_0,\ \big\lceil C^{-1/(rs^2+1-t)} \big\rceil\Big)$$

works. □

Step 1: g beats every polynomial. Put $\delta = 1 - \frac{1}{4r} > 0$. For every real s,

$$rs^2 + 1 - s = r\Big(s - \frac{1}{2r}\Big)^2 + 1 - \frac{1}{4r} \geq \delta,$$

so $s + \frac{\delta}{2} < rs^2 + 1$, and the lemma with $t = s + \frac{\delta}{2}$ says: if $g(n) \geq n^s$ for all large n, then $g(n) \geq n^{s+\delta/2}$ for all large n. Since $g(n) \geq 1 = n^0$ for all n, induction on j gives, for every $j \geq 0$, a threshold beyond which $g(n) \geq n^{j\delta/2}$. Hence for every real $s \geq 0$ there is n_s with $g(n) \geq n^s$ for all $n \geq n_s$ (choose j with $j\delta/2 \geq s$ and use $n^{j\delta/2} \geq n^s$ for $n \geq 1$).

Step 2: the reverse reading. Apply Step 1 with $s = 5$ and let $n_* = \max(n_5 + 1, 5)$. For $n \geq n_*$,

$$g(n) \;>\; g(n) - g(n-1) \;\geq\; g\big(g(n-1)\big)^r \;\geq\; g\big((n-1)^5\big)^r \;\geq\; g\big(n^4\big)^r \;\geq\; g\big(n^4\big)^{1/4}.$$

Here the first inequality uses $g(n-1) \geq 1$; the second is the hypothesis at $n-1$; the third uses $g(n-1) \geq (n-1)^5$ (as $n - 1 \geq n_5$) and monotonicity of g; the fourth uses $(n-1)^5 \geq n^4$ for $n \geq 5$ (equivalently $(1 - \frac{1}{n})^5 \geq \frac{1}{n}$, true at $n = 5$ since $0.32768 \geq 0.2$, and the left side increases while the right decreases) together with monotonicity; the fifth uses $g(n^4) \geq 1$ and $r > \frac{1}{4}$. Therefore

$$g(n^4) < g(n)^4 \qquad \text{for all } n \geq n_*.$$

Step 3: polynomial growth along a subsequence, and the contradiction. Fix $n = n_* \geq 5$ and choose a positive integer M with $g(n) \leq n^M$ (for instance $M = g(n)$, since $n^{g(n)} \geq 2^{g(n)} \geq g(n)$). Let

$N_j = n^{4^j}$ for $j \geq 0$. We claim $g(N_j) \leq N_j^M$ for all j. For $j = 0$ this is the choice of M. If it holds for j, then $N_j \geq n = n_*$, so Step 2 gives

$$g(N_{j+1}) = g(N_j^4) < g(N_j)^4 \leq N_j^{4M} = N_{j+1}^M.$$

Now apply Step 1 with $s = M + 1$: $g(N) \geq N^{M+1}$ for all $N \geq n_{M+1}$. Since $N_j \to \infty$, pick j with $N_j \geq n_{M+1}$. Then

$$N_j^{M+1} \leq g(N_j) \leq N_j^M,$$

so $N_j \leq 1$, contradicting $N_j \geq 5$. Hence no such g exists for $r > \frac{1}{4}$, and the largest admissible constant is $r = \frac{1}{4}$. □

Layer 1: WHAT

Block 1: the power-law ansatz locates the threshold $r = \frac{1}{4}$ at $s = 2$, and $g(n) = n^2$ verifies it in one line. Block 2: for $r > \frac{1}{4}$ assume g exists; increments are positive so g is strictly increasing and $g(n) \geq n$. Block 3: the bootstrap lemma, stated with "eventually" quantifiers: a rate n^s lifts to every rate below n^{rs^2+1}, through $g(g(m)) \geq m^{s^2}$ and a telescoping sum over the top half of $[1, n]$. Block 4: the exponent map $s \mapsto rs^2 + 1$ exceeds s by at least $\delta = 1 - \frac{1}{4r}$, so iterating the lemma from $s = 0$ beats every polynomial. Block 5: the reverse reading: $g(n) > g(g(n-1))^r \geq g(n^4)^{1/4}$ for large n, i.e. $g(n^4) < g(n)^4$. Block 6: iterate along $N_j = n^{4^j}$ to get $g(N_j) \leq N_j^M$, and collide with Block 4 at exponent $M + 1$.

Juxtapose. The nominal route runs the ansatz, perhaps several, and either stops at "no polynomial works" or starts bootstrapping with explicit constants and drowns. The bifurcation point is double. First, at Block 3, the zombie tracks c and n_0 through every round; you state the round once as a lemma whose conclusion is an "eventually" statement, so that rounds compose without bookkeeping. Second, at Block 5, the zombie has only ever read the inequality as a lower bound; you read it as an upper bound on $g \circ g$, which is what any inequality with $g \circ g$ on the large side must also be.

Layer 2: HOW

Block 1. **Cue.** "$g(g(n))$" on the right, a first difference on the left, an exponent r to be maximised. **Why natural.** Composition squares a polynomial exponent and differencing lowers it by one; those are the only two operations present, so the balance equation is $s - 1 = rs^2$. Maximising $(s-1)/s^2$ is a one-line calculus exercise with answer $\frac{1}{4}$ at $s = 2$. The ansatz is not a proof, but it tells you the answer, the extremal function, and the mechanism (fixed points of $s \mapsto rs^2 + 1$), which is everything the proof will need. Verifying $g(n) = n^2$ is mandatory: "largest r such that there exists" requires existence at the extremal value. **Link to the next block.** The impossibility half needs to handle arbitrary g; start by extracting the one property every solution shares.

Block 2. **Cue.** Positive integer values and an increment bounded below by a positive quantity. **Why natural.** $g(n+1) - g(n) \geq 1$ is strict monotonicity, and strict monotonicity of an integer-valued function is a growth bound: $g(n) \geq n$. Small as it is, this is what later lets you plug $g(m)$ into hypotheses that hold "for $n \geq n_0$" and lets you compare g at $(n-1)^5$ and n^4. **Link to the next block.** You now have $g \geq n^1$; the inequality should convert a lower bound on g into a better one.

Block 3. **Cue.** A lower bound on g feeds the composite $g \circ g$, which feeds the increments, which telescope back into g. **Why natural.** If $g(m) \geq m^s$ for $m \geq n_0$ then $g(g(m)) \geq g(m)^s \geq m^{s^2}$ for the same m, because $g(m) \geq m \geq n_0$ keeps you inside the range where the bound holds. The increments are then at least m^{rs^2}, and summing increments from a starting point to n gives $g(n)$ up to the value at the start, which is nonnegative and can be discarded. Summing over $m \in [n/2, n)$

rather than over $[n_0, n)$ is laziness with a purpose: it yields $\frac{n}{4}(\frac{n}{2})^{rs^2}$ with a constant that is visibly harmless, and the constant is then absorbed by weakening the exponent from rs^2+1 to any t below it. Stating the lemma with "eventually" on both sides is what makes it iterable. **Link to the next block.** One round raises the exponent from s to almost rs^2+1; ask when that is an improvement.

Block 4. Cue. The exponent map $\varphi(s) = rs^2+1$ and the hypothesis $r > \frac{1}{4}$. **Why natural.** $\varphi(s) - s = rs^2 - s + 1$ is a quadratic whose minimum is $1 - \frac{1}{4r}$, positive exactly when $r > \frac{1}{4}$. So every round gains at least $\delta/2$ in the exponent, and the orbit of 0 under the rounds passes every real s. This is the only place where $r > \frac{1}{4}$ is used in an essential way, and it is used through the discriminant of $rs^2 - s + 1$: at $r = \frac{1}{4}$ the double root $s = 2$ is the exponent of the extremal solution. **Link to the next block.** A superpolynomial g is now established; you need something that superpolynomial functions cannot do.

Block 5. Cue. The composite $g(g(n-1))$ is bounded above by $g(n)^{1/r}$, because the same inequality says so. **Why natural.** Read backwards, $g(g(n-1)) \le (g(n) - g(n-1))^{1/r} < g(n)^{1/r}$: the value of g at the huge argument $g(n-1)$ is controlled by a fixed power of g at the small argument n. When $g(n-1) \ge (n-1)^5 \ge n^4$, monotonicity turns this into $g(n^4) < g(n)^{1/r} \le g(n)^4$. The exponent 5 is chosen only to dominate 4 with room for the shift from n to $n-1$; the exponent 4 is chosen because $1/r < 4$ and $x^{1/r} \le x^4$ for $x \ge 1$. **Link to the next block.** $g(n^4) < g(n)^4$ is a self-similar bound: iterate it.

Block 6. Cue. A bound of the form $g(N^4) < g(N)^4$ valid for all $N \ge n_*$. **Why natural.** Along $N_j = n^{4^j}$ the bound composes: if $g(N_j) \le N_j^M$ then $g(N_{j+1}) < N_j^{4M} = N_{j+1}^M$. So g is polynomial of degree M along a sequence tending to infinity, while Block 4 says $g(N) \ge N^{M+1}$ for all large N. A contradiction needs only one subsequence, and the geometric subsequence is the one the bound naturally produces. M exists because a single value $g(n)$ is finite. **Link to the next block.** None; the proof is closed.

Layer 3: WHY

The mathematics underneath is the dynamics of the exponent map $\varphi_r(s) = rs^2 + 1$. A polynomial rate n^s is self-consistent with the inequality iff $s \le \varphi_r(s) - 1 + 1$, that is iff $s - 1 \ge rs^2$; the set of such s is nonempty iff the discriminant $1 - 4r$ is nonnegative. At $r = \frac{1}{4}$ the quadratic $\frac{1}{4}s^2 - s + 1 = \frac{1}{4}(s-2)^2$ has the double root $s = 2$: the extremal function has degree exactly 2, and the bootstrap from $s = 0$ at $r = \frac{1}{4}$ produces the increasing orbit $0, 1, 1.25, 1.39, \cdots \to 2$, so every solution at $r = \frac{1}{4}$ grows at least like $n^{2-\epsilon}$ eventually, which n^2 attains. For $r > \frac{1}{4}$ there is no fixed point, the orbit escapes to infinity at least linearly, and the bootstrap proves superpolynomial growth. The second half of the proof is the statement that superpolynomial growth is incompatible with $g \circ g$ being bounded by a fixed power of g: if g grows faster than n^5, then $g \circ g$ evaluated at $n-1$ dominates g evaluated at n^4, so "$g(n^4)$ is at most a fixed power of $g(n)$" along a geometric subsequence, which is polynomial growth. The two halves are the same inequality read in opposite directions, and the answer $\frac{1}{4}$ is the parameter value where the exponent map undergoes its saddle-node bifurcation.

The discernment mechanism is a four-step protocol for self-referential growth inequalities. One: run the power ansatz to find the threshold and the candidate extremal function, and verify the candidate immediately. Two: prove lower bounds by a bootstrap lemma stated with "eventually" quantifiers, never with explicit constants that must be carried; sum increments over the top half of the range so that the only constant is a power of 2, then weaken the exponent slightly to absorb it. Three: read the inequality backwards to obtain an upper bound on the composite, and use monotonicity to move the argument to a convenient power of n. Four: iterate the resulting self-similar bound along a geometric subsequence and collide with the lower bound. You train step two

by rewriting every "$g(n) \geq cn^s$ for $n \geq n_0$" you meet as "$g(n) \geq n^{s'}$ for all large n, for every $s' < s$", and step three by asking, for every inequality, "what does this bound from above?"

The knowledge gaps here are honest and specific. Nothing in the proof is beyond A-level calculus in content, but three habits are beyond it: composing "for all sufficiently large n" statements without losing track of thresholds; the comparison $\sum_{m=\lceil n/2 \rceil}^{n-1} m^t \geq \frac{n}{4}(\frac{n}{2})^t$ as a standing estimate; and the idea that a fixed-point analysis of an exponent map is a proof strategy, not a heuristic. The official alternative ending (obtain $g(n) \geq 3g(n-1)$ from $s > 16$, hence $g(n) > 2^n$, then compare $g(2^n)$ with $g(n)$) is the same mechanism with an exponential subsequence in place of the geometric one; know it exists, use the n^4 version because it is shorter.

Revolving concepts

Exponent maps and their fixed points. For an inequality relating Δg, g and $g \circ g$ by powers, the power ansatz yields a map φ on exponents; polynomial solutions correspond to fixed points, and the orbit of the trivial exponent under φ tracks what bootstrapping can prove. Generalised recursion: $s_{j+1} = \varphi(s_j)$ with $\varphi(s) = rs^2 + 1$; for $r \leq \frac{1}{4}$ the orbit of 0 increases to the smaller fixed point $\frac{1-\sqrt{1-4r}}{2r}$ (equal to 2 at $r = \frac{1}{4}$), for $r > \frac{1}{4}$ it is unbounded with $s_{j+1} - s_j \geq 1 - \frac{1}{4r}$. The same analysis applies to any inequality of the form $\Delta g \geq (g \circ g)^r g^q$ with the map $s \mapsto rs^2 + qs + 1$. See Book 1, field: Sequences and recurrences, topic: growth exponents and fixed points of quadratic maps.

Bootstrapping and "eventually". A statement $P(s)$: "$g(n) \geq n^s$ for all sufficiently large n". Lemmas of the form $P(s) \Rightarrow P(t)$ for all $t < \varphi(s)$ compose freely because the threshold in the conclusion is allowed to depend on s and t. Explicit constants are removed by weakening exponents. See Book 1, field: Real analysis, topic: asymptotic bounds and bootstrapping.

Telescoping over the top half. $g(n) - g(a) = \sum_{m=a}^{n-1} \Delta g(m)$; if $\Delta g(m) \geq m^t$ then $g(n) \geq \lfloor n/2 \rfloor (n/2)^t \geq \frac{n}{4}(\frac{n}{2})^t$ for $n \geq 2$. This replaces integral comparison and never needs $t > -1$ or a lower limit at 1. See Book 1, field: Sequences and recurrences, topic: sums of powers and telescoping.

Monotone integer functions. $g\colon \mathbb{N} \to \mathbb{N}$ strictly increasing implies $g(n) \geq n$; monotonicity transports bounds through composition: $g(u) \geq u^s$ and g increasing give $g(g(u)) \geq g(\lfloor u^s \rfloor)$, with the floor avoided here by choosing integer exponents. See Book 1, field: Functional equations, topic: monotone solutions on the integers.

Reverse reading and self-similar bounds. From $\Delta g(n) \geq (g \circ g)(n)^r$ one gets $(g \circ g)(n) \leq g(n+1)^{1/r}$; combined with $g(n) \geq n^s$ this becomes $g(n^k) \leq g(n)^{1/r}$ for $k < s$, a bound of the form $g(n^k) \leq g(n)^K$ which iterates along n^{k^j} to polynomial growth on a subsequence. Generalised: any bound $g(\psi(n)) \leq g(n)^K$ with ψ increasing and $\psi(n) \to \infty$ forces g to be at most polynomial in n along the orbit of ψ when ψ is itself polynomial. See Book 1, field: Inequalities, topic: iterating functional bounds along orbits.

The extremal example. $g(n) = n^2$ gives equality in the ansatz and slack in the inequality ($2n + 1$ against n); one can check that $g(n) = \lceil cn^2 \rceil$ also works for any $c > 0$ at $r = \frac{1}{4}$, so the extremal degree, not the constant, is what the problem pins down. See Book 1, field: Functional equations, topic: extremal solutions of growth inequalities.

Circuit Bank

- **WHEN** a growth inequality involves $g(g(n))$ and a first difference **DO** run the power ansatz $g \approx n^s$, $g \circ g \approx n^{s^2}$, $\Delta g \approx n^{s-1}$, and locate the threshold as the value of the parameter at which the exponent map acquires a double fixed point **BECAUSE** composition squares exponents and differencing subtracts one; the double root is the extremal degree
- **WHEN** you hold "$g(n) \geq n^s$ for large n" and increments bounded below by a power of $g \circ g$ **DO** bootstrap: $g \circ g \geq n^{s^2}$, telescope the increments over the top half of $[1, n]$, and conclude $g \geq n^t$ for large n for every $t < rs^2 + 1$ **BECAUSE** telescoping converts increment bounds

into value bounds and the top half keeps the constant a power of 2, which a slightly smaller exponent absorbs

- **WHEN** the exponent map satisfies $\varphi(s) \geq s + \delta$ for all s **DO** conclude that g beats every polynomial **BECAUSE** the orbit of 0 under φ is unbounded and "eventually" statements compose
- **WHEN** an inequality has $g \circ g$ on its large side **DO** also read it as an upper bound, $g(g(n)) \leq g(n+1)^{1/r}$, and move the inner argument to a power of n by monotonicity **BECAUSE** every inequality bounds something from above; for a superpolynomial g this caps $g(n^4)$ by $g(n)^4$
- **WHEN** you need to contradict a bound valid for all large N **DO** produce the opposite bound along one subsequence $N_j \to \infty$ by iterating a self-similar inequality **BECAUSE** a single subsequence suffices for a contradiction, and $g(N^4) < g(N)^4$ iterates along n^{4^j}

Backtesting

1. First useful cue: $g(g(n))^r$ on the right against $g(n+1) - g(n)$ on the left; the power ansatz $s - 1 \geq rs^2$.
2. Method the expression suggested: answer $\frac{1}{4}$ with $g(n) = n^2$; for $r > \frac{1}{4}$, a bootstrap lemma climbing through all polynomial rates, then the reverse reading $g(n^4) < g(n)^4$ iterated along n^{4^j}.
3. Where you would hesitate, and the thought to reinforce: whether the bootstrap's constants are circular (the threshold n_1 depends only on s, t, n_0); whether the hypothesis may be applied at $g(m)$ (yes, $g(m) \geq m \geq n_0$); whether $(n-1)^5 \geq n^4$ (from $n = 5$); whether the induction $g(N_j) \leq N_j^M$ needs $N_j \geq n_*$ (it does, and $N_j \geq n = n_*$ supplies it).
4. The trap the question sets: proving only that no polynomial works, or spending the hour on ansätze; and, subtler, believing that faster growth could rescue a larger r when in fact the composite punishes it.
5. What makes you recognise it faster next time: $g \circ g$ means "exponent squares"; a difference means "exponent drops by one"; the balance is a quadratic in the exponent whose discriminant is the answer.
6. The reusable decision rule: ansatz for the threshold and the example; bootstrap with "eventually" for the lower bound; reverse reading for the upper bound; collide along a geometric subsequence.

Mirror drills

1. (drill) Show that for every real r there is $g\colon \mathbb{N} \to \mathbb{N}$ with $g(n+1) - g(n) \geq g(n)^r$ for all n, and explain why the problem's version has a largest r but this one does not. *Answer:* define $g(1) = 1$ and $g(n+1) = g(n) + \lceil g(n)^r \rceil$; without the composite there is no upper bound on $g \circ g$ to cap growth, so faster growth is never punished.
2. (drill) Let $g\colon \mathbb{N} \to \mathbb{N}$ be strictly increasing with $g(n) \geq n^s$ for all $n \geq n_0$, where $s \geq 1$ is an integer. Show $g(g(n)) \geq n^{s^2}$ for all $n \geq n_0$. *Answer:* $g(n) \geq n \geq n_0$, so $g(g(n)) \geq g(n)^s \geq (n^s)^s$.
3. (drill) Show that $\varphi(s) = rs^2 + 1$ has a real fixed point iff $r \leq \frac{1}{4}$, and that for $r = \frac{1}{4}$ the orbit $s_0 = 0$, $s_{j+1} = \varphi(s_j)$ increases to 2. *Answer:* $rs^2 - s + 1 = 0$ has discriminant $1 - 4r$; for $r = \frac{1}{4}$, $\varphi(s) - s = \frac{1}{4}(s-2)^2 \geq 0$ and φ maps $[0, 2)$ into $[1, 2)$, so the orbit is increasing and bounded by 2, hence converges to the unique fixed point 2.

Chapter 2

Putnam 2024

2.1 A1. Valuation bookkeeping kills a Fermat-type equation

Determine all positive integers n for which there exist positive integers a, b, and c satisfying

$$2a^n + 3b^n = 4c^n.$$

Read it out loud

This is a homogeneous Diophantine equation of degree n in three unknowns, with three terms and the coefficients 2, 3, 4. The quantifier structure is "determine all n such that a solution exists", which on the Putnam almost always means: the answer set is tiny, one construction settles the members, and one structural obstruction settles the non-members. The fields wired in are elementary number theory (divisibility, p-adic valuations, residues) and nothing else; the equation is a Fermat lookalike, but the coefficients, not Fermat, are the whole story.

Read the coefficients as prime powers: $2 = 2^1$, $3 = 3^1$, $4 = 2^2$. Every unknown enters as an nth power, so the 2-adic valuation of each term is (the valuation of its coefficient) plus (a multiple of n). Thus, in other words, the three terms have 2-adic valuations congruent to $1, 0, 2$ modulo n. That sentence is the first useful cue, and it should be on the page within thirty seconds, next to the observation that $n = 1$ is a linear equation that obviously has solutions.

What is really being tested is whether you treat "b is even, so substitute $b = 2b'$" as a step to grind through or as a symptom of a valuation statement. The examiners planted 2 and 4 so that the exponents 1 and 2 differ, and they left $n = 2$ as the single case where the 2-adic residues tie and you must resolve the tie with a residue table (modulo 3 is the quickest; squares modulo 8 also work).

Approaches, ranked worst to best

1. **Search and guess.** *Cue:* "determine all n". *Circuit:* try small n, hope for a pattern. (No proof of impossibility is ever produced; you can find $(1, 2, 2)$ for $n = 1$ and nothing else, which is evidence, not mathematics.)

2. **Parity descent.** *Cue:* even coefficients 2 and 4. *Circuit:* normalise $\gcd(a, b, c) = 1$, deduce b even, substitute, repeat. (Correct for $n \geq 3$, and it is what the official solution does, but it costs three substitutions, and it stalls for $n = 2$ without warning: after b and a are even you are left with $2a'^2 + 3b'^2 = c^2$, on which parity says nothing more. You must notice the stall and reroute, either to the prime 3 or to the finer table of squares modulo 8.)

3. **Residues modulo** 3. *Cue:* the coefficient 3; nth powers are squares when n is even. *Circuit:* quadratic residues modulo 3 are 0 and 1. (Kills every even n in three lines, but says nothing for odd n, since cubes cover all residues modulo 3. Needed only for $n = 2$.)

4. **Valuation comparison.** *Cue:* homogeneous sum of three terms with prime-power coefficients. *Circuit:* in $x + y = z$ the minimum p-adic valuation is attained at least twice. (Best. No normalisation, no substitution: the 2-adic valuations are $1, 0, 2$ modulo n, pairwise distinct for $n \geq 3$, contradiction in one line. For $n = 2$ the same lemma at the prime 3 forces the tie between a and c, and one residue check finishes.)

The ideal solution

The answer is $\boxed{n = 1}$.

For $n = 1$ the triple $(a, b, c) = (1, 2, 2)$ works: $2 + 6 = 8$.

Lemma 2.1.1 (tie at the minimum)**.** *Let p be a prime and let x, y, z be nonzero integers with $x + y = z$. Then the minimum of $v_p(x), v_p(y), v_p(z)$ is attained by at least two of the three.*

Proof. If $v_p(x) = v_p(y)$ then $v_p(z) \geq v_p(x)$ and the minimum is already attained twice. Otherwise, say $v_p(x) = u < w = v_p(y)$, and write $x = p^u x'$, $y = p^w y'$ with $p \nmid x'y'$. Then $z = p^u(x' + p^{w-u}y')$ and $p \nmid x' + p^{w-u}y'$, so $v_p(z) = u = v_p(x)$, which is the minimum. The case $v_p(y) < v_p(x)$ is symmetric. □

Case $n \geq 3$. Suppose $2a^n + 3b^n = 4c^n$ with a, b, c positive. Put $\alpha = v_2(a)$, $\beta = v_2(b)$, $\gamma = v_2(c)$. Then

$$v_2(2a^n) = 1 + n\alpha, \qquad v_2(3b^n) = n\beta, \qquad v_2(4c^n) = 2 + n\gamma.$$

Modulo n these are $1, 0, 2$, which are pairwise distinct because $n \geq 3$. Hence the three valuations are pairwise distinct integers, and the minimum is attained exactly once, contradicting the lemma applied to $x = 2a^n$, $y = 3b^n$, $z = 4c^n$. No solution exists.

Case $n = 2$. Suppose $2a^2 + 3b^2 = 4c^2$. Now use the prime 3: with $\alpha = v_3(a)$, $\beta = v_3(b)$, $\gamma = v_3(c)$,

$$v_3(2a^2) = 2\alpha, \qquad v_3(3b^2) = 1 + 2\beta, \qquad v_3(4c^2) = 2\gamma.$$

The middle valuation is odd and the outer two are even, so the tie at the minimum demanded by the lemma must be between the outer two: $\alpha = \gamma$ and $2\alpha < 1 + 2\beta$. Write $a = 3^\alpha a'$ and $c = 3^\alpha c'$ with $3 \nmid a'c'$, and divide the equation by 9^α:

$$2a'^2 + \frac{3b^2}{9^\alpha} = 4c'^2, \qquad v_3\left(\frac{3b^2}{9^\alpha}\right) = 1 + 2\beta - 2\alpha \geq 1,$$

so the middle term is an integer divisible by 3. Reducing modulo 3 gives $2a'^2 \equiv c'^2 \pmod 3$. A square not divisible by 3 is $\equiv 1 \pmod 3$, so this reads $2 \equiv 1 \pmod 3$, absurd. No solution exists.

Thus solutions exist exactly when $n = 1$.

Layer 1: WHAT

Block 1: settle $n = 1$ by exhibiting $(1, 2, 2)$. Block 2: state the lemma that in $x + y = z$ the minimum p-adic valuation is attained twice. Block 3: for $n \geq 3$, read off the 2-adic valuations $1 + n\alpha$, $n\beta$, $2 + n\gamma$, note they are $1, 0, 2$ modulo n, hence distinct, hence the lemma is violated. Block 4: for $n = 2$, change prime to 3, use parity of the valuations to locate the forced tie (a with c), strip the common power of 3, and reduce modulo 3 to hit $2 \equiv 1$.

Juxtaposition. The nominal route normalises $\gcd(a, b, c) = 1$, reads the equation modulo 2 to get b even, substitutes $b = 2b'$, divides by 2, gets a even, substitutes again, gets c even, contradiction; then discovers that for $n = 2$ the third step does not close and starts over modulo 3. The ideal route never substitutes anything: it states what each substitution was measuring (a valuation) and compares the three measurements at once. The bifurcation point is the sentence "b must be even". The zombie writes $b = 2b'$; you write $v_2(3b^n) = n\beta$ and ask what the other two valuations are.

Layer 2: HOW

Block 1. **Cue.** "Determine all n" with an existential inner quantifier. **Why natural.** The examiners never ask this when the answer is "all n". The answer set is small and its members are certified by a construction, so the cheapest first move is to test $n = 1$, where the equation is linear and any triple with $2a + 3b$ divisible by 4 works. **Link to the next block.** Having certified $n = 1$, the remaining job is a uniform impossibility proof for $n \geq 2$, and impossibility of a homogeneous equation is a local (one prime at a time) statement.

Block 2. **Cue.** Three terms, one equation, small prime-power coefficients. **Why natural.** Any sum of two terms equal to a third is governed by the ultrametric inequality: the smallest p-adic valuation cannot stand alone, because the other two terms would then sum to something of strictly larger valuation. This is the definition-level content of "divide by the gcd" in the official solution: choosing a primitive solution is choosing the minimum valuation and asking who attains it. **Link to the next block.** The lemma converts the equation into a statement about three integers, and homogeneity makes those integers trivial to compute modulo n.

Block 3. **Cue.** Coefficients 2 and 4 are powers of the same prime with different exponents, and 3 is coprime to it. **Why natural.** Since $v_2(k\,t^n) = v_2(k) + n\,v_2(t)$, the unknown contributes only a multiple of n; the residues of the coefficient valuations modulo n are $1, 0, 2$. Three distinct residues means three distinct valuations, so no tie is possible. This is where you see why the problem was set with $2, 3, 4$ and not $2, 3, 8$ (exponent 3 would tie with exponent 0 when $n = 3$). **Link to the next block.** The same residues collapse when $n = 2$ ($1, 0, 0$: a tie between the b-term and the c-term is permitted), which tells you exactly why $n = 2$ needs a residue table. The quickest table is at the only other prime visible, 3; the tie at 2 can also be resolved with squares modulo 8, at the cost of one more substitution.

Block 4. **Cue.** At $n = 2$ the 2-adic argument produces no contradiction; the coefficient 3 is the other prime in the problem. **Why natural.** At the prime 3 the valuations $2\alpha, 1 + 2\beta, 2\gamma$ have parities even, odd, even, so the lemma forces $\alpha = \gamma$; after dividing by 9^α the leading parts $2a'^2$ and $4c'^2$ must agree modulo 3, and a residue table (squares modulo 3 are $0, 1$) closes it. The residue step is natural because a tie in valuation is precisely the statement that the leading coefficients cancel modulo p. **Link to the next block.** Nothing remains: $n = 1$ certified, $n \geq 3$ and $n = 2$ refuted.

Layer 3: WHY

The truth underneath is that this equation fails locally: there is a prime p at which it has no nontrivial solution even in the p-adic integers ($p = 2$ for $n \geq 3$, and $p = 3$ or $p = 2$ for $n = 2$), and the valuation lemma is the ultrametric inequality $v_p(x + y) \geq \min(v_p(x), v_p(y))$ with equality when the valuations differ. Homogeneity of degree n reduces the whole obstruction to arithmetic modulo n on the coefficient valuations. When the residues are pairwise distinct (here $1, 0, 2 \bmod n$ for $n \geq 3$), the obstruction is immediate; when two residues coincide, the leading parts of the tied terms must cancel modulo p, and that is a residue computation (quadratic residues for $n = 2$, cubic residues for $n = 3$, and so on).

The discernment mechanism: before touching the equation, list the primes dividing the coefficients and write the coefficient valuations modulo n for each. Distinct residues at some prime finish that n; a tie at every prime is resolved with residues, remembering that ties can go either way (the third mirror drill has a tie with a solution). Train it by refusing to write $b = 2b'$ ever again; write v_2 instead. The examiners nudged you with the visible 2 and 4; the nudge toward 3 at $n = 2$ is simply that 3 is the only other prime on the page.

Revolving concepts

p-adic valuation. $v_p(m)$ is the exponent of p in m; $v_p(xy) = v_p(x) + v_p(y)$ and $v_p(x + y) \geq \min(v_p(x), v_p(y))$ with equality if the two valuations differ. Consequence: in any vanishing sum of nonzero integers, the minimum valuation is attained at least twice. See Book 1, field: Number theory, topic: valuations and the ultrametric inequality.

Infinite descent as a recursion. The official route "b even, then a even, then c even, contradicting gcd $= 1$" is the recursion $(a, b, c) \mapsto (a/2, b/2, c/2)$ on solutions, and the general solution method for such a recursion is: a strictly decreasing sequence of positive integers terminates, so no solution

exists. The same recursion appears in every proof that $\sqrt{2}$ is irrational, in $x^2 + y^2 = 3z^2$, and in the $n = 4$ case of Fermat. Its closed form is exactly the valuation lemma: instead of running the descent, compare valuations once. See Book 1, field: Number theory, topic: descent.

Residue tables. Squares modulo 3, 4, 8 are $\{0, 1\}$, $\{0, 1\}$, $\{0, 1, 4\}$; cubes modulo 7 and 9 are $\{0, \pm 1\}$; -1 is a square modulo an odd prime p iff $p \equiv 1 \pmod 4$. These tables resolve valuation ties. See Book 1, field: Number theory, topic: residues of powers.

Local obstruction. An equation with no primitive solution modulo p^k for some p, k has no primitive integer solution; here that happens modulo 8 for $n \geq 3$ and modulo 9 for $n = 2$. See Book 1, field: Number theory, topic: local obstructions.

Circuit Bank

- **WHEN** you see a homogeneous equation $\sum k_i t_i^n = 0$ with prime-power coefficients **DO** write $v_p(k_i) \bmod n$ for each prime p dividing some k_i **BECAUSE** the unknowns contribute multiples of n, and a vanishing sum needs a tie at the minimum valuation, so distinct residues give an instant contradiction
- **WHEN** the valuation residues tie at a prime p **DO** strip the common power of p from the tied terms and reduce modulo p using the residue table of nth powers **BECAUSE** a tie means the leading parts cancel modulo p, which is a finite check that either fails (no solution) or succeeds (look for a solution)
- **WHEN** a model solution says "assume $\gcd(a, b, c) = 1$" and then descends **DO** read it as a valuation comparison and write the comparison instead **BECAUSE** descent is the recursion whose closed form is the ultrametric lemma; the closed form costs one line, the recursion costs three substitutions
- **WHEN** "determine all n" with an existence quantifier **DO** certify the small cases by construction first **BECAUSE** the impossibility argument must not waste effort on cases that hold, and the construction usually reveals which prime the obstruction lives at

Backtesting

1. First useful cue: the coefficients $2, 3, 4$ are $2^1, 3, 2^2$, and the unknowns are nth powers.
2. Method the expression suggested: p-adic valuations of the three terms, compared modulo n.
3. Where you would hesitate, and the thought to reinforce: at $n = 2$, when the 2-adic argument ties. The thought: a tie is information, it says which two terms lead; resolve it with a residue table, at the other prime on the page (3) or with squares modulo 8.
4. The trap the question sets: the visible Fermat shape invites you to think of $n \geq 3$ as the hard case, when it is the easy case; the real work is the one small exponent where residues coincide.
5. What makes you recognise it faster next time: any coefficient pattern (p^i, q, p^j) with $i \neq j$ screams "valuation residues $i, 0, j$ modulo n".
6. The reusable decision rule: in a vanishing homogeneous sum, compare coefficient valuations modulo the degree; distinct residues finish, tied residues go to a residue table.

Mirror drills

1. Show that $5a^3 + 25b^3 = c^3$ has no solution in positive integers. *Answer:* 5-adic valuations are $1, 2, 0$ modulo 3, pairwise distinct, so the minimum is attained once.
2. Show that $x^2 + y^2 = 3z^2$ has no solution in positive integers. *Answer:* 3-adic valuations $2\alpha, 2\beta, 1 + 2\gamma$ force $\alpha = \beta$; after dividing by 9^α, $x'^2 + y'^2 \equiv 1 + 1 \not\equiv 0 \pmod 3$.

3. Determine all n for which $a^n + 2b^n = 4c^n$ has a solution in positive integers. *Answer:* $n \in \{1, 2\}$. For $n \geq 3$ the 2-adic residues $0, 1, 2$ are distinct. For $n = 2$ the tie is between a and c and it is resolvable: $(a, b, c) = (2, 4, 3)$ gives $4 + 32 = 36$. Ties can go either way; the residue check decides.

2.2 A2. Expand the iterate modulo the fixed-point polynomial squared

For which real polynomials p is there a real polynomial q such that

$$p(p(x)) - x = (p(x) - x)^2 q(x)$$

for all real x?

Read it out loud

This is a divisibility statement in $\mathbb{R}[x]$: the second iterate of p minus the identity is divisible by the square of the first iterate minus the identity. The object the examiners want you to name is $r(x) = p(x) - x$, the fixed-point polynomial of p (its complex roots are exactly the fixed points of p). The fields wired in are polynomial algebra (divisibility, degrees, units in $\mathbb{R}[x]$), the calculus of polynomials (the derivative, Taylor expansion, which for polynomials is an exact finite identity), and a whiff of dynamics (iterates, fixed points, the multiplier $p'(\alpha)$ at a fixed point α).

The first useful cue is that the argument of the outer p is $p(x) = x + r(x)$. So $p(p(x)) = p(x + r)$: the outer p is being evaluated at a perturbation of x by r, and the modulus is r^2. Perturbation plus a square modulus means first-order Taylor expansion, and for polynomials that expansion is not an approximation but an identity: $p(x + r) = p(x) + rp'(x) + r^2(\cdots)$. Within thirty seconds you should have written $r = p - x$, $p(p(x)) = p(x + r) \equiv p(x) + rp'(x) \pmod{r^2}$, and the test cases $p = x + c$ and $p = -x + c$ (the involutions and translations, for which the left side is $2c$ or 0).

What is being tested is whether you expand a composition coefficientwise (zombie) or structurally (in powers of the perturbation). The degree check $\deg(p \circ p - x) = d^2$ versus $\deg r^2 = 2d$ gives no contradiction for $d \geq 2$, and that is the examiners telling you that degrees alone will not do it: you need the first-order term.

Approaches, ranked worst to best

1. **Coefficient bashing.** *Cue:* "for which polynomials". *Circuit:* write $p = a_d x^d + \cdots$, expand $p(p(x))$, compare. (Degree 1 is fine; degree 2 already produces a system in three unknowns; general d is hopeless. Consumption without analysis.)
2. **Degree comparison alone.** *Cue:* a divisibility $A \mid B$. *Circuit:* $\deg A \leq \deg B$ unless $B = 0$. (Stalls immediately since $d^2 \geq 2d$ for $d \geq 2$. Worth one line as a sanity check, and its failure is the cue that first-order information is needed.)
3. **Multipliers at fixed points.** *Cue:* $(p(x) - x)^2$: double roots at fixed points. *Circuit:* differentiate; at a fixed point α, $(p \circ p)'(\alpha) = p'(\alpha)^2$. (Sound, and it is the official second solution: r divides $(p' - 1)(p' + 1) = r'(r' + 2)$, and a multiplicity argument shows $r \mid r' + 2$. It costs a separate treatment of multiple roots and a complex-roots argument. Correct but more ink.)
4. **Taylor modulo r^2.** *Cue:* $p(p(x)) = p(x + r)$ with modulus r^2. *Circuit:* $g(x + r) \equiv g(x) + rg'(x) \pmod{r^2}$ for any polynomial g. (Best. The condition becomes $r^2 \mid r(1 + p')$, so $r = 0$ or $r \mid 1 + p'$, and a degree comparison finishes in three lines with no root analysis at all.)

The ideal solution

The answer is: $p(x) = x + c$ or $p(x) = -x + c$ for a real constant c (the case $c = 0$ of the first family is $p(x) = x$).

These work. If $p(x) = x + c$ then $p(p(x)) - x = 2c$ and $(p(x) - x)^2 = c^2$; take $q = 2/c$ if $c \neq 0$, and any q if $c = 0$. If $p(x) = -x + c$ then $p(p(x)) = -(-x + c) + c = x$, so the left side is 0 and $q = 0$ works.

Nothing else works. Let $r(x) = p(x) - x \in \mathbb{R}[x]$.

Lemma 2.2.1 (polynomial Taylor expansion). *For any $g \in \mathbb{R}[x]$ and any $r \in \mathbb{R}[x]$, the polynomial $g(x+r) - g(x) - r\,g'(x)$ is divisible by r^2 in $\mathbb{R}[x]$.*

Proof. Both sides are linear in g, so it suffices to take $g = x^k$. By the binomial theorem,

$$(x+r)^k - x^k - kx^{k-1}r = \sum_{j=2}^{k} \binom{k}{j} x^{k-j} r^j,$$

and every term on the right contains the factor r^2 (for $k \le 1$ the sum is empty and the left side is 0). □

Apply the lemma with $g = p$: there is $s \in \mathbb{R}[x]$ with $p(x+r) = p(x) + rp'(x) + r^2 s(x)$. Since $p(x) = x + r$,

$$p(p(x)) - x = p(x+r) - x = r + rp'(x) + r^2 s(x) = r\,(1 + p'(x)) + r^2 s(x).$$

Hence r^2 divides $p(p(x)) - x$ if and only if r^2 divides $r(1+p')$.

If $r = 0$ then $p(x) = x$, which is in the list. Assume $r \neq 0$; cancelling r (legitimate in the integral domain $\mathbb{R}[x]$), the condition is $r \mid 1 + p'$.

If $1 + p' = 0$ then $p' = -1$ and $p(x) = -x + c$ for some real c, which is in the list.

Otherwise $1 + p' \neq 0$ and divisibility gives $\deg r \le \deg(1 + p')$. Now compare degrees. If $\deg p \ge 2$ then $\deg r = \deg p$ while $\deg(1 + p') \le \deg p - 1$, contradiction. If $\deg p \le 0$ (so p is a constant, possibly 0) then $\deg r = 1$ while $1 + p' = 1$ has degree 0, contradiction. So $\deg p = 1$: $p(x) = mx + c$ with $m \neq 0$, whence $r = (m-1)x + c$ and $1 + p' = 1 + m$, a nonzero constant. A polynomial dividing a nonzero constant is a nonzero constant, so $m - 1 = 0$ and $p(x) = x + c$, which is in the list.

Therefore the polynomials are exactly $p(x) = x + c$ and $p(x) = -x + c$, $c \in \mathbb{R}$.

Layer 1: WHAT

Block 1: name $r = p - x$ and rewrite the composition as $p(x + r)$. Block 2: expand $p(x + r)$ to first order modulo r^2 (the binomial lemma). Block 3: the condition collapses to $r^2 \mid r(1 + p')$, hence to $r = 0$ or $r \mid 1 + p'$. Block 4: the branch $1 + p' = 0$ yields $-x + c$; the other branch is a degree comparison that forces $\deg p = 1$ and then $m = 1$. Block 5: verify both families.

Juxtaposition. The nominal route treats $p(p(x))$ as an unknown polynomial of degree d^2 and tries to extract information from its coefficients, or differentiates and chases roots of r with their multiplicities. The ideal route treats $p(p(x))$ as p evaluated at a point close to x, where "close" means "differs by something whose square is zero in the quotient ring". The bifurcation point is the first line after reading: writing $p(p(x))$ versus writing $p(x + r)$. Everything after that is forced.

Layer 2: HOW

Block 1. **Cue.** The same expression $p(x) - x$ appears squared on the right and, hidden, as the argument of the outer p on the left. **Why natural.** A polynomial identity involving $p \circ p$ and $p - x$ is a statement about p near its fixed points. Naming $r = p - x$ makes $p(x) = x + r$ a substitution you can perform inside the outer p; you do this because the modulus r^2 tells you that in the quotient ring $\mathbb{R}[x]/(r^2)$ the element $x + r$ is "x plus a nilpotent". **Link to the next block.** A polynomial evaluated at x plus a nilpotent of square zero is its first-order Taylor expansion, exactly.

Block 2. **Cue.** Perturbation $x \mapsto x + r$ with modulus r^2. **Why natural.** The identity $g(x + \varepsilon) = g(x) + \varepsilon g'(x)$ when $\varepsilon^2 = 0$ is the algebraic definition of the derivative (dual numbers). For polynomials it is the binomial theorem applied monomial by monomial, so no analysis is invoked and no "approximation" needs justifying. **Link to the next block.** Substituting back turns the

condition into a divisibility between r^2 and $r(1+p')$, which is a statement about r and p' only, both of degree at most $\deg p$.

Block 3. **Cue.** $r^2 \mid r \cdot (\text{something})$. **Why natural.** Cancelling a nonzero common factor in an integral domain is legal; you must first dispose of $r = 0$ separately (that is the polynomial $p = x$, which does work). The split into $r = 0$ and $r \neq 0$ is the first edge case a grader looks for. **Link to the next block.** $r \mid 1 + p'$ is a divisibility between two polynomials whose degrees you control, and controlled degrees mean a degree comparison.

Block 4. **Cue.** A divisibility $A \mid B$ with $\deg A$ known and $\deg B$ known. **Why natural.** If $B \neq 0$ then $\deg A \leq \deg B$; so the second edge case, $B = 1 + p' = 0$, must be split off, and it is precisely the family $-x + c$. Then $\deg r$ equals $\deg p$ when $\deg p \geq 2$, equals 1 when p is constant, and drops only when p is linear with slope 1; meanwhile $\deg(1 + p') \leq \deg p - 1$. The only survivor is the linear case, where "a divisor of a nonzero constant is a nonzero constant" finishes. **Link to the next block.** The candidates are now a list, and a list must be verified, which is Block 5.

Block 5. **Cue.** The problem asks "for which p", so the answer is a set, and set equality needs both inclusions. **Why natural.** Necessity has been shown; sufficiency is two one-line computations. Forgetting them costs a point; forgetting that $c = 0$ is allowed (and that q can be anything when both sides vanish) costs another. **Link to the next block.** None; the proof is closed.

Layer 3: WHY

The mathematical truth is that divisibility by the square of r is a tangency condition, and tangency is first-order information. In the ring $\mathbb{R}[x]/(r^2)$ the class of r is a nonzero nilpotent, $p(x) = x + r$ there, and evaluating any polynomial at $x + r$ produces exactly $g(x) + rg'(x)$. So the whole problem is the single congruence $p \circ p \equiv x + r(1 + p') \pmod{r^2}$, and the question "when is $p \circ p \equiv x$" becomes "when does r divide $1 + p'$". At a simple fixed point α this says $p'(\alpha) = -1$, the multiplier of an involution, and at a fixed point of multiplicity $m \geq 2$ it says $1 + p'$ vanishes to order m there, which forces r to be constant or $1 + p'$ to be identically zero. That is the structural reason the answer is "translations and reflections": these are the only polynomials that are either fixed-point free with p' never -1, or involutions.

The discernment mechanism is a two-step reflex: a composition $f(g(x))$ with $g = x + (\text{small})$ is expanded in the small quantity; a divisibility between polynomials of controlled degree is closed by degree comparison after the zero cases are removed. You train the first step by rewriting every iterate you meet as an evaluation at $x + r$, and the second by never writing "$A \mid B$" without asking whether B could be zero. The examiners nudged with the square on the right (first-order information suffices) and with the fact that the naive degree count fails (so you must find the first-order information).

Revolving concepts

Formal Taylor expansion. For $g \in \mathbb{R}[x]$ and any polynomial h, $g(x + h) = \sum_{k \geq 0} g^{(k)}(x) h^k / k!$, a finite exact identity; modulo h^2 only $g + hg'$ survives. Equivalent formulation: in $\mathbb{R}[x][\varepsilon]/(\varepsilon^2)$, $g(x + \varepsilon) = g(x) + \varepsilon g'(x)$, which can be taken as the definition of the formal derivative. See Book 1, field: Polynomials, topic: formal derivative and Taylor expansion.

Degrees and units. In $\mathbb{R}[x]$, $\deg(AB) = \deg A + \deg B$, $A \mid B \neq 0$ implies $\deg A \leq \deg B$, and the units are the nonzero constants. See Book 1, field: Polynomials, topic: divisibility in $k[x]$.

Iterates modulo r^2: the generalised recursion. Let $r = p - x$ and define $p^{\circ k}$ by $p^{\circ 1} = p$, $p^{\circ(k+1)} = p \circ p^{\circ k}$. Then

$$p^{\circ k}(x) \equiv x + r\left(1 + p' + p'^2 + \cdots + p'^{k-1}\right) \pmod{r^2}.$$

Proof by induction: if $p^{\circ k} = x + ru_k + r^2(\cdots)$ then $p^{\circ(k+1)} = p(x + ru_k + r^2(\cdots)) \equiv p(x) + ru_k p'(x) = x + r(1 + u_k p')$, so $u_{k+1} = 1 + p'u_k$ with $u_1 = 1$, a first-order linear recursion whose closed form is the geometric sum. The general method: a recursion of the form $u_{k+1} = Au_k + B$ with polynomial A, B is solved by the geometric sum $u_k = B(1 + A + \cdots + A^{k-1}) + A^{k-1}u_1$. The problem is the case $k = 2$, where $u_2 = 1 + p'$. See Book 1, field: Sequences and recurrences, topic: first-order linear recurrences; and field: Functional equations, topic: iterates and fixed points.

Fixed points and multipliers. If $p(\alpha) = \alpha$ then $(p \circ p)'(\alpha) = p'(\alpha)^2$ by the chain rule, so $r^2 \mid p \circ p - x$ forces $p'(\alpha)^2 = 1$ at every simple fixed point; the official second solution builds on this. Also $p(x) - x$ always divides $p(p(x)) - x$, because $g(y) - g(x)$ is divisible by $y - x$ for any polynomial g. See Book 1, field: Polynomials, topic: $y - x$ divides $g(y) - g(x)$.

Circuit Bank

- **WHEN** you see a composition $f(g(x))$ where $g(x) = x + r(x)$, especially with r^2 or r^k as a modulus **DO** write $f(x + r)$ and expand in powers of r, keeping terms below the modulus **BECAUSE** polynomial Taylor expansion is an exact identity, and modulo r^k only the first k terms survive

- **WHEN** a divisibility $A \mid B$ between polynomials is your remaining condition **DO** split off $B = 0$, then compare degrees **BECAUSE** in $k[x]$ a nonzero multiple of A has degree at least $\deg A$, and a divisor of a nonzero constant is a constant

- **WHEN** a condition involves the square of $p(x) - x$ **DO** think "tangency at fixed points, first derivative" **BECAUSE** divisibility by a square is vanishing to second order, which is controlled by p' at the roots of $p - x$

- **WHEN** the question is "for which polynomials" **DO** test degrees 0 and 1 by hand and write down the candidates before proving anything **BECAUSE** the answer is a small family, and knowing it tells you which branches of the proof are the real ones

Backtesting

1. First useful cue: the outer argument $p(x)$ equals $x + (p(x) - x)$, and the modulus is $(p(x) - x)^2$.

2. Method the expression suggested: first-order Taylor expansion of p at x with increment r, modulo r^2.

3. Where you would hesitate, and the thought to reinforce: after reaching $r \mid 1 + p'$, the temptation is to look at roots. The thought: you control both degrees, so compare them, after removing $1 + p' = 0$.

4. The trap the question sets: the naive degree count $d^2 \geq 2d$ looks like it permits large d; and the two edge cases $r = 0$ and $1 + p' = 0$ are each a full family of answers, not degenerate leftovers.

5. What makes you recognise it faster next time: any iterate $p \circ p$ next to $p - x$ is an evaluation at $x + r$; say it out loud.

6. The reusable decision rule: composition at a perturbation of x goes to Taylor; divisibility with known degrees goes to degree comparison; every branch where a side vanishes is an answer, not an exception.

Mirror drills

1. Show that for every polynomial p, $p(x) - x$ divides $p(p(x)) - x$. *Answer:* $p(p(x)) - p(x)$ is $g(y) - g(x)$ with $y = p(x)$, divisible by $y - x = p(x) - x$; add $p(x) - x$.
2. Find all real polynomials p for which $(p(x) - x)^2$ divides $p(p(x)) - p(x)$. *Answer:* modulo r^2 the left side is rp', so $r = 0$ or $r \mid p'$; degree comparison leaves the constants (where $p' = 0$) and $p = x + c$.
3. Let $r = p(x) - x \neq 0$. Show that r^2 divides $p(p(p(x))) - x$ if and only if r divides $1 + p' + p'^2$. *Answer:* the iterate recursion $u_{k+1} = 1 + p'u_k$ gives $p^{\circ 3} \equiv x + r(1 + p' + p'^2) \pmod{r^2}$.

2.3 A3. Where the entry two sits in a random tableau

Let S be the set of bijections

$$T\colon \{1,2,3\} \times \{1,2,\dots,2024\} \to \{1,2,\dots,6072\}$$

such that $T(1,j) < T(2,j) < T(3,j)$ for all $j \in \{1,2,\dots,2024\}$ and $T(i,j) < T(i,j+1)$ for all $i \in \{1,2,3\}$ and $j \in \{1,2,\dots,2023\}$. Do there exist a and c in $\{1,2,3\}$ and b and d in $\{1,2,\dots,2024\}$ such that the fraction of elements T in S for which $T(a,b) < T(c,d)$ is at least $1/3$ and at most $2/3$?

Read it out loud

Strip the notation. T is a filling of a 3×2024 array with the numbers 1 to 6072, each once, increasing left to right along every row and top to bottom down every column. That is the definition of a standard Young tableau of rectangular shape with three rows and $n = 2024$ columns, and S is the set of all of them. The question asks whether two cells exist whose relative order, under a uniformly random tableau, is balanced: probability in $[1/3, 2/3]$. So this is an enumerative combinatorics question (counting tableaux) wearing probability vocabulary, and the fields wired in are Young tableaux, the hook length formula, and the elementary poset fact that a tableau is a linear extension of the cell order.

Two immediate observations. First, if one cell is weakly above and weakly left of the other, the order is forced and the fraction is 0 or 1; so the pair must be incomparable: one cell strictly lower and strictly further left than the other. Second, you choose the pair. An existence question with a free choice is an invitation to choose the pair for which the event is simplest, and the simplest events in a tableau concern the smallest entries, whose positions are nearly forced: 1 is at $(1,1)$, and 2 is at $(1,2)$ or $(2,1)$. Thus the event $T(2,1) < T(1,2)$ is exactly "the entry 2 sits at $(2,1)$". Within thirty seconds you should have written that sentence and the words "hook length formula".

What is being tested is (i) recognition of the object, (ii) the reflex to pick the pair that turns a comparison into the position of a single small entry, and (iii) the technique of deleting the smallest entries and rotating the leftover skew shape into a straight shape so the hook length formula applies. The numbers $1/3$ and $2/3$ are the examiners hinting that the natural fractions cluster near $1/3$ (three rows) and that the correct pair lands just above it.

Approaches, ranked worst to best

1. **Attack a general pair.** *Cue:* "the fraction of T with $T(a,b) < T(c,d)$". *Circuit:* count linear extensions with one extra relation. (For an arbitrary incomparable pair this is a hard count with no closed form; you would drown. Wrong quantifier reading: you get to choose the pair.)
2. **Symmetry hunting.** *Cue:* "fraction between $1/3$ and $2/3$", which smells like $1/2$. *Circuit:* find an involution on S that swaps the order of two cells. (The only symmetry of a $3 \times n$ rectangle is rotation by 180° with complementation of entries, and it sends the event for a pair to the event for the antipodal pair; for antipodal cells the event is mapped to itself, not to its complement. Thirty seconds, then abandon.)
3. **Ballot words and a three-row recursion.** *Cue:* rows increase, columns increase. *Circuit:* read the row index of $1, 2, \dots, 3n$ as a lattice word; count words by a recursion on the row lengths. (Correct, and the official remark proves the three-row count this way, but verifying the induction identity is a page of algebra. Costs too much ink in the arena.)
4. **Position of the entry 2 plus hook lengths.** *Cue:* 2 must be adjacent to the corner. *Circuit:* delete the smallest entries, rotate the skew shape to a straight shape, apply the hook length formula to both shapes and take the ratio. (Best. The ratio of two hook products collapses to $(n+1)/(3n-1)$ in four lines.)

The ideal solution

Yes. Take $(a,b) = (2,1)$ and $(c,d) = (1,2)$. Write $n = 2024$; the argument works for every $n \geq 2$.

Regard $T \in S$ as a $3 \times n$ array whose entry in row i, column j is $T(i,j)$; the conditions say that every row increases from left to right and every column increases from top to bottom. So S is the set of standard Young tableaux of shape (n,n,n).

Step 1: the event. For $T \in S$ and a cell (i,j), every cell weakly above and weakly to the left of (i,j) carries a smaller entry, and there are $ij-1$ such cells other than (i,j) itself. The entry 2 has exactly one smaller entry, so it lies in a cell with $ij-1 \leq 1$ other than $(1,1)$, which carries 1: hence 2 is at $(1,2)$ or at $(2,1)$. If $T(2,1) = 2$ then $T(1,2) \geq 3 > T(2,1)$; if $T(1,2) = 2$ then $T(2,1) \geq 3 > T(1,2)$. Therefore

$$T(2,1) < T(1,2) \iff T(2,1) = 2.$$

Step 2: the count as a smaller shape. Let $S_2 = \{T \in S : T(2,1) = 2\}$. For $T \in S_2$ delete the cells $(1,1)$ and $(2,1)$, which carry 1 and 2; what remains is the set of cells $D = \{(1,j),(2,j) : 2 \leq j \leq n\} \cup \{(3,j) : 1 \leq j \leq n\}$ filled with $3,\dots,3n$, increasing along rows and down columns. Apply the cell map $(i,j) \mapsto (4-i,\ n+1-j)$ and the entry map $k \mapsto 3n+1-k$. The cell map sends D onto the straight shape $\lambda = (n, n-1, n-1)$ (row 3 of D becomes row 1 with n cells, rows 2 and 1 of D become rows 2 and 3 with $n-1$ cells each, aligned at the left), the entries become $1,\dots,3n-2$, and since both the cell order and the entry order are reversed, "increasing along rows and down columns" is preserved in both directions. Conversely, a standard Young tableau of shape λ pulled back through these maps and completed by 1 at $(1,1)$ and 2 at $(2,1)$ is an element of S_2: the two new entries are smaller than everything else and $(1,1)$ lies above $(2,1)$. Hence $|S_2| = f^{(n,n-1,n-1)}$, where f^{μ} denotes the number of standard Young tableaux of shape μ; likewise $|S| = f^{(n,n,n)}$.

Step 3: hook lengths. You must know the following theorem (Frame, Robinson and Thrall): for a partition μ with N cells,

$$f^{\mu} = \frac{N!}{\prod_{c \in \mu} h(c)},$$

where the hook length $h(c)$ of a cell is 1 plus the number of cells to its right in its row plus the number of cells below it in its column.

For $\mu = (n,n,n)$: the cell $(1,j)$ has hook $n-j+3$, so row 1 contributes $(n+2)(n+1)\cdots 3 = (n+2)!/2$; row 2 contributes $(n+1)!$ and row 3 contributes $n!$. Thus

$$f^{(n,n,n)} = \frac{2\,(3n)!}{(n+2)!\,(n+1)!\,n!}.$$

For $\lambda = (n, n-1, n-1)$: in row 1 the cells $(1,j)$ with $j \leq n-1$ have two cells below and $n-j$ to the right, hook $n-j+3$, giving $(n+2)(n+1)\cdots 4 = (n+2)!/6$, and the cell $(1,n)$ has hook 1; row 2 has hooks $n, n-1, \dots, 2$, product $n!$; row 3 has hooks $n-1,\dots,1$, product $(n-1)!$. Thus

$$f^{(n,n-1,n-1)} = \frac{6\,(3n-2)!}{(n+2)!\,n!\,(n-1)!}.$$

Step 4: the ratio.

$$\frac{|S_2|}{|S|} = \frac{6\,(3n-2)!}{(n+2)!\,n!\,(n-1)!} \cdot \frac{(n+2)!\,(n+1)!\,n!}{2\,(3n)!} = \frac{3\,(n+1)\,n}{3n\,(3n-1)} = \frac{n+1}{3n-1}.$$

Now $\frac{n+1}{3n-1} > \frac{1}{3}$ because $3n+3 > 3n-1$, and $\frac{n+1}{3n-1} \leq \frac{2}{3}$ because $3n+3 \leq 6n-2$ for $n \geq 2$. For $n = 2024$ the fraction is $\frac{2025}{6071}$, which lies in $[\frac{1}{3}, \frac{2}{3}]$. So the pair $(a,b) = (2,1)$, $(c,d) = (1,2)$ has the required property, and the answer is $\boxed{\text{yes}}$.

(Check at $n = 2$: the five tableaux of shape $(2,2,2)$ split 3 to 2 according to whether 2 is at $(2,1)$, and $(n+1)/(3n-1) = 3/5$.)

Layer 1: WHAT

Block 1: name the object: standard Young tableaux of shape (n, n, n); the fraction is a probability under the uniform tableau. Block 2: choose the pair $(2, 1), (1, 2)$ so that the event is "2 sits at $(2, 1)$". Block 3: delete 1 and 2, rotate the leftover skew shape by 180° with complemented entries, obtain the straight shape $(n, n-1, n-1)$. Block 4: hook length formula for both shapes; the ratio is $(n+1)/(3n-1)$. Block 5: check $1/3 < (n+1)/(3n-1) \leq 2/3$.

Juxtaposition. The nominal route reads "$T(a, b) < T(c, d)$" as a question about an arbitrary pair, looks for a symmetry that would give $1/2$, finds none, and either gives up or starts enumerating 3-letter ballot words by a recursion it cannot close. The ideal route reads the quantifier correctly (you choose the pair), chooses the pair adjacent to the corner, and reduces to two applications of a formula it already owns. The bifurcation point is the choice of pair: before any counting, decide that the event must be about the entry 2.

Layer 2: HOW

Block 1. **Cue.** A bijection onto $\{1, \ldots, 3n\}$ with increasing rows and increasing columns. **Why natural.** That is the definition of a standard Young tableau, and the tableau count is the one enumeration in this field with a closed form. Saying the name out loud pulls the hook length formula, the ballot-word model, and the rotation symmetry into working memory at once. **Link to the next block.** Once the object is named, "fraction of T" is "probability under the uniform tableau", and probabilities of events about small entries are ratios of tableau counts.

Block 2. **Cue.** You may choose (a, b) and (c, d); the entries near 1 have almost no freedom. **Why natural.** The cell holding k has at most $k-1$ cells weakly above-left of it, so the smallest entries are pinned near the corner: 1 at $(1, 1)$ and 2 on one of its two neighbours. For the pair of neighbours, "$T(2, 1) < T(1, 2)$" is equivalent to "2 is at $(2, 1)$", a single-entry event. This choice is not a guess; it is the unique pair for which the comparison is decided by the position of one entry. **Link to the next block.** An event "k sits in cell c" for small k is a count of tableaux on the cells that remain after removing $1, \ldots, k$.

Block 3. **Cue.** After removing 1 and 2 the remaining cells form a skew shape, not a partition. **Why natural.** The hook length formula applies to straight shapes. Reversing both the cell order (rotation by 180°) and the entry order (complementation $k \mapsto 3n + 1 - k$) preserves standardness, and for a rectangle minus a corner-anchored piece, rotation produces a straight shape. This is the standard complementation symmetry of rectangular tableaux. **Link to the next block.** Two straight shapes, two hook products.

Block 4. **Cue.** Two counts, one ratio. **Why natural.** Nearly every hook is common to the two products, so compute the ratio and let the factorials cancel; what survives is a rational function of degree zero in n, $(n+1)/(3n-1)$. Computing each count separately and dividing at the end is the same arithmetic done twice. **Link to the next block.** A rational function of n is compared with $1/3$ and $2/3$ by cross-multiplication.

Block 5. **Cue.** The problem asks for a fraction in a closed interval. **Why natural.** Both inequalities must be written out; the lower one is strict for all n, the upper one needs $n \geq 2$. State the value for $n = 2024$ so the grader sees the question answered as posed. **Link to the next block.** None.

Layer 3: WHY

The underlying truth is that a standard Young tableau is a linear extension of the poset of cells (ordered by "weakly above and weakly left"), and the position of the kth smallest element in a random linear extension is governed by counts of linear extensions of the poset minus a k-element lower set. For general posets those counts are intractable; for Young diagrams they are given exactly by the hook length formula, and removing the lower set $\{(1,1),(2,1)\}$ from a rectangle leaves a skew shape which rotation turns into a straight shape. So the problem sits precisely at the point where a hard general question (order statistics of linear extensions) becomes a two-line computation.

The discernment mechanism is quantifier discipline plus a bias toward extremes: when you choose the objects, choose the ones with the least freedom. In a tableau, freedom is minimal near the smallest and largest entries, so the computable pairs are the neighbours of the corner (and, by complementation, the neighbours of the opposite corner). You train this by asking, for any structure with forced elements, "which two positions are decided by one entry?" before computing anything. The examiners nudged twice: by allowing you to pick the pair, and by phrasing the target as $[1/3, 2/3]$, which tells you the answer will be near $1/3$, consistent with three rows and with the limit $(n+1)/(3n-1) \to 1/3$.

The knowledge gap is not disguised: without the hook length formula you cannot produce the exact value in the arena. Install it, with its hook definition, and install the two-row special case $f^{(n,n)} = C_n$ (Catalan) as the sanity check.

Revolving concepts

Standard Young tableaux. A partition $\mu = (\mu_1 \geq \mu_2 \geq \cdots)$ is drawn as left-aligned rows of μ_i cells; a standard Young tableau of shape μ is a filling by $1, \ldots, N$ increasing along rows and down columns; f^μ is their number. Two-row rectangles give Catalan numbers, $f^{(n,n)} = C_n$; the three-row rectangle gives $2(3n)!/(n!(n+1)!(n+2)!)$, the three-dimensional Catalan numbers. See Book 1, field: Combinatorics, topic: Young tableaux and the hook length formula.

The hook length formula and its recursion. $f^\mu = N!/\prod_c h(c)$. It is the closed-form solution of the branching recursion

$$f^\mu = \sum_{c \text{ a removable corner of } \mu} f^{\mu - c}, \qquad f^\varnothing = 1,$$

obtained by asking where the largest entry sits (it must occupy a corner cell). The same recursion holds for linear extensions of any finite poset (sum over maximal elements), and the hook formula is the rare case with a product solution; the official remark verifies the three-row case by checking that the product satisfies the recursion, which is the general method for closed forms of branching recursions: guess, then verify the recursion and the initial condition. Dividing the recursion by f^μ gives the probability that the maximum sits at a given corner, $f^{\mu-c}/f^\mu$, which is what this problem computes in complemented form. See Book 1, field: Combinatorics, topic: hook length formula; and field: Sequences and recurrences, topic: branching recursions and their verification.

Ballot words. Reading the row index of $1, 2, \ldots, N$ in order gives a word in which every prefix contains at least as many 1s as 2s and at least as many 2s as 3s (a lattice word); this is a bijection with tableaux of the corresponding shape. For two rows this is the ballot problem and the reflection principle; for three rows there is no reflection argument, which is why the hook formula is needed. See Book 1, field: Combinatorics, topic: ballot sequences.

Complementation. For a rectangle, $T \mapsto T^*$ with $T^*(i,j) = 3n + 1 - T(4-i, n+1-j)$ is an involution on S; it exchanges the roles of the smallest and largest entries, so the probability that 2 is at $(2,1)$ equals the probability that $3n-1$ is at $(2,n)$. See Book 1, field: Combinatorics, topic: symmetries of tableaux.

Circuit Bank

- **WHEN** you see a bijection onto $\{1, \ldots, N\}$ with increasing rows and increasing columns **DO** say "standard Young tableau" and write the hook length formula **BECAUSE** the count of tableaux of every straight shape is closed-form, and events about small or large entries are ratios of such counts
- **WHEN** you are free to choose positions in a structure with forced elements **DO** choose positions decided by a single extreme entry **BECAUSE** near the minimum or maximum the structure has the least freedom, so the event becomes "which corner holds entry k" and is a count of a smaller shape
- **WHEN** you delete the smallest entries of a rectangular tableau **DO** rotate by 180° and complement the entries **BECAUSE** reversing both orders preserves standardness and turns the leftover skew shape into a straight shape
- **WHEN** you need the ratio of two tableau counts **DO** divide the hook products directly **BECAUSE** almost every hook cancels and the ratio is a small rational function of n

Backtesting

1. First useful cue: "increasing along rows and down columns" with a bijection onto $\{1, \ldots, 6072\}$: a standard Young tableau of shape 3×2024.
2. Method the expression suggested: choose the pair of cells adjacent to the corner so the event is the position of the entry 2; count by hook lengths.
3. Where you would hesitate, and the thought to reinforce: after deleting 1 and 2 the shape is skew. The thought: rotate and complement; a rectangle minus a corner piece is a straight shape upside down.
4. The trap the question sets: reading the quantifiers as "for a given pair" and trying to count linear extensions in general; and expecting a symmetry that yields $1/2$.
5. What makes you recognise it faster next time: the interval $[1/3, 2/3]$ with three rows; the answer is near $1/3$ and comes from the two cells next to the corner.
6. The reusable decision rule: when you choose the positions, choose the ones with the least freedom; when you count tableaux, delete, rotate, and take a ratio of hook products.

Mirror drills

1. In a uniformly random standard Young tableau of shape (n, n), find the probability that 2 lies in the second row. *Answer:* deleting $1, 2$ and rotating gives shape $(n-1, n-1)$, so the probability is $C_{n-1}/C_n = (n+1)/(4n-2)$.
2. In a uniformly random tableau of shape (n, n, n), find the probability that 3 lies in the third row. *Answer:* $1, 2, 3$ fill the first column; deleting them and rotating gives $(n-1, n-1, n-1)$; the ratio of hook products is $(n+1)(n+2)/(3(3n-1)(3n-2))$, which is $1/5$ at $n = 2$.
3. Show that the number of standard Young tableaux of shape (n, n, n) equals the number of words using each of the letters $1, 2, 3$ exactly n times in which every prefix contains at least as many 1s as 2s and at least as many 2s as 3s. *Answer:* record the row of k for $k = 1, \ldots, 3n$; the prefix condition is exactly the column condition, and rows are automatically increasing.

2.4 A4. Complements turn a long progression into a short one

Find all primes $p > 5$ for which there exists an integer a and an integer r satisfying $1 \le r \le p-1$ with the following property: the sequence $1, a, a^2, \ldots, a^{p-5}$ can be rearranged to form a sequence $b_0, b_1, b_2, \ldots, b_{p-5}$ such that $b_n - b_{n-1} - r$ is divisible by p for $1 \le n \le p-5$.

Read it out loud

Translate the sentence into $\mathbb{F}_p$. The b_n satisfy $b_n \equiv b_0 + nr$, so they are the $p-4$ terms of an arithmetic progression with nonzero common difference r. "Can be rearranged" means set equality. So the statement is: the set of the first $p-4$ powers of a (a geometric progression) coincides with the term-set of a $(p-4)$-term arithmetic progression in $\mathbb{F}_p$. The fields wired in are the structure of the multiplicative group $\mathbb{F}_p^*$ (cyclic of order $p-1$, orders of elements, primitive roots), the rigidity of arithmetic and geometric progressions, and a counting reflex about complements.

The designed number is $p-5$. Not $p-2$, not $p-1$: the examiners chose the length so that the arithmetic progression, with $p-4$ of the p residues, misses exactly four residues, while the geometric progression, with $p-4$ of the $p-1$ nonzero residues, misses exactly three nonzero residues. Equality of two large sets is equality of two tiny complements. That is the first useful cue, and the second is that a progression of $p-4$ distinct powers forces the order of a to be at least $p-4$, which for $p \ge 11$ exceeds $(p-1)/2$ and makes a a primitive root. Within thirty seconds you should have written: distinct terms, so a is a primitive root; complement of the powers is $\{0, a^{-1}, a^{-2}, a^{-3}\}$; complement of the progression is a 4-term progression.

What is being tested is quantifier translation (rearrangement is set equality), the primitive-root reflex, and the discipline to pass to complements rather than compare two sets of $p-4$ elements directly. Once the complements are on the page, the problem is a finite check about four elements.

Approaches, ranked worst to best

1. **Hand search over small primes.** *Cue:* "find all primes $p > 5$". *Circuit:* compute the powers of candidate a modulo $7, 11, 13$ and look for progressions. (You find $p = 7$ quickly and then spend the hour failing to prove $p = 11$ is impossible. Evidence, not proof.)

2. **Power sums.** *Cue:* a geometric progression equals an arithmetic progression. *Circuit:* equate $\sum a^k$ with $\sum(b_0 + nr)$, then the sums of squares. (Two equations in three unknowns a, b_0, r with p-dependent coefficients; the sums of a $(p-4)$-term progression carry the full complexity. Stalls.)

3. **Closure properties.** *Cue:* the arithmetic progression is nearly closed under adding r; the powers are nearly closed under multiplying by a. *Circuit:* track where $x \mapsto x + r$ and $x \mapsto ax$ leave the set. (This is the complement idea done implicitly and badly: the "leaving" elements are exactly the complements, and it is far cleaner to name them.)

4. **Complements plus rigidity.** *Cue:* $p-4$ out of p; $p-4$ out of $p-1$. *Circuit:* distinctness forces a primitive root; the complements are $\{0, c, c^2, c^3\}$ and a 4-term progression; place 0, then scale. (Best. Everything reduces to whether $\{1, 2, 3\}$ can be ordered as a geometric progression modulo p, which happens only for $p \in \{5, 7\}$.)

The ideal solution

The answer is $\boxed{p = 7}$.

$p = 7$ works. Take $a = 3$, $r = 1$. The sequence $1, 3, 9$ rearranged as $(b_0, b_1, b_2) = (1, 9, 3)$ satisfies $b_1 - b_0 - 1 = 7$ and $b_2 - b_1 - 1 = -7$, both divisible by 7.

No prime $p \geq 11$ works. Suppose $p \geq 11$ and a, r have the property. Work in $\mathbb{F}_p$ and write $\bar{r} \neq 0$ for the class of r.

Step 1 (a primitive root). The condition says $b_n = b_0 + n\bar{r}$ for $0 \leq n \leq p-5$. These $p-4$ elements are pairwise distinct, because $b_n = b_m$ gives $(n-m)\bar{r} = 0$ with $0 \leq |n-m| \leq p-5 < p$, forcing $n = m$. Since the b_n are a rearrangement of $1, a, \ldots, a^{p-5}$, these powers are pairwise distinct in $\mathbb{F}_p$. In particular $a \neq 0$ (otherwise $a^1 = a^2 = 0$, and $p-5 \geq 2$). Let d be the multiplicative order of a; then $d \mid p-1$, and if $d \leq p-5$ then $a^d = a^0$ with both exponents in $\{0, \ldots, p-5\}$, contradicting distinctness. So $d \geq p-4$. Every divisor of $p-1$ other than $p-1$ itself is at most $(p-1)/2$, and $p-4 > (p-1)/2$ because $p > 7$. Hence $d = p-1$: a is a primitive root, and $\mathbb{F}_p^* = \{a^k : 0 \leq k \leq p-2\}$ with these $p-1$ elements distinct.

Step 2 (complements). Let $G = \{a^k : 0 \leq k \leq p-5\}$. Then $\mathbb{F}_p^* \setminus G = \{a^{p-4}, a^{p-3}, a^{p-2}\} = \{c^3, c^2, c\}$ where $c = a^{-1}$, using $a^{p-1} = 1$. So $\mathbb{F}_p \setminus G = \{0, c, c^2, c^3\}$. On the other side, $B = \{b_0 + n\bar{r} : 0 \leq n \leq p-5\}$, and since $n \mapsto b_0 + n\bar{r}$ is a bijection from $\mathbb{Z}/p\mathbb{Z}$ onto $\mathbb{F}_p$, its complement is

$$\mathbb{F}_p \setminus B = \{b_0 + n\bar{r} : n = p-4, p-3, p-2, p-1\} = \{b_0 - 4\bar{r},\ b_0 - 3\bar{r},\ b_0 - 2\bar{r},\ b_0 - \bar{r}\}.$$

As $B = G$, the complements agree: the four elements $0, c, c^2, c^3$ are, in some order, four consecutive terms of an arithmetic progression with common difference $\bar{r} \neq 0$. Multiplying every term by $c^{-1} = a$ preserves this (an arithmetic progression scaled by a nonzero constant is an arithmetic progression with scaled difference), so the set $\{0, 1, c, c^2\}$ is the term-set of an arithmetic progression x_1, x_2, x_3, x_4 with common difference $r' = a\bar{r} \neq 0$. Note that c, being the inverse of a primitive root, is a primitive root, so it has order $p-1 \geq 10$; in particular $1, c, c^2$ are distinct and nonzero, $c \neq -1$ and $c^2 \neq -1$.

Step 3 (0 is an endpoint). If $0 = x_2$ or $0 = x_3$, then its two neighbours in the progression satisfy $x_{k-1} + x_{k+1} = 2x_k = 0$, so two of $1, c, c^2$ are negatives of each other: $c = -1$, or $c^2 = -1$, or $c^2 = -c$ (again $c = -1$). All are excluded by the order of c. Hence $0 \in \{x_1, x_4\}$; reversing the progression (which replaces r' by $-r'$) we may assume $x_1 = 0$, so $(x_2, x_3, x_4) = (r', 2r', 3r')$ and

$$\{1, c, c^2\} = \{r', 2r', 3r'\}.$$

Step 4 (a geometric progression inside $\{1, 2, 3\}$). Multiply by $u = r'^{-1}$: $\{u, uc, uc^2\} = \{1, 2, 3\}$, and $1, 2, 3$ are distinct in $\mathbb{F}_p$ since $p \geq 5$. So $1, 2, 3$ can be listed in some order as $v_1 = u$, $v_2 = uc$, $v_3 = uc^2$, and then $v_2^2 = v_1 v_3$. The middle term v_2 is one of $1, 2, 3$. If $v_2 = 1$ then $1 = 2 \cdot 3$, so $p \mid 5$. If $v_2 = 2$ then $4 = 1 \cdot 3$, so $p \mid 1$, impossible. If $v_2 = 3$ then $9 = 1 \cdot 2$, so $p \mid 7$. None of these holds for $p \geq 11$, a contradiction.

Therefore no prime $p \geq 11$ has the property, and $p = 7$ is the only prime $p > 5$ that does.

Layer 1: WHAT

Block 1: certify $p = 7$ by an explicit (a, r). Block 2: distinct progression terms force distinct powers, hence order at least $p-4$, hence a primitive root for $p \geq 11$. Block 3: pass to complements: the powers miss $\{0, c, c^2, c^3\}$, the progression misses a 4-term progression, so $\{0, c, c^2, c^3\}$ is a 4-term progression. Block 4: scale by c^{-1} and place 0: interior positions force a pair of negatives among $1, c, c^2$, impossible for an element of order at least 10, so 0 is an endpoint and the rest is $r'\{1, 2, 3\}$. Block 5: $\{1, 2, 3\}$ must then be a geometric progression modulo p, which pins $p \in \{5, 7\}$.

Juxtaposition. The nominal route compares the two $(p-4)$-element sets head-on: sums, products, or a search. The ideal route notices that both sets are almost everything and compares what they miss. The bifurcation point is the reading of "$p-5$": the zombie sees a long sequence to be rearranged; you see four missing residues.

Layer 2: HOW

Block 1. Cue. "Find all primes $p > 5$" with an existential inner statement. **Why natural.** The answer is a finite list or a congruence class, and the smallest admissible prime is where a construction

lives. For $p = 7$ the sequence has three terms $1, a, a^2$, and three residues form a progression when twice one is the sum of the other two; $a = 3$ gives $\{1, 3, 2\}$, which is $\{1, 2, 3\}$. **Link to the next block.** With $p = 7$ certified, the task is a uniform impossibility proof for $p \geq 11$, and impossibility must come from structure that only appears when p is large enough: the order of a.

Block 2. **Cue.** $p - 4$ pairwise distinct powers of a. **Why natural.** A progression with nonzero difference and fewer than p terms has distinct terms, so the powers are distinct, so the order of a is at least the number of powers. An order that exceeds $(p-1)/2$ and divides $p - 1$ must equal $p - 1$. The threshold $p - 4 > (p-1)/2$ is exactly $p > 7$, which is why 7 is special and why the problem says $p > 5$ rather than $p > 7$: it wants you to find the boundary. **Link to the next block.** A primitive root makes the powers enumerate $\mathbb{F}_p^*$ in a known order, so the missing powers are named explicitly.

Block 3. **Cue.** $p - 4$ elements out of p (progression) and out of $p - 1$ (powers). **Why natural.** Two subsets of a finite set are equal iff their complements are equal, and here the complements have 4 and $3 + 1$ elements. The complement of a long progression is a short progression (the map $n \mapsto b_0 + n\bar{r}$ is a bijection of $\mathbb{Z}/p\mathbb{Z}$ with $\mathbb{F}_p$, so the missing indices are consecutive); the complement of the powers is the last three powers, which are a^{-1}, a^{-2}, a^{-3}, plus 0. This is the whole reduction: a statement about $p - 4$ elements becomes a statement about 4. **Link to the next block.** A 4-term arithmetic progression containing 0 and three powers of c is rigid enough to be classified by hand.

Block 4. **Cue.** A progression contains 0; the other members are $1, c, c^2$ after scaling. **Why natural.** Scaling by c^{-1} costs nothing (progressions are preserved) and reduces the number of symbols. In a progression, an interior term is the average of its neighbours, so 0 in the interior forces two of $1, c, c^2$ to sum to 0, which is a small-order condition on c; a primitive root has large order. So 0 sits at an end, and an end at 0 means the other terms are $r', 2r', 3r'$. **Link to the next block.** The set $\{1, c, c^2\}$ is a geometric progression; the set $\{r', 2r', 3r'\}$ is r' times $\{1, 2, 3\}$; equality of the two sets means $\{1, 2, 3\}$ is a geometric progression up to order.

Block 5. **Cue.** Three specific residues that must form a geometric progression. **Why natural.** Three elements in geometric progression satisfy (middle)^2 = (product of the ends), so there are three cases, each a congruence $p \mid 5$, $p \mid 1$, $p \mid 7$. This is a finite check and it explains the answer: $\{1, 2, 3\}$ is simultaneously an arithmetic and a geometric progression only in $\mathbb{F}_5$ and $\mathbb{F}_7$. **Link to the next block.** None; the contradiction for $p \geq 11$ closes the proof.

Layer 3: WHY

The truth underneath is the incompatibility of the two group structures of $\mathbb{F}_p$: an arithmetic progression is an orbit segment of the translation $x \mapsto x + r$, a geometric progression is an orbit segment of the multiplication $x \mapsto cx$, and a set that is simultaneously a long segment of both is impossible except for tiny sets in tiny fields. The problem hides this behind length $p - 4$; complements expose it, because the complement of a segment of a p-cycle is a segment, and the complement of a segment of the $(p-1)$-cycle generated by a primitive root is a segment. Rigidity of short progressions (an interior term is the mean of its neighbours; an endpoint at 0 forces multiples $r', 2r', 3r'$) then converts the question to a three-case congruence.

The discernment mechanism has three reflexes. First, "rearranged into" is set equality, and set equality of large sets is set equality of small complements. Second, "$1, a, \ldots, a^m$ distinct" with $m \geq (p-1)/2$ is "primitive root"; say it before anything else. Third, when a progression contains 0, place the 0: this is the extremal move that breaks the symmetry. You train these by rewriting every problem about $p - k$ objects as a problem about k objects, and by treating any element of large multiplicative order as a ban on small polynomial relations ($c = -1$, $c^2 = -1$). The examiners

nudged with $p-5$ and with $p>5$: the first says "four missing", the second says "the boundary case is small and you must find it".

Revolving concepts

The cyclic group $\mathbb{F}_p^*$. It is cyclic of order $p-1$; the order of any element divides $p-1$; an element of order $p-1$ is a primitive root; the inverse and every power a^k with $\gcd(k,p-1)=1$ of a primitive root are primitive roots; $a^{p-1-k}=a^{-k}$. Key lemma used here: if $1,a,\dots,a^m$ are distinct with $m\geq(p-1)/2$, then a is a primitive root, because the largest proper divisor of $p-1$ is at most $(p-1)/2$. See Book 1, field: Number theory, topic: orders and primitive roots.

Progressions as orbits, and the generalised recursion. The recursion $b_n=b_{n-1}+r$ has closed form $b_n=b_0+nr$; in $\mathbb{Z}/p\mathbb{Z}$ with $r\neq 0$ its orbit is the whole group with period p, so a $(p-k)$-term segment misses a k-term segment. The recursion $g_n=ag_{n-1}$ has closed form $g_n=a^n$ with period $\operatorname{ord}(a)$, so for a primitive root a $(p-1-k)$-term segment of $\mathbb{F}_p^*$ misses $\{a^{-1},\dots,a^{-k}\}$. The general problem "$1,a,\dots,a^{p-1-k}$ rearranges into an arithmetic progression" is therefore "$\{0,c,\dots,c^{k-1}\}$ is a k-term progression": for $k=2$ every prime works; for $k=3$ it works iff 0 is an endpoint and $c^2=2c$ or $c=2c^2$, i.e. iff 2 is a primitive root modulo p; for $k=4$ it is this problem, with answer $p\in\{5,7\}$; for $k\geq 4$ the scaled set $\{1,\dots,k-1\}$ would have to be a geometric progression, which confines p to finitely many values. See Book 1, field: Sequences and recurrences, topic: orbits of affine maps modulo p.

Rigidity of short progressions. Three elements x,y,z (in that order) are in arithmetic progression iff $2y=x+z$, in geometric progression iff $y^2=xz$; scaling by a nonzero constant and reversing preserve both. A k-term arithmetic progression whose term-set contains 0 has 0 at an endpoint unless two other terms are negatives. See Book 1, field: Number theory, topic: arithmetic progressions in $\mathbb{Z}/p\mathbb{Z}$.

Complement principle. A subset of size $m-k$ of an m-set is the same data as its k-subset complement; when k is small, every structural statement should be transported to the complement. See Book 1, field: Combinatorics, topic: complementation.

Circuit Bank

- **WHEN** the powers $1,a,\dots,a^m$ are forced to be distinct modulo p with $m\geq(p-1)/2$ **DO** write "a is a primitive root" **BECAUSE** the order of a is at least $m+1>(p-1)/2$ and divides $p-1$, so it equals $p-1$
- **WHEN** a subset of $\mathbb{F}_p$ or $\mathbb{F}_p^*$ has $p-k$ elements for small k **DO** transport every condition to the k-element complement **BECAUSE** equality of large sets is equality of complements, and the complement of a segment of a cyclic orbit is a segment
- **WHEN** an arithmetic progression contains 0 **DO** place the 0: interior means two other terms are negatives, endpoint means the rest is $r',2r',\dots$ **BECAUSE** an interior term is the average of its neighbours, and a progression starting at 0 is r' times $1,2,3,\dots$
- **WHEN** a set must be both an arithmetic and a geometric progression **DO** write (middle)^2 = (product of ends) for each possible middle **BECAUSE** this is a finite list of congruences on p, which classifies the exceptional primes

Backtesting

1. First useful cue: the length $p-5$, i.e. $p-4$ terms out of p residues.
2. Method the expression suggested: primitive root from distinctness, then complements, then rigidity of a 4-term progression containing 0.

3. Where you would hesitate, and the thought to reinforce: after obtaining "$\{0, c, c^2, c^3\}$ is a progression" you might start a case analysis on all 24 orderings. The thought: scale to $\{0, 1, c, c^2\}$, place 0, and the remaining condition is "$\{1, 2, 3\}$ is a geometric progression".
4. The trap the question sets: $p > 5$ invites you to assume the answer is a congruence class or "all p"; the primitive-root step needs $p > 7$, so $p = 7$ must be checked by hand and turns out to be the entire answer.
5. What makes you recognise it faster next time: any "$1, a, \ldots, a^{p-k}$" with small k is a primitive root plus a k-element complement.
6. The reusable decision rule: big subset, small complement; long progression, short missing progression; progression through 0, place the 0.

Mirror drills

1. Let p be an odd prime and a an integer such that $1, a, \ldots, a^{(p-1)/2}$ are pairwise incongruent modulo p. Show that a is a primitive root. *Answer:* the order is at least $(p+1)/2 > (p-1)/2$ and divides $p-1$.
2. For which primes $p \geq 7$ can $1, a, \ldots, a^{p-4}$ be rearranged into an arithmetic progression modulo p with nonzero difference, for some a? *Answer:* exactly when 2 is a primitive root modulo p: the complement $\{0, c, c^2\}$ is a 3-term progression, 0 is an endpoint since $c \neq -1$, so $c^2 = 2c$ or $c = 2c^2$, i.e. $c \in \{2, 1/2\}$.
3. Find all primes p for which $1, 2, 3$ can be ordered as a geometric progression modulo p. *Answer:* $p = 5$ (order $2, 1, 3$, ratio 3) and $p = 7$ (order $1, 3, 2$, ratio 3); the three cases are $1 = 6$, $4 = 3$, $9 = 2$.

2.5 A5. A random chord is a direction plus an offset

Consider a circle Ω with radius 9 and center at the origin $(0,0)$, and a disc Δ with radius 1 and center at $(r,0)$, where $0 \le r \le 8$. Two points P and Q are chosen independently and uniformly at random on Ω. Which value(s) of r minimize the probability that the chord $\overline{PQ}$ intersects Δ?

Read it out loud

A geometric probability question: a random chord of a large circle, a small disc inside it, and a one-parameter family of positions for the disc along a radius; minimise the hitting probability over the parameter. The fields wired in are geometric probability (the two-endpoint model of a random chord), coordinate geometry of lines and circles (a line is a direction plus an offset), a change of variables for uniform random variables, and one piece of circle geometry (a minor arc is an increasing function of its chord). No heavy machinery, but a rigour trap at every step.

The first useful cue is "chosen independently and uniformly at random on Ω". Write $P = 9(\cos\alpha, \sin\alpha)$, $Q = 9(\cos\beta, \sin\beta)$ with α, β independent and uniform. The chord PQ depends on (α, β) through $(\alpha+\beta)/2$, the direction of its perpendicular bisector, and $(\alpha-\beta)/2$, which fixes its distance $9|\cos((\alpha-\beta)/2)|$ from the centre. Sum and difference of two independent uniform angles are again independent and uniform. So a random chord in this model is a uniform random direction together with an independent offset of the form $9\cos\psi$ with ψ uniform. Within thirty seconds you should have written that decomposition and the sentence "condition on the direction, rotate so the chord is vertical".

What is being tested is whether you can turn a two-dimensional random object into a one-dimensional one per direction, prove a one-dimensional inequality pointwise, and integrate; and whether you notice that $r \le 8$ keeps Δ inside the big disc, so "the chord meets Δ" is the same as "the line meets Δ". The intuitive answer $r = 0$ is correct, but intuition is not a proof, and the examiners want the per-direction argument.

Approaches, ranked worst to best

1. **Intuition or simulation.** *Cue:* "which r minimises". *Circuit:* chords in this model cluster near the boundary, so the centre is hit least. (True, and worth zero marks. The heuristic does tell you what to prove.)

2. **Double integral over (α, β).** *Cue:* two uniform angles. *Circuit:* integrate the indicator of "chord meets Δ" over the torus. (The region in the (α,β)-square is bounded by transcendental curves; you cannot even write it down cleanly. Consumption without analysis.)

3. **Closed form and differentiate.** *Cue:* a probability depending smoothly on r. *Circuit:* direction-offset decomposition, then $P(r)$ as an integral of arccos differences, then differentiate under the integral sign. (The official first solution. Correct, and the derivative has a clean sign, but it costs the justification of differentiating under the integral and invites a sign slip; the official write-up itself carries a sign typo.)

4. **Direction-offset decomposition plus a per-direction chord comparison.** *Cue:* rotational symmetry; a strip of width 2. *Circuit:* for each direction, the arc of the circle cut by the strip is shortest when the strip is centred; integrate the pointwise inequality. (Best. No differentiation, one geometric lemma, strictness for free.)

The ideal solution

The probability is minimised at $\boxed{r = 0}$ and at no other value.

Step 1: a random chord is a random rotation of a vertical chord. Let α, β be independent and uniform on $[0, 2\pi)$, with $P = 9(\cos\alpha, \sin\alpha)$ and $Q = 9(\cos\beta, \sin\beta)$. Let U, ψ be independent and uniform on $[0, 2\pi)$ and consider $\Phi(U, \psi) = (U + \psi, U - \psi)$ reduced modulo 2π in each coordinate. The linear map with matrix $\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ has determinant -2 and maps the lattice $(2\pi\mathbb{Z})^2$ into itself with index 2, so Φ is a two-to-one map of the torus $[0, 2\pi)^2$ onto itself which multiplies area by 2 on each sheet. Hence for every measurable E, the preimage $\Phi^{-1}(E)$ consists of two sheets each of area $\text{area}(E)/2$, so $\text{area}(\Phi^{-1}(E)) = \text{area}(E)$: the pair $(U + \psi, U - \psi)$ is uniform on the torus, i.e. has the same law as (α, β). Consequently the pair (P, Q) has the same law as $(R_U P_0, R_U Q_0)$, where R_U is the rotation about the origin by U and

$$P_0 = 9(\cos\psi, \sin\psi), \qquad Q_0 = 9(\cos\psi, -\sin\psi).$$

All probabilities below are computed in this representation. The event $P = Q$ (that is, $\sin\psi = 0$) has probability 0 and is discarded; for $\sin\psi \neq 0$ the line P_0Q_0 is the vertical line $x = 9\cos\psi$.

Step 2: chord versus line. Every point of Δ is within distance $r + 1 \leq 9$ of the origin, so Δ lies in the closed disc $\bar{D}$ of radius 9. The chord $\overline{PQ}$ is exactly the intersection of the line PQ with $\bar{D}$. Hence the chord meets Δ if and only if the line PQ meets Δ. Applying R_{-U}: the line PQ meets Δ iff the line $x = 9\cos\psi$ meets $R_{-U}(\Delta)$, the closed unit disc centred at $(r\cos U, -r\sin U)$. A vertical line $x = x_0$ meets a closed unit disc with centre (u, v) iff $|x_0 - u| \leq 1$. Therefore

$$\overline{PQ} \cap \Delta \neq \varnothing \iff |9\cos\psi - r\cos U| \leq 1.$$

Step 3: the conditional probability given the direction. Fix U and put $c = r\cos U \in [-8, 8]$. Since $\cos\psi = \cos(2\pi - \psi)$, the law of $\cos\psi$ for ψ uniform on $[0, 2\pi)$ equals the law of $\cos\varphi$ for φ uniform on $[0, \pi]$, where cos is strictly decreasing. As $(c \pm 1)/9 \in [-1, 1]$,

$$|9\cos\varphi - c| \leq 1 \iff \arccos\frac{c+1}{9} \leq \varphi \leq \arccos\frac{c-1}{9},$$

so, with

$$g(c) := \arccos\frac{c-1}{9} - \arccos\frac{c+1}{9} \qquad (-8 \leq c \leq 8),$$

the conditional probability of a hit given U is $g(r\cos U)/\pi$, and by independence of U and ψ,

$$\mathrm{P}(r) := \mathrm{P}\big(\overline{PQ} \cap \Delta \neq \varnothing\big) = \frac{1}{2\pi}\int_0^{2\pi} \frac{g(r\cos U)}{\pi}\, dU.$$

Step 4: the strip lemma.

Lemma 2.5.1. *For $-8 \leq c \leq 8$, $g(c) \geq g(0)$, with equality if and only if $c = 0$.*

Proof. $g(c)$ is the angular measure of the arc of the upper half of the circle $x^2 + y^2 = 81$ whose points have $c - 1 \leq x \leq c + 1$; its endpoints are $A = (c - 1, a)$ and $B = (c + 1, b)$ with $a = \sqrt{81 - (c-1)^2}$ and $b = \sqrt{81 - (c+1)^2}$, both nonnegative. This arc lies in the upper semicircle and is not the whole semicircle (that would need $c - 1 = -9$ and $c + 1 = 9$), so $0 < g(c) < \pi$, and the chord AB has length $18\sin(g(c)/2)$ with $g(c)/2 \in (0, \pi/2)$, where sin is strictly increasing. Now

$$|AB|^2 = 2^2 + (a - b)^2 \geq 4,$$

with equality iff $a = b$, iff $(c-1)^2 = (c+1)^2$, iff $c = 0$. So $|AB| \geq 2 = |AB|_{c=0}$, hence $\sin(g(c)/2) \geq \sin(g(0)/2)$, hence $g(c) \geq g(0)$, with equality exactly when $c = 0$. □

Step 5: integrate. For $r = 0$, $\mathrm{P}(0) = g(0)/\pi$. For $0 < r \leq 8$, the function $U \mapsto g(r\cos U) - g(0)$ is continuous on $[0, 2\pi]$, nonnegative by the lemma, and strictly positive wherever $\cos U \neq 0$, in

particular at $U = 0$. A continuous nonnegative function that is positive somewhere has positive integral, so

$$\mathrm{P}(r) - \mathrm{P}(0) = \frac{1}{2\pi^2} \int_0^{2\pi} \big(g(r\cos U) - g(0)\big)\, dU > 0.$$

Thus $r = 0$ is the unique minimiser. For the record, $\mathrm{P}(0) = \big(\arccos(-\frac{1}{9}) - \arccos\frac{1}{9}\big)/\pi = \frac{2}{\pi}\arcsin\frac{1}{9}$, which agrees with the direct computation: the chord passes within distance 1 of the centre iff $9|\cos\varphi| \le 1$, an event of probability $(\pi - 2\arccos\frac{1}{9})/\pi$.

Layer 1: WHAT

Block 1: replace the two uniform endpoints by a uniform rotation of a vertical chord $x = 9\cos\psi$, ψ uniform, via the two-to-one linear change of variables on the torus. Block 2: since Δ sits inside the big disc, "chord meets Δ" is "line meets Δ", and after rotating back this is $|9\cos\psi - r\cos U| \le 1$. Block 3: for a fixed direction, the hit probability is the angle $g(r\cos U)$ of an arc divided by π. Block 4: the strip lemma: the arc of a circle cut by a strip of width 2 is shortest when the strip is centred, because its chord is shortest then and arcs increase with chords. Block 5: integrate the pointwise inequality; strictness comes from continuity.

Juxtaposition. The nominal route writes the event as a region in the (α, β)-square and tries to integrate, or computes $\mathrm{P}(r)$ in closed form and differentiates under the integral sign. The ideal route never integrates anything it does not have to: it identifies the one-dimensional picture per direction, proves the inequality there, and lets the integral inherit it. The bifurcation point is the choice of coordinates for a chord: endpoints (zombie) versus direction and offset (ideal). Once the direction is conditioned on, the rest is forced.

Layer 2: HOW

Block 1. **Cue.** Two independent uniform points on a circle; the problem is invariant under rotation about the centre. **Why natural.** A chord is determined by its direction and its offset, and in this model those are independent: the sum and difference of two independent uniform angles are independent uniform angles, which is the statement that the linear map $(U, \psi) \mapsto (U + \psi, U - \psi)$ is measure-preserving on the torus. You reach for it because the disc's position enters only through the direction (via $r\cos U$), and separating direction from offset separates the parameter from the randomness. **Link to the next block.** With the direction frozen, the chord is a vertical line at a random abscissa $9\cos\psi$, and the question becomes one-dimensional.

Block 2. **Cue.** $r \le 8$ and radius 1: the disc is inside the circle. **Why natural.** The chord is the intersection of its line with the closed big disc, so anything inside the big disc is met by the chord iff it is met by the line. Rotating the whole picture by $-U$ moves the line to $x = 9\cos\psi$ and the disc centre to $(r\cos U, -r\sin U)$; a vertical line meets a unit disc iff the horizontal distance from the centre is at most 1. The only coordinate of the disc that matters is its abscissa $r\cos U$. **Link to the next block.** The event is now an interval condition on $\cos\psi$, and $\cos\psi$ with ψ uniform has the same law as $\cos\varphi$ with φ uniform on $[0, \pi]$.

Block 3. **Cue.** An interval condition on $\cos\varphi$ with φ uniform on $[0, \pi]$. **Why natural.** Uniform φ means probability equals angular measure over π; inverting cos on $[0, \pi]$ turns the interval $[(c-1)/9, (c+1)/9]$ into an interval of angles of length $g(c)$. Geometrically, $g(c)$ is the angle of the arc of the upper semicircle inside the vertical strip of width 2 centred at $x = c$. **Link to the next block.** The minimisation over r is now a minimisation of $g(r\cos U)$ for each U, and it suffices to minimise g on $[-8, 8]$.

Block 4. **Cue.** Compare arcs cut from a fixed circle by a strip of fixed width at different positions. **Why natural.** Comparing arcs directly means comparing differences of arccos, which is calculus; comparing their chords is geometry. The endpoints of the arc lie on the two boundary lines of the strip, so the chord is at least the width 2 of the strip, with equality only when it is perpendicular to the lines, i.e. when the strip is symmetric about the y-axis. The minor arc is $2R\sin^{-1}(\text{chord}/2R)$, increasing in the chord; the only care needed is that the arc is indeed minor, which holds because it sits inside a semicircle. **Link to the next block.** A pointwise inequality in U with a single equality point per direction is ready to be integrated.

Block 5. **Cue.** An average of a nonnegative continuous function that is not identically zero. **Why natural.** Integration preserves inequalities, and a continuous nonnegative integrand that is positive at one point has positive integral. Writing this sentence is what makes "and no other value" a proven statement rather than a remark. **Link to the next block.** None; the minimiser is unique.

Layer 3: WHY

The mathematical truth is a decoupling and a monotonicity. The decoupling: in the two-endpoint model, the direction of the chord is uniform and independent of the offset, and the offset is $9\cos\psi$ with ψ uniform, so it has the arcsine law with density $1/(\pi\sqrt{81-t^2})$ on $(-9,9)$, largest near the boundary. That density is why the centre is hit least: chords in this model crowd the rim. The monotonicity: for each direction, hitting the disc is the offset falling in a window of fixed width 2 centred at the disc's projection, and the arcsine density is symmetric and increasing away from 0, so a window of fixed width captures least mass when centred at 0. The strip lemma is this monotonicity stated in the language of arcs and chords.

The discernment mechanism: when a probability is an average over a symmetry group, look for an inequality that holds for every group element separately, because pointwise domination integrates and strictness survives integration by continuity. You train it by refusing to compute an integral before asking whether the integrand can be compared pointwise; and by keeping a short list of exact facts about uniform points on circles (sum and difference of angles, the arcsine law of the projection, the 2 sin chord formula). The examiners nudged with the numbers: radius 9, disc radius 1, and $r \le 8$ so that $r+1 \le 9$, which guarantees the chord-versus-line equivalence and keeps both boundary lines of the strip inside the circle. They also nudged with "value(s)", an invitation to prove uniqueness.

Revolving concepts

Random chords and Bertrand's paradox. "Random chord" has no meaning until the model is fixed; two uniform endpoints, a uniform midpoint, and a uniform offset along a uniform direction give different answers (probability $1/3$, $1/4$, $1/2$ that the chord exceeds the inscribed equilateral triangle's side). In the two-endpoint model the direction is uniform and the signed offset $t = 9\cos\psi$ has the arcsine density $1/(\pi\sqrt{81-t^2})$. See Book 1, field: Probability, topic: geometric probability and Bertrand's paradox.

Uniform angles under linear maps. If (U,ψ) is uniform on the torus and M is an integer matrix with $\det M \neq 0$, then $M(U,\psi)$ reduced modulo 2π is uniform: the map is $|\det M|$-to-one and scales area by $|\det M|$. In particular sums and differences of independent uniform angles are independent uniform angles. See Book 1, field: Probability, topic: transformations of uniform random variables.

Arc and chord. An arc of angle $\theta \in [0,\pi]$ on a circle of radius R has chord $2R\sin(\theta/2)$, strictly increasing in θ; so among minor arcs, longer chord means longer arc. The strip lemma follows: the arc cut by a strip of width $w < 2R$ is shortest when the strip is symmetric about the parallel diameter. See Book 1, field: Geometry, topic: circle, chord and arc.

Pointwise domination before integration. If $h_r(U) \geq h_0(U)$ for all U with strict inequality on a set of positive measure and both continuous, then $\int h_r > \int h_0$. This is the general solution method for "minimise an average": minimise the integrand for each value of the averaging variable. The same idea handles any convex body K inside the circle: the hit probability is the average over directions of the arc cut by the strip between the two supporting lines of K perpendicular to that direction. See Book 1, field: Real analysis, topic: monotonicity of the integral.

Differentiation under the integral sign. The alternative route: $\mathrm{P}'(r) = \frac{1}{\pi^2} \int \partial_r g(r \cos U)\, dU$ is legitimate because $\partial_r g$ is continuous on the compact parameter set, and $\partial_c g(c)$ has the sign of c; so P is strictly increasing on $[0, 8]$. See Book 1, field: Calculus and integrals, topic: Leibniz rule.

Circuit Bank

- **WHEN** two points are chosen independently and uniformly on a circle **DO** write the chord as a uniform direction plus an independent offset $R \cos \psi$, ψ uniform **BECAUSE** the sum and difference of two independent uniform angles are independent and uniform, so direction and offset decouple
- **WHEN** a probability is an average over rotations (or any symmetry group) and must be optimised over a parameter **DO** prove the inequality for each direction separately, then integrate **BECAUSE** pointwise domination integrates, and continuity turns one strict point into a strict integral
- **WHEN** you must compare two arcs of the same circle **DO** compare their chords, after checking both arcs are minor **BECAUSE** the minor arc is $2R \sin^{-1}(\text{chord}/2R)$, strictly increasing in the chord
- **WHEN** a target region sits inside the disc bounded by the circle **DO** replace "the chord meets the region" by "the line meets the region" **BECAUSE** the chord is the full intersection of its line with the closed disc

Backtesting

1. First useful cue: "independently and uniformly on Ω" together with a problem invariant under rotation.
2. Method the expression suggested: condition on the chord's direction, reduce to a vertical line at abscissa $9 \cos \psi$, and compare arcs cut by a strip of width 2.
3. Where you would hesitate, and the thought to reinforce: justifying that direction and offset are independent and uniform. The thought: it is a linear change of variables on the torus with determinant -2, two-to-one and area-doubling, so uniform goes to uniform.
4. The trap the question sets: the answer looks obvious and the temptation is to write it with a symmetry hand-wave; the marks are in the per-direction inequality, in the chord-versus-line remark, and in the strictness.
5. What makes you recognise it faster next time: any "random chord" phrased with two uniform endpoints is direction plus arcsine offset, and any "strip of fixed width across a circle" is the chord-arc lemma.
6. The reusable decision rule: decouple the randomness from the parameter by conditioning on the symmetry variable, prove pointwise, integrate.

Mirror drills

1. Two points are chosen independently and uniformly on a circle of radius R. Show that the probability that the chord passes within distance s of the centre is $\frac{2}{\pi}\arcsin\frac{s}{R}$. *Answer:* the distance is $R|\cos\varphi|$ with φ uniform on $[0,\pi]$; the set $|\cos\varphi| \le s/R$ has measure $\pi - 2\arccos(s/R) = 2\arcsin(s/R)$.

2. In the same model, find the probability that the chord is longer than the side of the inscribed equilateral triangle. *Answer:* the chord has length $2R|\sin\psi|$, and $|\sin\psi| > \sqrt{3}/2$ on a set of measure $1/3$; this is the Bertrand value $1/3$ for the two-endpoint model.

3. A disc of radius ρ is centred at distance r from the centre of a circle of radius R, with $r + \rho \le R$; two points are uniform on the circle. Show that the probability that the chord meets the disc is strictly increasing in r on $[0, R-\rho]$. *Answer:* per direction the strip has width 2ρ and centre $r\cos U$, and $\frac{d}{dc}\big(\arccos\frac{c-\rho}{R} - \arccos\frac{c+\rho}{R}\big)$ has the sign of c, so each conditional probability is increasing in $|c|$; integrate.

2.6 A6. Hankel determinants through a self-similar inverse series

Let $c_0, c_1, c_2, \ldots$ be the sequence defined so that

$$\frac{1 - 3x - \sqrt{1 - 14x + 9x^2}}{4} = \sum_{k=0}^{\infty} c_k x^k$$

for sufficiently small x. For a positive integer n, let A be the n-by-n matrix with i, j-entry c_{i+j-1} for i and j in $\{1, \ldots, n\}$. Find the determinant of A.

Read it out loud

A determinant whose entries depend only on $i + j$: a Hankel determinant. The entries are the coefficients of a generating function that is a square root of a quadratic, so the generating function satisfies a quadratic equation and the coefficients satisfy a convolution recursion of Catalan type. The fields wired in are generating functions (algebraic power series), linear algebra (determinants under unimodular row and column operations, block triangular factorisation), and the classical circle of ideas around Hankel matrices: continued fractions, orthogonal polynomials, moment functionals, and lattice paths. The words to say out loud are "Hankel matrix of a Catalan-like sequence", and the theorem to pull is: the Hankel determinants of a sequence whose generating function has a continued fraction expansion with denominators $\lambda_1, \lambda_2, \ldots$ equal $\lambda_1^{n-1}\lambda_2^{n-2}\cdots\lambda_{n-1}$.

Two things to write in the first minute. First, the quadratic: squaring $1 - 3x - 4f = \sqrt{1 - 14x + 9x^2}$ gives $f = x + 3xf + 2f^2$, so $c_0 = 0$, $c_1 = 1$, $c_2 = 5$, $c_3 = 35$, $c_4 = 295$, $c_5 = 2765$. Second, the small determinants: $n = 1$ gives 1, $n = 2$ gives $35 - 25 = 10$, $n = 3$ gives 1000. The pattern $10^0, 10^1, 10^3$ is $10^{n(n-1)/2}$, which is $\prod_{k=1}^{n-1} \lambda_k^{n-k}$ with every $\lambda_k = 10$. So the target is known within five minutes; the problem is the proof, and the proof needs a theorem you must have installed, or the one lemma that proves it.

Brutal honesty about the knowledge gap: without knowing that Hankel determinants factor through continued fraction coefficients, or without the reduction lemma below, this problem is not approachable in the arena. There is no elementary reroute. The lemma is short and its proof is a single unitriangular factorisation; install it, and the problem becomes a five-line induction.

Approaches, ranked worst to best

1. **Compute and guess.** *Cue:* "find the determinant" for general n. *Circuit:* evaluate c_k and the first few determinants. (Necessary as reconnaissance, worthless as a proof. It tells you the answer $10^{n(n-1)/2}$ and the shape $\prod \lambda_k^{n-k}$.)

2. **Numeric row reduction.** *Cue:* a concrete matrix. *Circuit:* eliminate using the recursion $c_m = 3c_{m-1} + 2\sum c_i c_{m-i}$. (The recursion is quadratic in the c's, and unorganised elimination produces no pattern. This is the lemma below attempted without its organising principle.)

3. **Lattice paths and nonintersecting families.** *Cue:* Catalan-like recursion. *Circuit:* Flajolet's theorem (continued fraction coefficients weight Motzkin paths) plus the Lindström, Gessel and Viennot lemma. (A beautiful proof, but it stacks two theorems, each with its own proof, and the path model must be set up with care. Too much to reconstruct in the arena.)

4. **Orthogonal polynomials.** *Cue:* Hankel matrix as a Gram matrix. *Circuit:* three-term recurrence from the continued fraction, $UAU^{\mathsf{T}} = D$ with U unitriangular. (The official solution. Correct and conceptual, but it requires the whole dictionary between continued fractions, convergents, and orthogonality; heavy to justify from scratch.)

5. **Reduction lemma plus self-similarity.** *Cue:* $c_1 = 1$, so f is invertible as a Laurent series; $f^{-1} = x^{-1} - (\text{power series})$. *Circuit:* $h_n(\alpha) = h_{n-1}(\beta)$ when $\alpha^{-1} = x^{-1} - \beta$; iterate on a

series that reproduces itself. (Best. One lemma with a two-paragraph proof, then the algebra $f^{-1} = x^{-1} - 5 - 10f_1$, $f_1^{-1} = x^{-1} - 7 - 10f_1$, then induction.)

The ideal solution

The answer is $\boxed{\det A = 10^{n(n-1)/2}}$.

Notation. For a power series $\gamma = \sum_{i\geq 0} g_i x^i$ and $m \geq 1$ let $H_m(\gamma)$ be the $m \times m$ matrix with entries g_{i+j-1} $(1 \leq i, j \leq m)$, and $h_m(\gamma) = \det H_m(\gamma)$; put $h_0(\gamma) = 1$. Note that $H_m(\gamma)$ involves only $g_1, g_2, \ldots, g_{2m-1}$, so $H_m(\gamma) = H_m(\gamma - g_0)$, and $H_m(\lambda\gamma) = \lambda H_m(\gamma)$, so $h_m(\lambda\gamma) = \lambda^m h_m(\gamma)$. With $f(x) = \sum_{k\geq 0} c_k x^k$, the matrix in the problem is $A = H_n(f)$. All identities below are identities of formal power series (equivalently of convergent series near 0); a series with nonzero coefficient of x and zero constant term is invertible in the field of formal Laurent series.

Step 1: the algebraic equation and the self-similar companion. Write s for the power series $\sqrt{1 - 14x + 9x^2}$ with $s(0) = 1$, so $4f = 1 - 3x - s$ and $s = 1 - 3x - 4f$. Squaring,

$$1 - 6x + 9x^2 - 8f + 24xf + 16f^2 = 1 - 14x + 9x^2,$$

which simplifies to

$$f = x + 3xf + 2f^2. \tag{1}$$

Comparing constant terms, $c_0 = 2c_0^2$, and $f(0) = (1-1)/4 = 0$ gives $c_0 = 0$; comparing coefficients of x then gives $c_1 = 1$. (For $m \geq 2$, (1) gives $c_m = 3c_{m-1} + 2\sum_{i=1}^{m-1} c_i c_{m-i}$, so $f = x + 5x^2 + 35x^3 + 295x^4 + \cdots$.)

Since $c_1 = 1$, define the power series $f_1 = (f - x)/(5x) = x + 7x^2 + 59x^3 + \cdots$; it has zero constant term and coefficient 1 at x, and $f = x + 5xf_1$. Dividing (1) by f gives $1 = xf^{-1} + 3x + 2f$, so

$$f^{-1} = x^{-1} - 3 - 2\frac{f}{x} = x^{-1} - 3 - 2(1 + 5f_1) = x^{-1} - 5 - 10f_1. \tag{2}$$

Substituting $f = x + 5xf_1$ into (1):

$$x + 5xf_1 = x + 3x^2 + 15x^2 f_1 + 2x^2(1 + 5f_1)^2 = x + 5x^2 + 35x^2 f_1 + 50x^2 f_1^2,$$

so $f_1 = x + 7xf_1 + 10xf_1^2$, and dividing by f_1,

$$f_1^{-1} = x^{-1} - 7 - 10f_1. \tag{3}$$

Step 2: the reduction lemma.

Lemma 2.6.1. *Let $\alpha = \sum_{i\geq 1} a_i x^i$ with $a_1 = 1$, and let $\beta = \sum_{i\geq 0} b_i x^i$ be the power series with $\alpha^{-1} = x^{-1} - \beta$. Then $h_n(\alpha) = h_{n-1}(\beta)$ for every $n \geq 1$.*

Proof. First, β is a power series: $\alpha^{-1} = x^{-1}(1 + a_2 x + \cdots)^{-1}$ and $(1 + a_2 x + \cdots)^{-1} - 1$ is divisible by x. The relation $\alpha(x^{-1} - \beta) = 1$ reads $x^{-1}\alpha = 1 + \alpha\beta$; comparing coefficients of x^m for $m \geq 1$,

$$a_{m+1} = \sum_{r=1}^{m} a_r\, b_{m-r}. \tag{4}$$

Let $M = H_n(\alpha)$, so $M_{ij} = a_{i+j-1}$. Let L be the $n \times n$ lower unitriangular matrix with $L_{ii} = 1$, $L_{ik} = -b_{i-1-k}$ for $k < i$, and $L_{ik} = 0$ for $k > i$. Row 1 of LM is row 1 of M, beginning with $a_1 = 1$. For $i \geq 2$ and any j, using (4) with $m = i + j - 2 \geq 1$ and the substitution $r = k + j - 1$,

$$(LM)_{ij} = a_{i+j-1} - \sum_{k=1}^{i-1} b_{i-1-k}\, a_{k+j-1} = \sum_{r=1}^{i+j-2} a_r b_{i+j-2-r} - \sum_{r=j}^{i+j-2} a_r b_{i+j-2-r} = \sum_{r=1}^{j-1} a_r\, b_{i+j-2-r}.$$

In particular $(LM)_{i1} = 0$ for $i \geq 2$ (empty sum). For $i, j \geq 2$ put $i' = i-1$, $j' = j-1$ and $l = j - r$; then

$$(LM)_{ij} = \sum_{l=1}^{j'} b_{i'+l-1}\, a_{j'-l+1} = \big(H_{n-1}(\beta)\, V\big)_{i'j'},$$

where V is the $(n-1)\times(n-1)$ upper unitriangular matrix with $V_{lj'} = a_{j'-l+1}$ for $l \leq j'$ (so $V_{ll} = a_1 = 1$) and 0 below the diagonal. Hence, in block form,

$$LM = \begin{pmatrix} 1 & * \\ 0 & H_{n-1}(\beta)\, V \end{pmatrix},$$

and taking determinants, with $\det L = \det V = 1$, gives $h_n(\alpha) = \det(LM) = \det\big(H_{n-1}(\beta)\big) = h_{n-1}(\beta)$. For $n = 1$ both sides equal 1. □

Step 3: iterate. By (2) and the lemma applied to $\alpha = f$, $\beta = 5 + 10f_1$,

$$h_n(f) = h_{n-1}(5 + 10f_1) = h_{n-1}(10f_1) = 10^{n-1} h_{n-1}(f_1).$$

By (3) and the lemma applied to $\alpha = f_1$ (leading coefficient 1), $\beta = 7 + 10f_1$, for every $m \geq 1$,

$$h_m(f_1) = h_{m-1}(7 + 10f_1) = 10^{m-1} h_{m-1}(f_1),$$

and by induction on m, starting from $h_0(f_1) = 1$, $h_m(f_1) = 10^{(m-1)+(m-2)+\cdots+0} = 10^{m(m-1)/2}$. Therefore

$$\det A = h_n(f) = 10^{n-1} \cdot 10^{(n-1)(n-2)/2} = 10^{n(n-1)/2}.$$

Check: $n = 2$ gives $c_1 c_3 - c_2^2 = 35 - 25 = 10$; $n = 3$ gives 1000.

Layer 1: WHAT

Block 1: square out the root to get $f = x + 3xf + 2f^2$, compute c_1, c_2, c_3 and the determinants $1, 10, 1000$, and conjecture $10^{n(n-1)/2}$. Block 2: recognise the Hankel matrix as $H_n(f)$ and recall that Hankel determinants are computed by peeling off the first row and column, which corresponds to inverting the series: $f^{-1} = x^{-1} - \beta$. Block 3: the reduction lemma $h_n(\alpha) = h_{n-1}(\beta)$, proven by the factorisation $LM = \left(\begin{smallmatrix} 1 & * \\ 0 & H_{n-1}(\beta)V \end{smallmatrix}\right)$ with L and V unitriangular. Block 4: the algebra: $f^{-1} = x^{-1} - 5 - 10f_1$ with $f_1 = (f - x)/(5x)$, and f_1 reproduces itself, $f_1^{-1} = x^{-1} - 7 - 10f_1$. Block 5: iterate and multiply the powers of 10.

Juxtaposition. The nominal route treats A as a numeric matrix: compute $c_1, \ldots, c_{2n-1}$ and eliminate. The ideal route treats the entries as the coefficients of an algebraic series and asks what elimination does to the series: one step of elimination is inversion of the series and removal of its polar part. The bifurcation point is the moment you write f^{-1} instead of another row operation. After it, the self-similarity of f_1 is a two-line computation and the induction is automatic.

Layer 2: HOW

Block 1. Cue. A square root of a quadratic in the generating function. **Why natural.** An expression $\big(u(x) - \sqrt{u(x)^2 - 4bx}\big)/(2b)$ is the solution of $bf^2 - uf + x = 0$ with $f(0) = 0$; here $1 - 14x + 9x^2 = (1 - 3x)^2 - 8x$, which is the discriminant of $2f^2 - (1 - 3x)f + x$. The examiners wrote the closed form to hide the recursion $c_m = 3c_{m-1} + 2\sum c_i c_{m-i}$; squaring recovers it. Small determinants are computed because the shape of the answer decides the method: powers of a single number mean a constant λ and a self-similar continued fraction. **Link to the next block.** A quadratic equation for f with $c_1 = 1$ makes f invertible and makes f^{-1} computable in one line, which is exactly the input of the lemma.

Block 2. Cue. Entries c_{i+j-1}: the matrix is $H_n(f)$. **Why natural.** Hankel matrices are Gram matrices of the monomials $1, x, x^2, \ldots$ under the functional $x^k \mapsto c_{k+1}$, and Gaussian elimination on a Gram matrix is Gram-Schmidt. The first elimination step removes the component along 1; in series language this is passing from f to the series β with $f^{-1} = x^{-1} - \beta$, because the convolution identity $a_{m+1} = \sum a_r b_{m-r}$ says precisely that each row of $H_n(f)$ is a combination of the earlier rows plus a row of $H(\beta)$. **Link to the next block.** You need the lemma in a form you can prove in the arena: a unitriangular factorisation, not a theory of orthogonal polynomials.

Block 3. Cue. A determinant unchanged by adding multiples of earlier rows and later columns. **Why natural.** Multiplying by a lower unitriangular L on the left performs the row operations; the convolution identity makes the first column collapse to $(1, 0, \ldots, 0)^{\mathsf{T}}$ and every other entry of rows $2, \ldots, n$ into a convolution of b's with a's, which is $H_{n-1}(\beta)$ times an upper unitriangular V. Writing the factorisation rather than performing operations one at a time is what keeps the proof checkable: every entry is an explicit finite sum with matching indices. **Link to the next block.** The lemma is only useful if β is again of the form "constant plus a multiple of a series with leading coefficient 1", which is the self-similarity question.

Block 4. Cue. $f^{-1} = x^{-1} - 5 - 10f_1$ with $f_1 = (f - x)/(5x)$. **Why natural.** The constant term of β is irrelevant to $H_{n-1}(\beta)$, and the factor 10 comes out as 10^{n-1}. Whether f_1 is again reducible depends on its own equation; substituting $f = x + 5xf_1$ into the quadratic gives $f_1 = x + 7xf_1 + 10xf_1^2$, whose form $g = x + b'xg + \lambda xg^2$ is exactly the self-similar one: $g^{-1} = x^{-1} - b' - \lambda g$. The number $10 = 2 \cdot 5 = b(a + b)$ appears at every level; the number $7 = a + 2b$ never matters. **Link to the next block.** Self-similarity turns the lemma into a first-order recursion $h_m(f_1) = 10^{m-1} h_{m-1}(f_1)$.

Block 5. Cue. A recursion $h_m = \lambda^{m-1} h_{m-1}$ with $h_0 = 1$. **Why natural.** Its closed form is $\lambda^{0+1+\cdots+(m-1)} = \lambda^{m(m-1)/2}$; the extra factor 10^{n-1} from the first step combines to $10^{n(n-1)/2}$ because $(n-1) + (n-1)(n-2)/2 = n(n-1)/2$. Verify against $n = 2, 3$. **Link to the next block.** None.

Layer 3: WHY

The truth beneath the route is the dictionary between three objects: the Hankel matrix $H_n(f)$, the continued fraction of f, and the orthogonal polynomials of the functional $x^k \mapsto c_{k+1}$. Because the functional satisfies $L(xp \cdot q) = L(p \cdot xq)$, Gram-Schmidt on $1, x, x^2, \ldots$ is a three-term recurrence, its pivots are $\lambda_1 \lambda_2 \cdots \lambda_k$ up to sign, and the determinant is the product of the pivots, $\prod_{k=1}^{n-1} \lambda_k^{n-k}$. Unrolling the continued fraction one level is the identity $f^{-1} = x^{-1} - b_0 - \lambda_1 f_1$, and the reduction lemma is the statement that one level of the continued fraction is one step of elimination. A periodic continued fraction is the same thing as a quadratic equation for f, and every sequence of the form $c_m = ac_{m-1} + b \sum c_i c_{m-i}$ has one: after a single non-periodic step ($b_0 = a + b$, $\lambda_1 = b(a + b)$) the fraction repeats with $b_k = a + 2b$ and $\lambda_k = b(a + b)$. So the determinant is $(b(a + b))^{n(n-1)/2}$; the problem is $(a, b) = (3, 2)$.

The discernment mechanism: "Hankel" triggers "continued fraction denominators", "square root of a quadratic" triggers "quadratic equation, hence periodic fraction, hence constant λ", and the small determinants confirm λ. Then choose the proof engine you can reproduce under pressure: the reduction lemma, because it is one factorisation. You train it by running the lemma on the Catalan, Motzkin and Schröder sequences until the algebra $f \mapsto f_1$ is a reflex, and by memorising the general formula $(b(a + b))^{n(n-1)/2}$ as a check. The examiners nudged with c_{i+j-1} (starting at $c_1 = 1$, which makes f invertible with leading coefficient 1), with the closed form (whose discriminant $(1 - 3x)^2 - 8x$ is the fingerprint of $a = 3$, $b = 2$), and with "find" rather than "show that", which tells you to compute small cases first.

Knowledge you must install before this problem is approachable, stated without disguise: the definition of a Hankel matrix; the continued fraction (J-fraction) of a power series and the theorem

$\det(\mu_{i+j})_0^{n-1} = \prod \lambda_k^{n-k}$; the reduction lemma as its proof engine; and the fact that Catalan-type recursions give periodic fractions.

Revolving concepts

Hankel matrices and moment functionals. $H_n(\gamma) = (g_{i+j-1})$ depends only on $i+j$. Define $L(x^k) = g_{k+1}$; then $H_n(\gamma)$ is the Gram matrix $(L(x^{i-1}x^{j-1}))$ of the monomials, and $L(xp \cdot q) = L(p \cdot xq)$. Gram-Schmidt produces monic polynomials $B_0, B_1, \ldots$ with $L(B_iB_j) = 0$ for $i \neq j$, satisfying $B_{k+1} = (x - b_k)B_k - \lambda_k B_{k-1}$, and $UH_nU^{\mathsf{T}} = \operatorname{diag}(L(B_0^2), \ldots, L(B_{n-1}^2))$ with U unitriangular, $L(B_k^2) = \lambda_1 \cdots \lambda_k$. See Book 1, field: Matrices and determinants, topic: Hankel matrices and orthogonal polynomials.

J-fractions. $\sum_{k\geq 0} \mu_k x^k = 1/(1 - b_0x - \lambda_1x^2/(1 - b_1x - \lambda_2x^2/(1 - \cdots)))$, with $\mu_0 = 1$. Flajolet's theorem: μ_k is the total weight of Motzkin paths of length k with level steps at height i weighted b_i and down steps from height i weighted λ_i. Hankel theorem: $\det(\mu_{i+j})_{i,j=0}^{n-1} = \prod_{k=1}^{n-1} \lambda_k^{n-k}$, proven by orthogonal polynomials, by the Lindström, Gessel and Viennot lemma on nonintersecting paths, or by iterating the reduction lemma. In the notation of this problem $\mu_k = c_{k+1}$. See Book 1, field: Generating functions, topic: continued fractions and Hankel determinants.

The reduction lemma. If $\alpha = x + a_2x^2 + \cdots$ and $\alpha^{-1} = x^{-1} - \beta$, then $h_n(\alpha) = h_{n-1}(\beta)$. Unrolling: $\beta = b_0 + \lambda_1\alpha_1$ with α_1 monic, so $h_n(\alpha) = \lambda_1^{n-1}h_{n-1}(\alpha_1)$, and iterating gives the Hankel theorem. See Book 1, field: Matrices and determinants, topic: block unitriangular factorisation.

Catalan-type recursions: the generalised recursion. Let $c_1 = 1$ and $c_m = ac_{m-1} + b\sum_{i=1}^{m-1} c_ic_{m-i}$ for $m \geq 2$. The generating function satisfies $f = x + axf + bf^2$, so $f = \left(1 - ax - \sqrt{(1-ax)^2 - 4bx}\right)/(2b)$. With $f_1 = (f - x)/((a + b)x)$ one gets $f^{-1} = x^{-1} - (a + b) - b(a + b)f_1$ and $f_1 = x + (a + 2b)xf_1 + b(a + b)xf_1^2$, so $f_1^{-1} = x^{-1} - (a + 2b) - b(a + b)f_1$. Hence $\det(c_{i+j-1})_{n\times n} = (b(a + b))^{n(n-1)/2}$. Cases: $(a, b) = (0, 1)$ Catalan, determinant 1; $(1, 1)$ large Schröder, determinant $2^{n(n-1)/2}$; $(3, 2)$ this problem, determinant $10^{n(n-1)/2}$. The general method for any recursion with a convolution term: form the generating function, turn the convolution into f^2, solve the quadratic, and for Hankel questions invert the series rather than expand it. See Book 1, field: Sequences and recurrences, topic: convolution recursions and algebraic generating functions.

Formal Laurent series. A power series with zero constant term and nonzero coefficient of x is invertible in the field of formal Laurent series, with inverse x^{-1} times a power series; all manipulations in the solution are identities there, and convergence for small x is a bonus, not a requirement. See Book 1, field: Generating functions, topic: formal power series.

Circuit Bank

- **WHEN** a generating function is given as a square root of a quadratic **DO** square it out into $f = x + axf + bf^2$ and read off the convolution recursion **BECAUSE** the closed form hides the recursion, and the recursion (equivalently the quadratic) carries all the structure
- **WHEN** a matrix has entries indexed by $i + j$ **DO** say "Hankel", and write the determinant as $\prod_{k=1}^{n-1} \lambda_k^{n-k}$ with λ_k the continued fraction denominators **BECAUSE** Gaussian elimination on a Hankel matrix is the orthogonal polynomial recursion and its pivots are the λ's
- **WHEN** you must prove a Hankel determinant from scratch **DO** invert the series, $f^{-1} = x^{-1} - \beta$, and apply $h_n(f) = h_{n-1}(\beta)$ **BECAUSE** one level of the continued fraction is one step of elimination, and the lemma is a single unitriangular factorisation
- **WHEN** the small determinants are $1, \lambda, \lambda^3, \lambda^6, \ldots$ **DO** look for self-similarity: a series g with $g^{-1} = x^{-1} - b' - \lambda g$ **BECAUSE** constant λ means a periodic continued fraction, which is the same as a quadratic equation for g
- **WHEN** a sequence satisfies $c_m = ac_{m-1} + b\sum c_ic_{m-i}$ with $c_1 = 1$ **DO** write $\det(c_{i+j-1}) = (b(a + b))^{n(n-1)/2}$ **BECAUSE** one reduction step gives $\lambda_1 = b(a + b)$ and the companion series is self-similar with the same λ

Backtesting

1. First useful cue: $\sqrt{1-14x+9x^2}$ in the generating function, and entries c_{i+j-1}.
2. Method the expression suggested: the quadratic $f = x + 3xf + 2f^2$, then the Hankel reduction through f^{-1}.
3. Where you would hesitate, and the thought to reinforce: in the lemma, which operations to perform. The thought: row i minus the convolution of the earlier rows with $b_{i-2}, b_{i-3}, \ldots, b_0$; the recursion $a_{m+1} = \sum a_r b_{m-r}$ is built to make the first column vanish, and what remains in the block is $H_{n-1}(\beta)$ times a unitriangular matrix.
4. The trap the question sets: computing coefficients and expanding; also the index shift: A starts at c_1, not c_0, which is what makes f invertible with leading coefficient 1 and makes the lemma apply directly.
5. What makes you recognise it faster next time: any Hankel determinant of a Catalan-like sequence is a power of $b(a+b)$; the discriminant $(1-ax)^2 - 4bx$ is the fingerprint.
6. The reusable decision rule: Hankel plus algebraic generating function means invert the series and iterate the reduction lemma; never expand the determinant.

Mirror drills

1. Let C_k be the Catalan numbers, $C(x) = 1 + xC(x)^2$. Show that $\det(C_{i+j})_{i,j=0}^{n-1} = 1$. *Answer:* $\alpha = xC$ satisfies $\alpha = x + \alpha^2$, so $\alpha^{-1} = x^{-1} - 1 - f_1$ with $f_1 = xC^2 = x + 2x^2 + \cdots$, and $f_1 = x + 2xf_1 + xf_1^2$ gives $f_1^{-1} = x^{-1} - 2 - f_1$; every λ equals 1.
2. Let M_k be the Motzkin numbers, $M(x) = 1 + xM + x^2M^2$. Show that $\det(M_{i+j})_{i,j=0}^{n-1} = 1$. *Answer:* $g = xM$ satisfies $g = x + xg + xg^2$, which is already self-similar: $g^{-1} = x^{-1} - 1 - g$, so $h_m(g) = h_{m-1}(g)$ and all determinants equal 1.
3. Let S_k be the large Schröder numbers $1, 2, 6, 22, 90, \ldots$, $S(x) = 1 + xS + xS^2$. Show that $\det(S_{i+j})_{i,j=0}^{n-1} = 2^{n(n-1)/2}$. *Answer:* $g = xS$ satisfies $g = x + xg + g^2$, the case $(a, b) = (1, 1)$, so $\lambda = b(a+b) = 2$; check $S_0S_2 - S_1^2 = 6 - 4 = 2$.

2.7 B1. Transversal sums force the middle offset

Let n and k be positive integers. The square in the ith row and jth column of an n-by-n grid contains the number $i + j - k$. For which n and k is it possible to select n squares from the grid, no two in the same row or column, such that the numbers contained in the selected squares are exactly $1, 2, \ldots, n$?

Read it out loud

An n-by-n grid whose entry depends only on $i + j$, so the entries are constant along anti-diagonals and increase by one as you step down or right. You must choose n squares with no two sharing a row or column: in other words, a permutation σ of $\{1, \ldots, n\}$, the square in row i being column $\sigma(i)$. The selected numbers must be exactly $1, 2, \ldots, n$, a fixed multiset with a fixed sum.

The fields wired in are combinatorics (a permutation is the object being selected) and the arithmetic of sums. What is being tested is whether you notice that the entry $i + \sigma(i) - k$ has a sum over i that does not depend on σ at all, because $\sum_i \sigma(i)$ is the same for every permutation. That single sentence is the whole of the necessity direction, and it is the first thing you should write down, within thirty seconds: $\sum_i (i + \sigma(i) - k) = n(n+1) - nk$.

The command terms are "no two in the same row or column" (permutation) and "exactly $1, 2, \ldots, n$" (a fixed sum, $n(n+1)/2$). When a question fixes a multiset of outputs and lets you vary a permutation, the circuit is: compare an invariant of the outputs with the same invariant computed structurally. The second half is a construction: a permutation σ such that $i + \sigma(i)$ takes n consecutive values, which is a complete mapping of $\mathbb{Z}_n$.

Approaches, ranked worst to best

1. **Small cases and pattern guessing.** *Cue:* the question says "for which n and k". *Circuit:* enumerate $n = 1, 2, 3, 4$ by hand and conjecture. (it costs a page of case work, it never produces a proof of impossibility for even n, and the pattern "n odd, $k = (n+1)/2$" is only visible once you already suspect a sum argument; ranks last because it is consumption without analysis)

2. **Row-by-row greedy.** *Cue:* each row is a run of n consecutive integers $i + 1 - k, \ldots, i + n - k$. *Circuit:* assign the value 1 to a row that contains it, then 2, and so on. (it stalls immediately, because the constraint "no two in the same column" is global and a greedy assignment collides; it also gives no necessity argument)

3. **Sum invariant plus explicit transversal.** *Cue:* the entry is $g(i) + h(j)$ with $g(i) = i, h(j) = j - k$, so any transversal has the same sum. *Circuit:* compare the forced sum $n(n+1) - nk$ with the required sum $n(n+1)/2$, then build σ with $i + \sigma(i) - k$ hitting $1, 3, 5, \ldots$ then $2, 4, \ldots$. (two lines for necessity, one displayed permutation for sufficiency; this is the ideal)

The ideal solution

The selection is possible if and only if n is odd and $k = \dfrac{n+1}{2}$.

Necessity. A choice of n squares with no two in the same row or column is a permutation σ of $\{1, \ldots, n\}$: the chosen square in row i sits in column $\sigma(i)$. The chosen numbers are $i + \sigma(i) - k$ for $i = 1, \ldots, n$. Since σ is a bijection of $\{1, \ldots, n\}$ onto itself, $\sum_{i=1}^{n} \sigma(i) = \sum_{i=1}^{n} i = \frac{n(n+1)}{2}$, so

$$\sum_{i=1}^{n} \big(i + \sigma(i) - k\big) = \frac{n(n+1)}{2} + \frac{n(n+1)}{2} - nk = n(n+1) - nk.$$

If the chosen numbers are exactly $1, 2, \ldots, n$ their sum is $\frac{n(n+1)}{2}$. Equating, $nk = \frac{n(n+1)}{2}$, so $k = \frac{n+1}{2}$; as k is an integer, n is odd.

Sufficiency. Let n be odd and $k = \frac{n+1}{2}$. Define

$$\sigma(i) = \begin{cases} i + \frac{n-1}{2}, & 1 \le i \le \frac{n+1}{2}, \\ i - \frac{n+1}{2}, & \frac{n+3}{2} \le i \le n. \end{cases}$$

The first branch takes the values $\frac{n+1}{2}, \frac{n+3}{2}, \ldots, n$ and the second takes $1, 2, \ldots, \frac{n-1}{2}$, each exactly once, so σ is a permutation of $\{1, \ldots, n\}$ and the squares $(i, \sigma(i))$ lie in distinct rows and distinct columns. The selected numbers are

$$i + \sigma(i) - k = \begin{cases} 2i - 1, & 1 \le i \le \frac{n+1}{2}, \\ 2i - (n+1), & \frac{n+3}{2} \le i \le n, \end{cases}$$

which run through $1, 3, 5, \ldots, n$ and then $2, 4, \ldots, n-1$: exactly the numbers $1, 2, \ldots, n$. (For $n = 1$ the single square contains $1 + 1 - 1 = 1$, consistent with the formula.) □

Layer 1: WHAT

Block 1: translate "no two in the same row or column" into a permutation σ, so the chosen numbers are $i + \sigma(i) - k$. Block 2: sum the chosen numbers structurally; $\sum \sigma(i)$ is permutation-independent, so the sum is $n(n+1) - nk$ whatever you choose. Block 3: equate with $\sum_{v=1}^{n} v$ to force $k = (n+1)/2$ and hence n odd. Block 4: construct σ so that $i + \sigma(i) - k$ hits the odd numbers on the first $\frac{n+1}{2}$ rows and the even numbers on the rest; verify it is a bijection.

Nominal route: try to place the numbers $1, \ldots, n$ one at a time, or grind small grids, and hope the pattern reveals itself. Ideal route: refuse to place anything until you know what is forced. The bifurcation point is the first line after reading: the zombie writes out a 4-by-4 grid; you write $\sum_i (i + \sigma(i) - k)$ and notice σ disappears.

Layer 2: HOW

Block 1. Cue. "Select n squares, no two in the same row or column."

Why natural. This is the definition of a permutation matrix (a transversal). Naming the object σ is what lets you write a formula for the selected entries instead of a picture.

Link to the next block. Once the entries are $i + \sigma(i) - k$, the additive separation of i from $\sigma(i)$ begs to be summed.

Block 2. Cue. The entry is a sum of a function of the row and a function of the column.

Why natural. For $M_{ij} = g(i) + h(j)$ the transversal sum $\sum_i M_{i\sigma(i)} = \sum_i g(i) + \sum_j h(j)$ is independent of σ, because σ merely reorders the h values. This is a definition-level fact about bijections, not an observation you need luck for.

Link to the next block. An invariant that does not depend on the free choice must be matched against the fixed target; the target is the multiset $\{1, \ldots, n\}$.

Block 3. Cue. "Exactly $1, 2, \ldots, n$" is a fixed multiset; its sum is $n(n+1)/2$.

Why natural. Equating the two sums is the only equation available at this point, and it happens to pin k completely. Parity of n falls out because k is an integer; you did not look for a parity argument, the equation handed it to you.

Link to the next block. Necessity leaves one candidate pair (n odd, $k = (n+1)/2$) and the question "for which" obliges you to construct.

Block 4. Cue. You need $i + \sigma(i)$ to run through n consecutive integers as σ runs through a permutation.

Why natural. If $i + \sigma(i) - k = \tau(i)$ for permutations σ, τ, then $\sigma(i) = \tau(i) - i + k$, so $\tau(i) - i$ must itself be injective modulo nothing: the simplest injective choice is $\tau(i) - i = i - 1$, that is $\tau(i) = 2i - 1$, the doubling map, which is a bijection of $\mathbb{Z}_n$ precisely when n is odd. Wrapping the doubling map around n gives the two branches of σ.

Link to the next block. The construction is verified by listing the values on each branch; nothing further is needed.

Layer 3: WHY

The underlying truth is that for matrices of the form $g(i) + h(j)$ every transversal has the same sum, so "which transversal" is invisible to the sum and only the distribution of values is negotiable. The examiners chose entries $i + j - k$ so that this invariant determines k exactly, and the target $\{1, \ldots, n\}$ so that its sum is the cleanest expression available.

The discernment mechanism: whenever a problem lets you choose a permutation and asks for a prescribed set of outputs, compute every permutation-independent statistic of the outputs before choosing anything: sum, product, sum of squares, residues modulo small numbers, in that order of cheapness. Here the sum suffices, which is why this is a B1.

The construction half needs one small object: a permutation σ of $\mathbb{Z}_n$ with $i + \sigma(i)$ also a permutation (a complete mapping). It exists if and only if n is odd, and for odd n the identity works modulo n because 2 is invertible. Once you know that, sufficiency is not a search but a translation of "multiply by 2 modulo n" into integers; the two-branch formula for σ is the unwrapping of the modular shift. Train this by asking, for every construction you produce, which modular fact made it exist.

Revolving concepts

Transversal of a matrix. A set of n cells with one in each row and one in each column; equivalently a permutation σ with cells $(i, \sigma(i))$. Orbiting facts: the sum of a transversal of $g(i) + h(j)$ is $\sum g + \sum h$ for every σ; the product of a transversal of $g(i)h(j)$ is $\prod g \prod h$; the determinant is a signed sum over all transversals of the product, which is why $\det(g(i) + h(j)) = 0$ for $n \geq 3$ (rank at most two). See Book 1, field: Combinatorics, topic: transversals and permutation matrices.

Complete mapping of a group. A bijection σ of a finite group G such that $x \mapsto x\,\sigma(x)$ is also a bijection. For $G = \mathbb{Z}_n$ one exists if and only if n is odd (the identity map works when 2 is a unit; for even n summing $x + \sigma(x)$ over G gives a contradiction modulo n, exactly the sum argument of this problem). Equivalent statement: the Cayley table of $\mathbb{Z}_n$ has a transversal if and only if n is odd. See Book 1, field: Abstract algebra, topic: Latin squares and complete mappings.

Recursion, generalised. There is no recursion in the solution, but the invariant generalises: for any matrix $M_{ij} = g(i) + h(j)$ and any target multiset V, a transversal realising V exists only if $\sum V = \sum g + \sum h$; for $M_{ij} = g(i)h(j)$ replace sums by products. For a matrix of the form $g(i) + h(j)$ with g, h arithmetic progressions of common difference d, transversals realising a run of n consecutive multiples of d exist exactly when n is odd, by the same doubling construction.

Circuit Bank

- **WHEN** a selection of one cell per row and column **DO** name the permutation σ and write the selected entries as $M_{i\sigma(i)}$ **BECAUSE** a formula can be summed, a picture cannot
- **WHEN** an entry of the form $g(i) + h(j)$ with a prescribed output multiset **DO** sum over the transversal and equate with the sum of the multiset before constructing anything **BECAUSE** the transversal sum is permutation-independent, so it is a free necessary condition

- **WHEN** you need $i + \sigma(i)$ to be a permutation **DO** use $\sigma(i) \equiv i + c \pmod{n}$ with n odd, then unwrap into two integer branches **BECAUSE** doubling is a bijection of $\mathbb{Z}_n$ exactly when n is odd
- **WHEN** a question says "for which n" and your invariant forces a parity **DO** expect a construction that uses that same parity in an invertibility step **BECAUSE** the necessary condition and the construction usually rest on the same modular fact

Backtesting

1. First useful cue: "no two in the same row or column" together with an entry depending on $i + j$.
2. Method the expression suggested: sum the selected entries symbolically; the permutation drops out.
3. Where you would hesitate, and the thought to reinforce: at the construction, wondering whether to search. The thought: I need $i + \sigma(i)$ to be a permutation, which is the doubling map on $\mathbb{Z}_n$; write $\sigma(i) \equiv i + \frac{n-1}{2}$ and unwrap.
4. The trap the question sets: fiddling with small grids and believing k is free; the sum shows k is rigid.
5. What makes you recognise it faster next time: the phrase "exactly $1, 2, \ldots, n$" is a fixed multiset, and fixed multisets have fixed sums; compare with the structural sum immediately.
6. The reusable decision rule: when the free choice is a permutation and the target is fixed, compute permutation-invariant statistics first; construct second, and construct with a modular shift.

Mirror drills

1. The cell (i, j) of an n-by-n grid contains ij. For which n can you pick a transversal whose entries are exactly $1^2, 2^2, \ldots, n^2$? *Answer:* the product of any transversal is $(n!)^2$, which equals $\prod v^2$, so the product invariant is silent; but $\sum_i i\sigma(i) = \sum i^2$ forces σ to be the identity by the rearrangement inequality (equality only when σ is order-preserving), so it is always possible, uniquely, for every n.
2. Show that the addition table of $\mathbb{Z}_n$ (entry $i + j \bmod n$) has no transversal when n is even. *Hint:* sum $i + \sigma(i)$ over all i modulo n: the left side is $2 \cdot \frac{n(n-1)}{2} \equiv 0$ but a transversal hitting every residue once sums to $\frac{n(n-1)}{2} \equiv \frac{n}{2} \not\equiv 0$.
3. The cell (i, j) contains $i + 2j$. Find all n for which some transversal has entries forming n consecutive integers. *Answer:* the sum is $3 \cdot \frac{n(n+1)}{2}$ and n consecutive integers starting at s sum to $ns + \frac{n(n-1)}{2}$, forcing $s = n + 2$ for every n; the anti-diagonal $\sigma(i) = n + 1 - i$ gives entries $2n + 2 - i$, which are exactly $n + 2, \ldots, 2n + 1$, so every n works. (Contrast with $i + j$, where the anti-diagonal is constant; the coefficient gap between i and $2j$ is what makes $\sigma(i) = n + 1 - i$ injective on the entries.)

2.8 B2. A fixed centre and two concentric circles

Two convex quadrilaterals are called partners *if they have three vertices in common and they can be labeled $ABCD$ and $ABCE$ so that E is the reflection of D across the perpendicular bisector of the diagonal $\overline{AC}$. Is there an infinite sequence of convex quadrilaterals such that each quadrilateral is a partner of its successor and no two elements of the sequence are congruent?*

Read it out loud

A move on convex quadrilaterals: keep three vertices, and replace the fourth by its mirror image in the perpendicular bisector of the diagonal joining its two neighbours. The question asks whether iterating the move can produce infinitely many pairwise non-congruent shapes. So this is a dynamics question in disguise: a move, an orbit, and the word "congruent", which tells you the answer must be phrased in terms of invariants under the move that survive up to congruence.

The fields are Euclidean geometry (reflections, perpendicular bisectors as loci of equidistance, convexity forcing the diagonals to cross) and the finiteness logic of combinatorics (finitely many values of an invariant, finitely many states). What is really being tested is whether you extract from the definition of the move the objects it fixes. A reflection fixes every point of its axis; the axis is the perpendicular bisector of AC; so anything defined from that axis alone is fixed by the move.

The first useful cue is the phrase "reflection across the perpendicular bisector of $\overline{AC}$". Within thirty seconds you should have written: the reflection swaps A and C, so $CE = AD$ and $AE = CD$; the side lengths are permuted, the diagonal AC and the area are kept. Then the harder question: what is not merely permuted but literally fixed? A point on the axis defined symmetrically from both diagonals: the intersection of their perpendicular bisectors. Expect the answer "no".

Approaches, ranked worst to best

1. **Coordinates and algebraic functions.** *Cue:* a reflection has an explicit formula. *Circuit:* parametrise the quadrilateral, fix the invariants, and argue that a nonconstant algebraic function takes each value finitely often. (it needs the sides and area invariants first anyway, then a page of coordinates and a fact about algebraic functions that you cannot prove in the arena; it ranks last on ink and on rigour risk)

2. **Side lengths and area, then Bretschneider.** *Cue:* $CE = AD$, $AE = CD$, and area is preserved because $ACE \cong ACD$. *Circuit:* a convex quadrilateral with given ordered sides is determined by one diagonal f; Bretschneider's formula $K^2 = (s-a)(s-b)(s-c)(s-d) - abcd\cos^2\frac{\alpha+\gamma}{2}$ fixes $\cos^2\frac{\alpha+\gamma}{2}$, and $\alpha+\gamma = 2\pi - (\beta+\delta)$ is strictly decreasing in f because the angles β, δ opposite the diagonal f increase with f. (valid and short once you own Bretschneider, but that formula is a knowledge gap for you, and the monotonicity step is easy to get wrong: each of the two angles at A separately is not monotone in f, only the sum of the two angles opposite f is; ranks second)

3. **Fixed centre and two concentric circles.** *Cue:* the axis of the reflection is a perpendicular bisector, so the move fixes any point on it; the perpendicular bisectors of both diagonals meet at a point O because the diagonals of a convex quadrilateral cross. *Circuit:* O, the two radii $OA = OC$ and $OB = OD$, and the multiset of side lengths are all invariant; each side subtends an angle at O determined by its length, so there are finitely many shapes up to rotation. (a half page, nothing beyond the definition of a reflection and the cosine rule; the ideal)

The ideal solution

No such sequence exists.

Step 1: the centre. Let $ABCD$ be a convex quadrilateral. Its diagonals AC and BD cross at an interior point, so they are not parallel, so their perpendicular bisectors are not parallel and meet in exactly one point O. Call O the *centre* of the quadrilateral. By construction $OA = OC$ and $OB = OD$.

Step 2: the centre and the radii are invariant under the move. Let $ABCE$ be a partner of $ABCD$, with E the reflection of D across the perpendicular bisector ℓ of AC; write ρ for this reflection. Since $O \in \ell$, $\rho(O) = O$, and reflections preserve distance, so

$$OE = |\rho(O)\rho(D)| = OD = OB.$$

Hence O lies on the perpendicular bisector of BE and on ℓ. The quadrilateral $ABCE$ is convex, so by Step 1 these two lines meet in exactly one point, which must be O: the centre of $ABCE$ is the centre of $ABCD$. Moreover A and C keep their common distance $r_1 := OA = OC$ to O, and the pair $\{B, E\}$ has the same common distance $r_2 := OB = OD$ as the pair $\{B, D\}$ had. Note $r_1 > 0$, since $r_1 = 0$ would force $A = O = C$, and likewise $r_2 > 0$.

Step 3: the side lengths are invariant as a multiset. Since ρ swaps A and C and sends D to E,

$$CE = |\rho(A)\rho(D)| = AD, \qquad AE = |\rho(C)\rho(D)| = CD,$$

so the sides of $ABCE$, namely AB, BC, CE, EA, form the same multiset as the sides AB, BC, CD, DA of $ABCD$.

Step 4: finiteness. Consider any sequence $Q_1, Q_2, \ldots$ of convex quadrilaterals in which each is a partner of its successor. By Steps 2 and 3 applied along the sequence, all Q_i share the same centre O, the same two radii $r_1, r_2 > 0$ (with the endpoints of one diagonal on the circle of radius r_1 about O and the endpoints of the other diagonal on the circle of radius r_2), and the same finite set S of side lengths, $|S| \le 4$.

Place O at the origin. Consecutive vertices of any Q_i are endpoints of different diagonals, so one of them is $r_1(\cos\theta, \sin\theta)$ and the other is $r_2(\cos\varphi, \sin\varphi)$ for some polar angles θ, φ, and by the cosine rule the side joining them has length s with

$$s^2 = r_1^2 + r_2^2 - 2r_1 r_2 \cos(\theta - \varphi).$$

Since $r_1 r_2 \neq 0$, this determines $\cos(\theta - \varphi)$, and therefore $\theta - \varphi \equiv \pm\delta(s) \pmod{2\pi}$ with $\delta(s) = \arccos \frac{r_1^2 + r_2^2 - s^2}{2r_1 r_2} \in [0, \pi]$. Thus every step from a vertex to the next vertex changes the polar angle by an element of the finite set $G = \{\pm\delta(s) : s \in S\}$, $|G| \le 8$. Start at a vertex on the circle of radius r_1 and go round the quadrilateral: the radii alternate r_1, r_2, r_1, r_2, and the polar angles of the other three vertices are the starting angle plus partial sums of three elements of G. Rotating about O so that the starting vertex has polar angle 0 is a congruence, so every Q_i is congruent to one of at most $|G|^3 \le 512$ quadrilaterals. A sequence of pairwise non-congruent quadrilaterals therefore has at most 512 terms, and no infinite sequence with the required property exists. □

A caveat worth clarifying: the partner relation is symmetric (D is the reflection of E across the same line), so "each is a partner of its successor" and "each is a partner of its predecessor" give the same sequences, and the invariance argument runs in whichever direction you like.

Layer 1: WHAT

Block 1: read the move as a reflection ρ in the perpendicular bisector ℓ of AC; list what ρ does to the four vertices ($A \leftrightarrow C$, $D \mapsto E$, B untouched). Block 2: find a point fixed by every possible move: the intersection O of the perpendicular bisectors of the two diagonals, which exists because convexity makes the diagonals cross. Block 3: show O is the centre of the partner too, and that the distances from O to the diagonal endpoints are preserved. Block 4: record the cheap invariant, the multiset of side lengths. Block 5: convert "vertices on two concentric circles with sides of prescribed lengths" into "angular steps from a finite set", count, conclude finiteness.

Nominal route: write the quadrilateral in coordinates, apply the reflection formula, try to find what is preserved by inspection of the algebra, then fight an infinite-versus-finite question with algebraic geometry. Ideal route: ask what a reflection fixes (its axis) and what a perpendicular bisector is (an equidistance locus), and let the fixed point O emerge from definitions. The bifurcation point is Block 2: the zombie asks "what does the move do to the shape?" and you ask "what does the move leave alone?".

Layer 2: HOW

Block 1. **Cue.** "E is the reflection of D across the perpendicular bisector of $\overline{AC}$."

Why natural. A reflection is an isometry, so every distance between images equals the distance between preimages; and the perpendicular bisector of AC is exactly the axis that swaps A and C. Writing $CE = |\rho(A)\rho(D)| = AD$ is therefore not an idea, it is the definition read twice.

Link to the next block. You now know which lengths survive the move. The next question is which *points* survive, because a fixed point turns an orbit into a rigid picture.

Block 2. **Cue.** The axis ℓ depends on the diagonal AC; a different move (reflecting B, say) uses the other diagonal. You want something fixed by both.

Why natural. Points of ℓ are fixed by ρ. Among them, the one you can name without reference to which vertex is being moved is the intersection of the perpendicular bisectors of *both* diagonals. It exists because the diagonals of a convex quadrilateral cross and so are not parallel; this is where the hypothesis "convex" is spent, and you should notice that you needed it.

Link to the next block. Having named O, you must check it is still the centre after the move, otherwise "fixed" is only a hope.

Block 3. **Cue.** $O \in \ell$ and $OB = OD$.

Why natural. $\rho(O) = O$ and $\rho(D) = E$, so $OE = OD = OB$: O is equidistant from B and E, hence on the perpendicular bisector of the new diagonal BE, and it is on ℓ, the perpendicular bisector of the old diagonal AC. Uniqueness of the intersection (convexity of the partner) then identifies the new centre with O. The radii are preserved for the same reason: the replaced vertex has the same distance to O as the vertex it replaced.

Link to the next block. With O, r_1, r_2 fixed, the vertices of every quadrilateral in the sequence live on two concentric circles, and the only remaining freedom is angular.

Block 4. **Cue.** The multiset of side lengths came free in Block 1.

Why natural. A finite set of admissible side lengths is what you need to make the angular freedom finite. Without it the vertices could slide around the circles.

Link to the next block. Combine: a side joins a point on the circle of radius r_1 to a point on the circle of radius r_2; the cosine rule turns its length into the angle it subtends at O.

Block 5. **Cue.** Two concentric circles, a chord between them of known length, centre O.

Why natural. The cosine rule in triangle OPQ with $OP = r_1$, $OQ = r_2$ gives $\cos \angle POQ$ from PQ, so the angular step is $\pm\delta(s)$: a finite set. Four vertices, three steps, at most 8^3 configurations up to rotation. Congruence classes are finite, so the sequence is finite.

Link to the next block. Nothing remains but to state the count and the conclusion.

Layer 3: WHY

The mathematical truth underneath is that a reflection in a line through a point O preserves distance from O, so a sequence of reflections in lines through a common point moves every vertex around a

circle centred at O. The move in this problem is engineered so that all the axes pass through one point: each axis is the perpendicular bisector of a diagonal, and O is on the perpendicular bisectors of both diagonals, and stays there because the new diagonal BE is still bisected perpendicularly by a line through O. The examiners nudged toward this by choosing the perpendicular bisector (an equidistance locus) as the mirror, rather than an arbitrary line through the midpoint of AC.

The second truth is that "non-congruent" is a statement about orbits modulo isometry, and to bound an orbit modulo isometry you fix a point and reduce to rotations about it. Once O is fixed, congruence is rotation, and rotation is one real parameter, killed by the choice of starting angle.

The discernment mechanism: for any "move" problem, ask three questions in order. What does the move preserve (lengths, areas, multisets)? What does it fix pointwise (points on the axis, centres)? What finite data determines the state up to the allowed equivalence? The first question is where the nominal route stops; the second is where the ideal route lives. Train it by practising on reflections, rotations and inversions: for each, write the fixed set before writing anything else. It is worth repeating: a reflection is defined by its axis, so its fixed set is the first object to name.

On the Bretschneider route, one caveat: the monotonicity of the angle sum in the diagonal must be argued for the pair of angles *opposite* the diagonal (each increases with it by the cosine rule), not for the two angles at one vertex individually, which are not monotone.

Revolving concepts

Reflection in a line. The isometry fixing the line pointwise and swapping the half-planes. Orbiting facts: isometries preserve all distances, hence all congruence classes of sub-figures; a reflection in a line through O maps the circle of radius r about O to itself; the composition of two reflections in lines through O is a rotation about O. The perpendicular bisector of PQ is the locus of points equidistant from P and Q, and equivalently the axis of the unique reflection swapping P and Q. See Book 1, field: Geometry, topic: isometries and their fixed sets.

Convex quadrilateral. A quadrilateral whose diagonals intersect at an interior point. Orbiting facts: the diagonal splits it into two triangles whose areas add; the diagonals are not parallel, so their perpendicular bisectors meet; the vertices are in convex position. This is the only place convexity is used, and it is essential: for a self-intersecting quadrilateral the diagonals can be parallel and no centre exists. See Book 1, field: Geometry, topic: convexity.

Bretschneider's formula. For a quadrilateral with sides a, b, c, d in order, semiperimeter s, and a pair of opposite angles α, γ: $K^2 = (s-a)(s-b)(s-c)(s-d) - abcd\cos^2\frac{\alpha+\gamma}{2}$. Brahmagupta's formula is the cyclic case $\alpha + \gamma = \pi$. Knowledge gap: install it, but note that in this problem it is the heavier route. See Book 1, field: Geometry, topic: area formulae for quadrilaterals.

Recursion, generalised. The sequence $Q_{i+1} = \text{move}(Q_i)$ is an iterated map on a state space. The general principle: if every move preserves a function I of the state that takes finitely many values, and if I together with finitely many further choices determines the state up to the equivalence in question, then the orbit is finite modulo that equivalence. Here $I = (O, r_1, r_2, S)$ and the further choices are the three angular signs. The same generalisation solves "can a sequence of triangles obtained by reflecting one vertex in the opposite side's perpendicular bisector be pairwise non-congruent" (no: the circumcentre is fixed) and many "infinite process" questions where the answer is finiteness by invariants.

Circuit Bank

- **WHEN** a move defined by a reflection **DO** write the fixed set (the axis) and the images of all named points before anything else **BECAUSE** a reflection is defined by its axis, and its fixed points are the rigid skeleton of any orbit
- **WHEN** a perpendicular bisector **DO** read it as an equidistance locus, and look for a point equidistant from more than one pair **BECAUSE** equidistance from two pairs simultaneously

names a point, and named points are invariants

- **WHEN** "no two congruent" in an iterated process **DO** fix a point and reduce congruence to rotation about it; then count angular data **BECAUSE** congruence modulo a fixed point is one real parameter
- **WHEN** two points on concentric circles about O with known distance **DO** use the cosine rule in triangle OPQ to read off the angle at O **BECAUSE** the angle is determined up to sign by one length
- **WHEN** a hypothesis you have not used (here, convex) **DO** find the line where it is spent and say so **BECAUSE** an unused hypothesis is a sign of an incomplete or wrong argument

Backtesting

1. First useful cue: "reflection across the perpendicular bisector of $\overline{AC}$", which swaps A and C and fixes its axis pointwise.
2. Method the expression suggested: hunt for a fixed point of all possible moves; the intersection of the perpendicular bisectors of the diagonals.
3. Where you would hesitate, and the thought to reinforce: after finding the side-length invariant, being tempted to invoke area and Bretschneider. The thought: I want a point, not a number; what point does every axis pass through?
4. The trap the question sets: believing that two invariants (sides and area) force finiteness without a lemma, or misproving the lemma by claiming the wrong angles are monotone.
5. What makes you recognise it faster next time: the word "partner" is decorative; the content is "reflect one vertex in a line through the centre of the figure". Strip the decoration and the fixed centre is visible.
6. The reusable decision rule: preserved quantities bound values, fixed points bound positions; for congruence questions you need the fixed point.

Mirror drills

1. A triangle ABC is replaced by $A'BC$ where A' is the reflection of A in the perpendicular bisector of BC. Show that iterating (choosing any vertex each time) produces finitely many triangles up to congruence. *Answer:* the circumcentre is fixed and the circumradius preserved, and the side multiset is preserved; each side subtends a determined angle at the circumcentre, so finitely many shapes up to rotation.
2. Points P on a circle of radius r_1 and Q on a concentric circle of radius r_2 satisfy $PQ = s$. How many possible values of the angle $\angle POQ$ are there? *Answer:* at most one value in $[0, \pi]$, namely $\arccos \frac{r_1^2+r_2^2-s^2}{2r_1r_2}$, so the signed angle takes at most two values.
3. Explain in one line why a self-intersecting quadrilateral may have no centre in the sense of the solution. *Answer:* for $A = (0,0)$, $C = (1,0)$, $B = (0,1)$, $D = (1,1)$ the diagonals AC and BD are parallel, so their perpendicular bisectors never meet; convexity excludes this.

2.9 B3. Consecutive roots via the tangent addition formula

Let r_n be the nth smallest positive solution to $\tan x = x$*, where the argument of tangent is in radians. Prove that*

$$0 < r_{n+1} - r_n - \pi < \frac{1}{(n^2+n)\pi}$$

for $n \geq 1$.

Read it out loud

An implicitly defined sequence: the positive roots of $\tan x = x$, one per branch of the tangent. You are asked for a two-sided estimate of the gap between consecutive roots: the gap exceeds π (the period of tan), but by less than $\frac{1}{(n^2+n)\pi}$. So the roots creep up their branches, each one slightly further past $n\pi$ than the last, and the creep decays like $1/n^2$.

The fields are real analysis (locating roots by monotonicity and the intermediate value theorem), trigonometry (periodicity and the addition formula), and a dose of asymptotics. What is really being tested is whether you can turn the defining equation into a relation between consecutive roots without ever solving it. The roots satisfy $\tan r_n = r_n$: that is not an obstacle, it is a substitution rule. Whenever $\tan r_n$ appears you may replace it by r_n, and the tangent addition formula is the machine that makes $\tan r_n$ and $\tan r_{n+1}$ appear together.

The first useful cue is the shape of the bound, $\frac{1}{(n^2+n)\pi} = \frac{\pi}{(n\pi)((n+1)\pi)}$: a product of two consecutive quantities of size $n\pi$ and $(n+1)\pi$, which are the crude sizes of r_n and r_{n+1}. A product $r_n r_{n+1}$ is exactly what the denominator $1 + \tan A \tan B$ of the addition formula produces. Within thirty seconds you should have written: $r_n = n\pi + \theta_n$ with $\theta_n \in (0, \frac{\pi}{2})$, and $\tan(\theta_{n+1} - \theta_n) = \dfrac{r_{n+1} - r_n}{1 + r_n r_{n+1}}$.

Approaches, ranked worst to best

1. **Taylor expansion of $f(x) = \tan x - x$ around $r_n + \pi$.** *Cue:* $f(r_n + \pi) = -\pi$ and $f(r_{n+1}) = 0$. *Circuit:* all derivatives of f are positive polynomials in $\tan x$, so a full Taylor lower bound gives a geometric series in the gap. (it works, but it needs an induction on the form of $f^{(k)}$, a remainder estimate, a limit in k, and a subtlety about strict inequalities surviving the limit; a page of ink for a two-line fact)

2. **Mean value theorem once.** *Cue:* $f(r_n + \pi) = -\pi$, $f'(x) = \tan^2 x$ increasing on the branch. *Circuit:* $\pi = \delta \tan^2 \xi > \delta r_n^2$. (one line, but it only gives $\delta < \frac{1}{n^2\pi}$, weaker than the target by the factor $\frac{n}{n+1}$; the mean value theorem sees one point, the target needs both endpoints)

3. **Inverse function of $t(x) = x - \arctan x$.** *Cue:* $\tan x = x$ if and only if $x - \arctan x = n\pi$. *Circuit:* $r_n = x(n\pi)$ for the inverse $x(t)$, and $x(t) - t$, $x(t) - t + 1/t$ are monotone. (neat and rigorous, moderate ink; it hides the same product $r_n r_{n+1}$ inside the monotonicity of $x(t) - t + 1/t$)

4. **Tangent addition formula.** *Cue:* $\tan r_n = r_n$ is a substitution rule and the bound contains $r_n r_{n+1}$. *Circuit:* $\tan(\theta_{n+1} - \theta_n) = \frac{\pi+\delta}{1+r_n r_{n+1}}$ gives both inequalities from $0 < \delta < \tan\delta$. (three lines after locating the roots; the ideal)

The ideal solution

Step 1: locate the roots. Let $f(x) = \tan x - x$ on each branch $I_m = \left(m\pi - \frac{\pi}{2}, m\pi + \frac{\pi}{2}\right)$, $m \in \mathbb{Z}$. On I_m, f is continuous, $f'(x) = \sec^2 x - 1 = \tan^2 x \geq 0$ with equality only at $x = m\pi$, so f is strictly increasing on I_m; and $f(x) \to -\infty$ as $x \to (m\pi - \frac{\pi}{2})^+$, $f(x) \to +\infty$ as $x \to (m\pi + \frac{\pi}{2})^-$. Hence f has exactly one zero in each I_m. For $m = 0$ that zero is $x = 0$, not positive; for $m < 0$ the branch is

negative. For $m \geq 1$, $f(m\pi) = -m\pi < 0$, so the zero lies in $(m\pi, m\pi + \frac{\pi}{2})$. Since the branches are disjoint and ordered, the positive roots in increasing order are these zeros for $m = 1, 2, \ldots$, and so

$$r_n = n\pi + \theta_n \quad \text{with} \quad \theta_n \in \left(0, \tfrac{\pi}{2}\right), \qquad \tan\theta_n = \tan r_n = r_n \quad (n \geq 1).$$

Step 2: the exact relation between consecutive roots. Put $\delta = r_{n+1} - r_n - \pi = \theta_{n+1} - \theta_n \in \left(-\frac{\pi}{2}, \frac{\pi}{2}\right)$. Both θ_n, θ_{n+1} lie in $(0, \frac{\pi}{2})$, so the addition formula applies and its denominator is positive:

$$\tan\delta = \frac{\tan\theta_{n+1} - \tan\theta_n}{1 + \tan\theta_{n+1}\tan\theta_n} = \frac{r_{n+1} - r_n}{1 + r_n r_{n+1}} = \frac{\pi + \delta}{1 + r_n r_{n+1}}.$$

Step 3: the lower bound. Since $\delta > -\frac{\pi}{2}$ we have $\pi + \delta > \frac{\pi}{2} > 0$, and $1 + r_n r_{n+1} > 0$, so $\tan\delta > 0$. As $\delta \in (-\frac{\pi}{2}, \frac{\pi}{2})$ and tan is negative on $(-\frac{\pi}{2}, 0]$ (zero at 0), this forces $\delta \in (0, \frac{\pi}{2})$. Thus $r_{n+1} - r_n - \pi > 0$.

Step 4: the upper bound. For $0 < \delta < \frac{\pi}{2}$ we have $\delta < \tan\delta$ (this is $f(\delta) > f(0) = 0$ with f strictly increasing on I_0, from Step 1). Therefore

$$\delta < \frac{\pi + \delta}{1 + r_n r_{n+1}} \implies \delta\,(1 + r_n r_{n+1}) < \pi + \delta \implies \delta < \frac{\pi}{r_n r_{n+1}}.$$

Finally $r_n > n\pi$ and $r_{n+1} > (n+1)\pi$ from Step 1, so

$$\delta < \frac{\pi}{(n\pi)\big((n+1)\pi\big)} = \frac{1}{(n^2+n)\pi},$$

which is the required upper bound. □

Layer 1: WHAT

Block 1: locate each root on its own branch, $r_n = n\pi + \theta_n$ with $\theta_n \in (0, \frac{\pi}{2})$, using monotonicity of $\tan x - x$ on a branch and the sign of $f(n\pi)$. Block 2: name the quantity to be bounded, $\delta = \theta_{n+1} - \theta_n$, and compute $\tan\delta$ by the addition formula, replacing $\tan\theta_n$ by r_n. Block 3: read the sign of $\tan\delta$ to get $\delta > 0$. Block 4: apply $\delta < \tan\delta$ and the crude bounds $r_n > n\pi$, $r_{n+1} > (n+1)\pi$.

Nominal route: treat r_{n+1} as a perturbation of $r_n + \pi$, expand f in a Taylor series with all derivatives, and control an infinite series. Ideal route: never expand; the roots satisfy an exact functional relation, so ask what identity contains $\tan r_n$ and $\tan r_{n+1}$ simultaneously. The bifurcation point is Block 2: the zombie writes $f(r_n + \pi + \delta)$ and starts differentiating; you write $\tan(\theta_{n+1} - \theta_n)$ and substitute.

Layer 2: HOW

Block 1. **Cue.** "nth smallest positive solution to $\tan x = x$."

Why natural. An implicitly defined sequence must be pinned to an interval before it can be compared with anything. tan is periodic with period π, so the branches are the natural cells; on each, $\tan x - x$ has derivative $\tan^2 x \geq 0$, so it is monotone and has one zero. The sign $f(n\pi) = -n\pi < 0$ pushes the zero to the right half of the branch. That gives $\theta_n \in (0, \frac{\pi}{2})$, which is precisely the domain on which the later use of the addition formula and of $\delta < \tan\delta$ is legitimate.

Link to the next block. Once $r_n = n\pi + \theta_n$, the periodicity of tan converts $\tan r_n = r_n$ into $\tan\theta_n = r_n$: a substitution rule for $\tan\theta_n$.

Block 2. **Cue.** The target bound is $\frac{\pi}{(n\pi)((n+1)\pi)}$, a product of the sizes of consecutive roots.

Why natural. The only elementary identity that manufactures a product $\tan A \tan B$ is the addition formula, and the quantity you want, $\delta = \theta_{n+1} - \theta_n$, is a difference of angles whose tangents you know. So $\tan\delta$ is computable exactly, with no approximation, and the answer $\frac{\pi+\delta}{1+r_n r_{n+1}}$ contains the target denominator already.

Link to the next block. An exact identity for $\tan\delta$ yields sign information (lower bound) and size information (upper bound) in that order.

Block 3. **Cue.** $\tan\delta = \frac{\pi+\delta}{1+r_n r_{n+1}}$ with a positive numerator and denominator.

Why natural. On $(-\frac{\pi}{2}, \frac{\pi}{2})$ the sign of $\tan\delta$ is the sign of δ. Positivity of the right side is immediate from $\delta > -\frac{\pi}{2}$. So the lower bound is not a separate argument, it is the same identity read for sign.

Link to the next block. Knowing $\delta \in (0, \frac{\pi}{2})$ unlocks the inequality $\delta < \tan\delta$, which is the only comparison between an angle and its tangent you ever need on that interval.

Block 4. **Cue.** $\delta < \tan\delta$, then a linear inequality in δ.

Why natural. Substituting the identity, $\delta(1 + r_n r_{n+1}) < \pi + \delta$ cancels the δ on both sides and leaves $\delta r_n r_{n+1} < \pi$. The crude bounds $r_n > n\pi$ from Block 1 finish it. Notice the cancellation: the δ in the numerator was never a nuisance.

Link to the next block. End of proof; no limit, no series.

Layer 3: WHY

The truth beneath the route: for roots of an equation of the form $\tan x = g(x)$, the addition formula turns the difference of two roots into an exact expression in g at the two roots. Consecutive roots of $\tan x = x$ differ by π plus a correction whose tangent is $\frac{\pi+\delta}{1+r_n r_{n+1}}$; since $r_n r_{n+1} \sim n^2\pi^2$, the correction is of order $\frac{1}{n^2\pi}$, and the problem's bound is the crude version of this asymptotic. The examiners nudged you by writing the bound as $\frac{1}{(n^2+n)\pi}$ rather than $\frac{1}{n^2\pi}$: the factor $n(n+1)$ is a signature of a product of consecutive roots, and a mean value argument (which sees one intermediate point) cannot produce it. That is why approach 2 stalls at $\frac{1}{n^2\pi}$ and why the intended route is two-endpoint.

The discernment mechanism is the sentence "the defining equation is a substitution rule, not an obstacle". For an implicitly defined object, do not try to solve; ask which identities involve the defining expression and rewrite them using the equation. Here $\tan r_n = r_n$ lets every occurrence of $\tan r_n$ become r_n, so any identity in tangents becomes an identity in the roots themselves. Train this by taking each classical implicit equation ($x = \cos x$, $xe^x = 1$, $\tan x = x$) and listing which identities (addition formula, functional equation of exp, etc.) convert into exact relations between roots.

A second truth, on rigour: every use of tan needs the argument inside a branch, and every use of the addition formula needs a nonzero denominator. Locating θ_n in $(0, \frac{\pi}{2})$ first is what makes the later three lines airtight, and it costs half the write-up. Full marks are earned in Step 1, not in Step 4.

Revolving concepts

Branches of tan *and root location.* tan is continuous and strictly increasing from $-\infty$ to $+\infty$ on each $I_m = (m\pi - \frac{\pi}{2}, m\pi + \frac{\pi}{2})$. For $\tan x = g(x)$ with g continuous, the number of roots in I_m is governed by the monotonicity of $\tan x - g(x)$; when $g' \le \tan^2 x$ on the branch (as for $g(x) = x$) there is exactly one. See Book 1, field: Real analysis, topic: intermediate value theorem and monotone root location.

Tangent addition formula and its substitution use. $\tan(A - B) = \frac{\tan A - \tan B}{1+\tan A \tan B}$ when $A, B, A - B$ avoid odd multiples of $\frac{\pi}{2}$. If $\tan A = a$, $\tan B = b$ are known numbers, $A - B$ is known modulo π exactly. See Book 1, field: Calculus and integrals, topic: trigonometric identities as functional equations.

The inequality $x < \tan x$ *on* $(0, \frac{\pi}{2})$, with the companions $\sin x < x < \tan x$; all three are monotonicity statements about $\tan x - x$ and $x - \sin x$. See Book 1, field: Inequalities, topic: elementary function inequalities.

Asymptotics of the roots. Writing $r_n = (n + \frac{1}{2})\pi - \varepsilon_n$ gives $\cot\varepsilon_n = r_n$, so $\varepsilon_n = \arctan(1/r_n)$ and $r_n = (n + \frac{1}{2})\pi - \frac{1}{(n+\frac{1}{2})\pi} + O(n^{-3})$. These roots are the eigenvalue equation of several physical problems and also the positive zeros of the spherical Bessel function j_1. See Book 1, field: Sequences and recurrences, topic: asymptotic expansion of implicitly defined sequences.

Recursion, generalised. The sequence r_n is defined by a functional condition rather than a recurrence, but the gap $\delta_n = r_{n+1} - r_n - \pi$ satisfies the exact relation $\tan\delta_n = \frac{\pi+\delta_n}{1+r_n r_{n+1}}$. General form:

if x_n solves $h(x) = x$ on the nth branch of a π-periodic h with an addition law (tangent, or any Möbius-type law), then the gaps satisfy an exact equation of the shape $\Phi(\delta_n) = \Psi(x_n, x_{n+1})$, and both bounds on δ_n come from one such equation plus crude bounds on x_n. The same generalisation handles $\tan x = ax$, $\tan x = a/x$, and $\cot x = x$.

Circuit Bank

- **WHEN** an implicitly defined sequence of roots of a periodic equation **DO** locate each root on its own branch by monotonicity, and write it as $n\pi + \theta_n$ with θ_n in a fixed interval **BECAUSE** every later inequality needs a domain, and the branch is that domain
- **WHEN** $\tan r = r$ (or any defining equation) and a quantity involving tan of a difference of roots **DO** apply the addition formula and replace every $\tan r$ by r **BECAUSE** the defining equation is a substitution rule; the addition formula is the identity that puts two roots in one expression
- **WHEN** a bound with denominator $n(n+1)$ or $r_n r_{n+1}$ **DO** expect a two-endpoint identity, not a one-point mean value estimate **BECAUSE** a mean value argument only produces one root's square
- **WHEN** an exact identity $\tan\delta = (\text{positive})$ with $\delta \in (-\frac{\pi}{2}, \frac{\pi}{2})$ **DO** read the sign first, then apply $\delta < \tan\delta$ **BECAUSE** sign gives the lower bound for free and unlocks the domain for the upper bound

Backtesting

1. First useful cue: the target $\frac{1}{(n^2+n)\pi} = \frac{\pi}{(n\pi)((n+1)\pi)}$, a product of consecutive root sizes.
2. Method the expression suggested: an identity producing $r_n r_{n+1}$, namely the denominator of the tangent addition formula.
3. Where you would hesitate, and the thought to reinforce: after locating the roots, the temptation to expand $\tan(r_n + \pi + \delta)$ as a series. The thought: I know tan at both roots exactly, so I know tan of their difference exactly.
4. The trap the question sets: a single mean value step gives $\frac{1}{n^2\pi}$ and feels like victory; it is short of the target by the factor $\frac{n}{n+1}$, and a grader will not accept it.
5. What makes you recognise it faster next time: "$\tan x = x$" means "tan of a root is the root"; any identity in tangents of roots is an identity in the roots.
6. The reusable decision rule: for roots of $\tan x = g(x)$, the consecutive gap satisfies $\tan(\text{gap} - \pi) = \frac{g(x_{n+1}) - g(x_n)}{1 + g(x_n)g(x_{n+1})}$; bound the gap from that, never from a series.

Mirror drills

1. With r_n as in the problem, show $r_n = (n + \frac{1}{2})\pi - \frac{1}{(n+\frac{1}{2})\pi} + O(n^{-3})$. *Hint:* write $r_n = (n + \frac{1}{2})\pi - \varepsilon_n$; then $\tan r_n = \cot\varepsilon_n = r_n$, so $\varepsilon_n = \arctan(1/r_n) = \frac{1}{r_n} + O(r_n^{-3})$, and substitute $r_n = (n + \frac{1}{2})\pi + O(1/n)$ into $1/r_n$.
2. Prove the matching lower bound $r_{n+1} - r_n - \pi > \dfrac{\pi^2}{4(1 + r_n r_{n+1})}$. *Hint:* $\delta < \frac{1}{2\pi} < \frac{\pi}{4}$ and tan is convex on $[0, \frac{\pi}{4}]$, so $\tan\delta \le \frac{4}{\pi}\delta$ there; combine with $\tan\delta > \frac{\pi}{1 + r_n r_{n+1}}$.
3. Let s_n be the nth positive root of $\tan x = 2x$. Show $s_{n+1} - s_n - \pi < \dfrac{2\pi}{4 s_n s_{n+1} - 1}$. *Hint:* first check that $\tan x - 2x$ has exactly one positive root in each $(m\pi + \frac{\pi}{4}, m\pi + \frac{\pi}{2})$, $m \ge 0$, and no

other positive roots (its derivative $\tan^2 x - 1$ is negative on $(m\pi - \frac{\pi}{4}, m\pi + \frac{\pi}{4})$ and positive on the rest of the branch, and the local maximum at $m\pi - \frac{\pi}{4}$ is negative); so s_n lies on the branch $m = n - 1$ and $\delta = s_{n+1} - s_n - \pi \in (-\frac{\pi}{4}, \frac{\pi}{4})$; then $\tan\delta = \frac{2(\pi+\delta)}{1+4s_n s_{n+1}}$, which gives $\delta > 0$, and $\delta < \tan\delta$ gives the bound.

2.10 B4. Affine drift makes the mean a geometric sequence

Let n be a positive integer. Set $a_{n,0} = 1$. For $k \geq 0$, choose an integer $m_{n,k}$ uniformly at random from the set $\{1, \ldots, n\}$, and let

$$a_{n,k+1} = \begin{cases} a_{n,k} + 1, & \text{if } m_{n,k} > a_{n,k}; \\ a_{n,k}, & \text{if } m_{n,k} = a_{n,k}; \\ a_{n,k} - 1, & \text{if } m_{n,k} < a_{n,k}. \end{cases}$$

Let $E(n)$ be the expected value of $a_{n,n}$. Determine $\lim_{n\to\infty} E(n)/n$.

Read it out loud

A random walk on $\{1, \ldots, n\}$ that starts at 1, and at each step moves up with probability $\frac{n-a}{n}$, stays with probability $\frac{1}{n}$, and moves down with probability $\frac{a-1}{n}$, where a is the current position. It is run for exactly n steps and you are asked for the expected position, normalised by n, in the limit. So the object is a Markov chain with state-dependent step probabilities, and the question is about its mean after a number of steps equal to the size of the state space.

The fields are probability (conditional expectation, the tower law), sequences and recurrences (a first-order linear recurrence with constant coefficients), and the limit $(1 - \frac{2}{n})^n \to e^{-2}$. What is really being tested is whether you compute the conditional expectation of one step before doing anything else. The transition rule is given by comparing m with a, so the expected change in one step is $P(m > a) - P(m < a) = \frac{(n-a)-(a-1)}{n} = \frac{n+1-2a}{n}$, which is affine in a. That single line is the whole problem: an affine drift means the expectation satisfies a closed linear recurrence with no knowledge of the distribution.

The first useful cue is the case split by comparison with a uniform variable: "$m > a$", "$m = a$", "$m < a$". Within thirty seconds you should have written $\mathbb{E}[a_{k+1} \mid a_k = a] = a + \frac{n+1-2a}{n} = \left(1 - \frac{2}{n}\right) a + \frac{n+1}{n}$. Everything after that is A-level: solve the recurrence, evaluate at $k = n$, take the limit.

Approaches, ranked worst to best

1. **Full spectral analysis of the transition matrix.** *Cue:* the process is a Markov chain on n states. *Circuit:* write the tridiagonal matrix A, find all eigenvalues $\frac{n-2j}{n}$ and eigenvectors, expand the initial vector. (correct but enormous: you need every eigenvector to expand v_0, when the question only asks for one linear functional of v_n; costs pages)

2. **Coupling two starting points.** *Cue:* the update depends on a only through the comparison with m. *Circuit:* walks started at j and $j+1$ coalesce when $m \in \{j, j+1\}$, otherwise stay one apart, so $\mathbb{E}$ is affine in the start with slope $(1 - \frac{2}{n})^n$; combine with the symmetry $a \mapsto n + 1 - a$. (short and rigorous, and natural once you notice the update depends on a only through the comparison, but it needs the symmetry observation and a coupling argument that a grader will want written carefully; more ink than necessary)

3. **Bulb reinterpretation.** *Cue:* transition probabilities $\frac{a-1}{n}$, $\frac{1}{n}$, $\frac{n-a}{n}$ are the Ehrenfest urn with one stuck ball. *Circuit:* one red bulb always lit, $n - 1$ white bulbs toggled by a uniformly chosen bulb; a is the number of lit bulbs; linearity of expectation over bulbs and the parity of a binomial. (gives the exact answer and the full distribution and explains the e^{-2}, but requires justifying that the two chains have the same law; the best explanation, not the shortest proof)

4. **Affine drift recurrence.** *Cue:* the one-step change has expectation $\frac{n+1-2a}{n}$, affine in a. *Circuit:* tower law gives $e_{k+1} = (1 - \frac{2}{n})e_k + \frac{n+1}{n}$; solve by fixed point. (four lines, nothing beyond A-level, exact closed form; the ideal)

The ideal solution

Fix n and write $a_k = a_{n,k}$, $m_k = m_{n,k}$, $e_k = \mathbb{E}[a_k]$. By construction a_k is a function of $m_0, \dots, m_{k-1}$, so m_k is independent of a_k, and $a_k \in \{1, \dots, n\}$ for all k (the walk cannot leave the range, since at $a = n$ the event $m > a$ is impossible and at $a = 1$ the event $m < a$ is impossible).

Step 1: the one-step drift. For $a \in \{1, \dots, n\}$,

$$\mathbb{E}[a_{k+1} \mid a_k = a] = a + P(m_k > a) - P(m_k < a) = a + \frac{n-a}{n} - \frac{a-1}{n} = \left(1 - \frac{2}{n}\right) a + \frac{n+1}{n}.$$

Step 2: the recurrence for the mean. Since the right side is affine in a, the tower law gives

$$e_{k+1} = \mathbb{E}\big[\mathbb{E}[a_{k+1} \mid a_k]\big] = \left(1 - \frac{2}{n}\right) e_k + \frac{n+1}{n}, \qquad e_0 = 1.$$

Step 3: solve. The fixed point of $e \mapsto (1 - \frac{2}{n})e + \frac{n+1}{n}$ is $\mu = \frac{n+1}{2}$ (solve $\frac{2}{n}\mu = \frac{n+1}{n}$). Subtracting, $e_{k+1} - \mu = (1 - \frac{2}{n})(e_k - \mu)$, so

$$e_k - \mu = \left(1 - \frac{2}{n}\right)^k (e_0 - \mu) = -\frac{n-1}{2}\left(1 - \frac{2}{n}\right)^k.$$

Therefore

$$E(n) = e_n = \frac{n+1}{2} - \frac{n-1}{2}\left(1 - \frac{2}{n}\right)^n.$$

(Checks: $E(1) = 1$, as the walk never moves; $E(2) = \frac{3}{2}$, as a_2 is 1 or 2 with equal probability.)

Step 4: the limit. Dividing by n,

$$\frac{E(n)}{n} = \frac{n+1}{2n} - \frac{n-1}{2n}\left(1 - \frac{2}{n}\right)^n \longrightarrow \frac{1}{2} - \frac{1}{2}e^{-2},$$

using $\frac{n\pm1}{2n} \to \frac{1}{2}$ and the standard limit $(1 + \frac{x}{n})^n \to e^x$ with $x = -2$ (equivalently, $n \ln(1 - \frac{2}{n}) = -2 + O(\frac{1}{n}) \to -2$). Hence

$$\boxed{\lim_{n\to\infty} \frac{E(n)}{n} = \frac{1 - e^{-2}}{2}}.$$

□

Layer 1: WHAT

Block 1: compute the conditional expectation of one step; it is affine in the current state. Block 2: take expectations (tower law) to get a first-order linear recurrence for e_k. Block 3: solve the recurrence by subtracting the fixed point $\frac{n+1}{2}$. Block 4: evaluate at $k = n$, divide by n, use $(1 - \frac{2}{n})^n \to e^{-2}$.

Nominal route: set up the n-by-n transition matrix, look for eigenvalues, or simulate small n and guess $\frac{1-e^{-2}}{2}$ from decimals. Ideal route: ask only for what the question asks, the mean, and notice the mean closes on itself. The bifurcation point is Block 1: the zombie writes the matrix; you write $\mathbb{E}[a_{k+1} \mid a_k]$ and see the letter a appear linearly.

Layer 2: HOW

Block 1. Cue. The update is decided by comparing a uniform m with the current state a: the three cases have probabilities $\frac{n-a}{n}$, $\frac{1}{n}$, $\frac{a-1}{n}$.

Why natural. Expected change is (probability up) minus (probability down). Both probabilities are linear in a because "the number of values of m above a" is $n - a$ and "below a" is $a - 1$. There is no idea here: it is the definition of expectation applied to a three-valued step.

Link to the next block. A conditional expectation that is affine in the state is the hypothesis of the tower-law step: $\mathbb{E}[\lambda a_k + c] = \lambda e_k + c$.

Block 2. **Cue.** $\mathbb{E}[a_{k+1} \mid a_k] = \lambda a_k + c$ with $\lambda = 1 - \frac{2}{n}$, $c = \frac{n+1}{n}$.

Why natural. The tower law $\mathbb{E}[X] = \mathbb{E}[\mathbb{E}[X \mid Y]]$ is the only tool needed, and it works because the conditional expectation is a linear function of a_k whose expectation you can take without knowing the law of a_k. If the drift had been quadratic in a you would have needed $\mathbb{E}[a_k^2]$ as well, and the hierarchy would not close at the first level.

Link to the next block. A first-order linear recurrence with constant coefficients has a one-line solution via its fixed point.

Block 3. **Cue.** $e_{k+1} = \lambda e_k + c$, $|\lambda| < 1$ for $n \geq 2$.

Why natural. Subtracting the fixed point $\mu = \frac{c}{1-\lambda}$ turns the affine recurrence into a geometric one. The fixed point $\frac{n+1}{2}$ is the centre of $\{1, \ldots, n\}$, which is where you expect the walk to settle by the symmetry $a \mapsto n + 1 - a$ of the transition rule; seeing that number appear is a sanity check, not a surprise.

Link to the next block. You have e_k for all k; the problem chose $k = n$, which makes $\lambda^k = (1 - \frac{2}{n})^n$, and the limit of that is the reason the answer involves e^{-2}.

Block 4. **Cue.** $(1 - \frac{2}{n})^n$ with the same n in base and exponent.

Why natural. This is the standard limit $(1 + \frac{x}{n})^n \to e^x$. The examiners chose exactly n steps so that the decay factor λ^n has a nontrivial limit: fewer steps ($o(n)$) would give $\frac{E}{n} \to 0$, more ($\omega(n)$) would give $\frac{1}{2}$. The number of steps is tuned to the relaxation time $\frac{n}{2}$ of the chain.

Link to the next block. Assemble and box.

Layer 3: WHY

The structural truth is that this chain is the Ehrenfest urn with one stuck ball. Picture n bulbs, one red and permanently lit, $n - 1$ white and initially unlit; at each step choose a bulb uniformly and toggle it if it is white. If a bulbs are lit (counting the red one), the chosen bulb is a lit white one with probability $\frac{a-1}{n}$ (the count drops), the red one with probability $\frac{1}{n}$ (no change), an unlit white one with probability $\frac{n-a}{n}$ (the count rises). These are the problem's transition probabilities, and the start $a = 1$ is "all white bulbs off". Two Markov chains on the same state space with the same transition probabilities and the same initial law are the same process in law, so $a_{n,k}$ has the law of the number of lit bulbs.

That reinterpretation explains everything in the answer. By linearity of expectation over bulbs, $E(n) = 1 + (n-1)\,P(\text{a given white bulb is lit after } n \text{ steps})$, and a given white bulb is lit exactly when it has been chosen an odd number of times; the number of times is $\mathrm{Bin}(n, \frac{1}{n})$, and $P(\mathrm{Bin}(n,p) \text{ odd}) = \frac{1-(1-2p)^n}{2}$ (expand $(q+p)^n - (q-p)^n$). With $p = \frac{1}{n}$ that is $\frac{1-(1-\frac{2}{n})^n}{2} \to \frac{1-e^{-2}}{2} = P(\mathrm{Poisson}(1) \text{ is odd})$. So the answer $\frac{1-e^{-2}}{2}$ is the probability that a Poisson variable of mean 1 is odd, and the mean 1 is because each bulb is touched about once in n steps. It is worth repeating: the recurrence proves the answer in four lines, the bulbs tell you why the answer has that shape. Both belong in your head, in that order.

The discernment mechanism: for any random process, before modelling the whole distribution, compute the conditional expectation of one step and check whether it is affine in the state. If it is, the mean is a first-order linear recurrence and you are done with the mean; if the conditional second moment is a polynomial of degree two in the state, the variance closes too. The examiners nudged you by making the drift affine (the comparison with a uniform variable makes the up and down probabilities linear in a) and by asking only for the mean. Train this by computing $\mathbb{E}[X_{k+1} \mid X_k]$ for every chain you meet, and by recognising the eigenfunction structure: for the Ehrenfest chain, $a \mapsto a - \frac{n+1}{2}$ is an eigenfunction of the transition operator with eigenvalue $1 - \frac{2}{n}$, and affine drift is exactly the statement that a linear function is an eigenfunction.

Revolving concepts

Conditional expectation and the tower law. $\mathbb{E}[X] = \mathbb{E}[\mathbb{E}[X \mid Y]]$; if $\mathbb{E}[X_{k+1} \mid X_k] = \lambda X_k + c$ then $\mathbb{E}[X_{k+1}] = \lambda \mathbb{E}[X_k] + c$. This is the mean-field reduction of a Markov chain, and it needs no knowledge of the distribution of X_k. See Book 1, field: Probability, topic: conditional expectation and martingale-type reductions.

First-order linear recurrence. $e_{k+1} = \lambda e_k + c$ has fixed point $\mu = \frac{c}{1-\lambda}$ ($\lambda \neq 1$) and solution $e_k = \mu + \lambda^k(e_0 - \mu)$. Generalised recursion: for $x_{k+1} = \lambda x_k + c_k$ the solution is $x_k = \lambda^k x_0 + \sum_{j<k} \lambda^{k-1-j} c_j$ (variation of constants), and for vector states the same formula holds with λ a matrix, which is the spectral approach in disguise. See Book 1, field: Sequences and recurrences, topic: linear recurrences and fixed points.

Ehrenfest urn. n balls in two urns, one ball moved at random per step; the count in one urn is a birth-death chain with rates $\frac{n-a}{n}$ up and $\frac{a}{n}$ down, stationary law $\mathrm{Bin}(n, \frac{1}{2})$, eigenvalues $1 - \frac{2j}{n}$ for $j = 0, \ldots, n$ (Krawtchouk polynomials as eigenfunctions), relaxation time of order n. The problem's chain is the Ehrenfest urn with one ball frozen. See Book 1, field: Probability, topic: Markov chains, birth-death chains, Ehrenfest model.

Parity of a binomial and the Poisson limit. $P(\mathrm{Bin}(n, p) \text{ odd}) = \frac{1-(1-2p)^n}{2}$; $P(\mathrm{Poisson}(\lambda) \text{ odd}) = e^{-\lambda} \sinh \lambda = \frac{1-e^{-2\lambda}}{2}$. Generating-function reason: evaluate the probability generating function at ± 1. See Book 1, field: Generating functions, topic: roots-of-unity filter for parity.

The limit $(1 + \frac{x}{n})^n \to e^x$, including the version with $x_n \to x$: $(1 + \frac{x_n}{n})^n \to e^x$. See Book 1, field: Real analysis, topic: the exponential limit.

Circuit Bank

- **WHEN** a random process defined step by step and a question about its mean **DO** compute $\mathbb{E}[X_{k+1} \mid X_k]$ first and check whether it is affine in X_k **BECAUSE** affine drift closes the mean into a first-order linear recurrence without touching the distribution
- **WHEN** a step decided by comparing the state with a uniform draw **DO** write the up and down probabilities as counts over n; they are linear in the state **BECAUSE** comparison with a uniform variable is a counting statement
- **WHEN** $e_{k+1} = \lambda e_k + c$ **DO** subtract the fixed point $\frac{c}{1-\lambda}$ and read off $e_k = \mu + \lambda^k(e_0 - \mu)$ **BECAUSE** an affine map is a geometric map about its fixed point
- **WHEN** a factor $(1 - \frac{c}{n})^n$ or $(1 - \frac{c}{n})^{tn}$ in an answer **DO** write e^{-c} or e^{-ct} in the limit and interpret t as time measured in relaxation units **BECAUSE** the number of steps was tuned to the relaxation time by the examiners
- **WHEN** transition probabilities $\frac{a-1}{n}$, $\frac{1}{n}$, $\frac{n-a}{n}$ or $\frac{a}{n}$, $\frac{n-a}{n}$ **DO** recognise the Ehrenfest urn and switch to independent bulbs plus linearity of expectation **BECAUSE** each bulb is toggled by an independent binomial count, so parity gives the exact law

Backtesting

1. First useful cue: the three-way case split by comparison with a uniform m, giving up and down probabilities linear in a.
2. Method the expression suggested: one-step conditional expectation, then a linear recurrence for the mean.
3. Where you would hesitate, and the thought to reinforce: seeing an n-state Markov chain and reaching for the matrix. The thought: the question asks for the mean only; test whether the mean closes on itself before modelling anything else.

4. The trap the question sets: the normalisation $E(n)/n$ and the limit tempt you into asymptotic hand-waving about the walk being "about halfway"; the answer is not $\frac{1}{2}$, and only the exact recurrence exposes the e^{-2} deficit.
5. What makes you recognise it faster next time: the stuck-ball Ehrenfest transition probabilities, and the fact that the number of steps equals n, the scale of the relaxation time.
6. The reusable decision rule: mean of a Markov chain with affine drift equals fixed point plus λ^k times the initial deviation; check affinity of the drift in the first thirty seconds.

Mirror drills

1. The genuine Ehrenfest urn: $a_0 = 0$, and a moves up with probability $\frac{n-a}{n}$ and down with probability $\frac{a}{n}$. Find $\lim \mathbb{E}[a_n]/n$. *Answer:* drift $1 - \frac{2a}{n}$, so $e_{k+1} = (1 - \frac{2}{n})e_k + 1$, fixed point $\frac{n}{2}$, $e_n = \frac{n}{2}(1 - (1 - \frac{2}{n})^n)$, limit $\frac{1-e^{-2}}{2}$.
2. Prove $P(\mathrm{Bin}(n,p) \text{ odd}) = \frac{1-(1-2p)^n}{2}$ and deduce the exact value $E(n) = 1 + (n-1)\frac{1-(1-\frac{2}{n})^n}{2}$ for the problem's chain. *Answer:* $(q+p)^n - (q-p)^n = 2\sum_{i \text{ odd}} \binom{n}{i} p^i q^{n-i}$ with $q = 1 - p$; then each white bulb is lit with that probability and linearity of expectation over the $n-1$ white bulbs adds the constant 1 for the red bulb.
3. Run the problem's walk for $\lfloor tn \rfloor$ steps with $t > 0$ fixed. Find the limit of the mean over n and interpret $t \to \infty$. *Answer:* $\frac{1-e^{-2t}}{2}$; as $t \to \infty$ it tends to $\frac{1}{2}$, the stationary mean $\frac{n+1}{2}$ normalised, so t counts time in units of the relaxation time $\frac{n}{2}$.

2.11 B5. Real negative roots give nonnegative coefficients

Let k and m be positive integers. For a positive integer n, let $f(n)$ be the number of integer sequences $x_1, \dots, x_k, y_1, \dots, y_m, z$ satisfying $1 \le x_1 \le \cdots \le x_k \le z \le n$ and $1 \le y_1 \le \cdots \le y_m \le z \le n$. Show that $f(n)$ can be expressed as a polynomial in n with nonnegative coefficients.

Read it out loud

Two weakly increasing chains, of lengths k and m, both capped by a common top element $z \le n$. Counting by the value of z: the x-chain is a multiset of size k from $\{1, \dots, z\}$, the y-chain a multiset of size m, so

$$f(n) = \sum_{z=1}^{n} R(z,k)\, R(z,m), \qquad R(z,j) := \binom{z+j-1}{j} = \frac{z(z+1)\cdots(z+j-1)}{j!}.$$

Read out loud: f is the partial sum of a product of two rising factorials. That it is a polynomial in n is immediate (a partial sum of a polynomial is a polynomial). The content of the problem is the sign of the coefficients, and that is a statement about f as an algebraic object, not about its values at positive integers.

The fields are combinatorics (multisets, the stars-and-bars count), polynomials (the summation operator, difference equations, roots), and a small piece of real analysis (the intermediate value theorem to locate roots). What is really being tested is whether you know the one structural mechanism that produces nonnegative coefficients: a polynomial with positive leading coefficient whose roots are all real and nonpositive is a product of factors $(x+s)$ with $s \ge 0$, and such a product has nonnegative coefficients. So the problem is secretly "show all roots of f are real and nonpositive", and the difference equation $F(x) - F(x-1) = R(x,k)R(x,m)$ hands you $m+1$ roots for free at $0, -1, \dots, -m$, because the right side vanishes there.

The first useful cue is the pair of rising factorials with their known zeros at $0, -1, \dots$. Within thirty seconds you should have written the sum formula, the difference equation, and the observation $F(0) = F(-1) = \cdots = F(-m) = 0$ (with $k \le m$ by symmetry). The remaining k roots are the real work.

Approaches, ranked worst to best

1. **Faulhaber and Bernoulli numbers.** *Cue:* a sum of a polynomial in z from 1 to n. *Circuit:* expand $R(z,k)R(z,m)$ in powers of z and sum each power. (it proves polynomiality but Bernoulli numbers alternate in sign, so the coefficient signs are invisible; stalls completely on the actual question)

2. **Rising-factorial basis and hockey stick.** *Cue:* $\sum_{z \le n} R(z,j) = R(n,j+1)$. *Circuit:* expand the product $R(z,k)R(z,m)$ in the basis $R(z,j)$ and sum termwise. (the expansion coefficients alternate in sign, for instance $z^2 = 2R(z,2) - R(z,1)$, so positivity is again invisible; stalls)

3. **Summation by parts and an explicit formula.** *Cue:* $R(z,j) - R(z-1,j) = R(z,j-1)$. *Circuit:* derive $f_{k,m} = R(n,k)R(n,m+1) + f_{k-1,m} - f_{k-1,m+1}$, guess $f_{k,m}(n) = \frac{R(n,m+1)}{R(m+2,k)} \sum_{i=0}^{k} R(m+1,i)R(n,i)$, prove by induction on k. (a complete proof, and the formula is manifestly positive, but you must guess it from $k = 0, 1, 2$ and the induction is a page of algebra; ranks second on ink)

4. **Root location through the difference equation.** *Cue:* the right side $R(x,k)R(x,m)$ vanishes at $0, -1, \dots$. *Circuit:* F vanishes at $0, \dots, -m$; the cofactor Q satisfies a two-term relation at $x = -j$ that forces sign alternation, hence k real roots in $(-k, 0)$; a real-rooted polynomial with

nonpositive roots has nonnegative coefficients. (half a page, no guessing, and it explains the answer; the ideal)

The ideal solution

Step 1: set-up. For $j \geq 0$ let $R(x,j) = \frac{x(x+1)\cdots(x+j-1)}{j!}$, a polynomial in x of degree j with $R(x,0) = 1$. For a positive integer z, $R(z,j) = \binom{z+j-1}{j}$ counts the weakly increasing sequences $1 \leq u_1 \leq \cdots \leq u_j \leq z$ (stars and bars: j stars and $z-1$ bars). Classifying the sequences in the problem by the value of z,

$$f(n) = \sum_{z=1}^{n} R(z,k)R(z,m).$$

Since f is symmetric in k and m, assume $k \leq m$.

Step 2: the polynomial and its difference equation. Let $g(x) = R(x,k)R(x,m)$, a polynomial of degree $k+m$. There is a unique polynomial F of degree $k+m+1$ with $F(0) = 0$ and $F(x) - F(x-1) = g(x)$ identically: indeed the linear map $F \mapsto F(x) - F(x-1)$ from the space of polynomials of degree at most $d+1$ to the space of polynomials of degree at most d has kernel the constants (a polynomial with $F(x) = F(x-1)$ for all x is periodic, hence constant), so by dimension count it is onto; a solution exists, has degree exactly $d+1$ (the difference lowers degree by one for nonconstant F), and $F(0) = 0$ fixes it. Then $F(n) = \sum_{z=1}^{n} g(z) = f(n)$ for every positive integer n by telescoping. So f is the polynomial F, and it remains to show that F has nonnegative coefficients.

Step 3: $m+1$ roots for free. $R(x,m)$ vanishes at $x = 0, -1, \ldots, -(m-1)$. Using $F(-j) = F(-j+1) - g(-j+1)$ for $j = 1, \ldots, m$, and $g(-j+1) = 0$ for those j, induction from $F(0) = 0$ gives

$$F(0) = F(-1) = \cdots = F(-m) = 0.$$

Hence $F(x) = x(x+1)\cdots(x+m)\,Q(x)$ for a polynomial Q of degree k.

Step 4: the difference equation for Q. Write $x(x+1)\cdots(x+m) = m!\,R(x,m)(x+m)$ and $(x-1)x\cdots(x+m-1) = m!\,R(x,m)(x-1)$. Then

$$F(x) - F(x-1) = m!\,R(x,m)\big[(x+m)Q(x) - (x-1)Q(x-1)\big] = R(x,k)R(x,m),$$

and cancelling the nonzero polynomial $m!\,R(x,m)$,

$$(x+m)Q(x) - (x-1)Q(x-1) = \frac{R(x,k)}{m!}.$$

Substituting $x = -j$ for $j = 0, 1, \ldots, k-1$ kills the right side (as $R(-j,k)$ contains the factor $(-j+j)$), giving

$$(m-j)\,Q(-j) = -(j+1)\,Q(-j-1) \qquad (j = 0, 1, \ldots, k-1).$$

Since $k \leq m$, every coefficient $m-j$ and $j+1$ here is a positive integer.

Step 5: sign alternation and k more roots. From Step 4, $Q(-j) = 0$ if and only if $Q(-j-1) = 0$, so the values $Q(0), Q(-1), \ldots, Q(-k)$ are either all zero or all nonzero. All zero is impossible: Q would have $k+1$ distinct roots and degree k, so $Q \equiv 0$, so $F \equiv 0$, contradicting $F(1) = f(1) = 1$. So they are all nonzero, and consecutive ones have opposite signs. By the intermediate value theorem Q has a root $-s_j$ in each open interval $(-j-1, -j)$, $j = 0, \ldots, k-1$; these are k distinct roots of a degree-k polynomial, so

$$Q(x) = q\prod_{j=0}^{k-1}(x+s_j), \qquad 0 < s_0 < s_1 < \cdots < s_{k-1} < k,$$

with q the leading coefficient of Q.

Step 6: conclusion. The leading coefficient of F equals that of Q, namely q, and it is positive because $F(n) = f(n) > 0$ for all positive integers n forces the leading coefficient to be positive (a polynomial with negative leading coefficient is eventually negative). Therefore

$$F(x) = q\ x(x+1)\cdots(x+m)\prod_{j=0}^{k-1}(x+s_j)$$

is a positive constant times a product of linear factors $x+s$ with $s \geq 0$. Each factor has nonnegative coefficients, and products and positive multiples of polynomials with nonnegative coefficients have nonnegative coefficients. Hence $f(n) = F(n)$ is a polynomial in n with nonnegative coefficients. □

A caveat worth clarifying: the assumption $k \leq m$ is used exactly once, to guarantee $m - j > 0$ in Step 4; without it you would divide by zero at $j = m$. The symmetry of f in (k, m) makes the assumption free, and a full-marks write-up says so in one sentence.

Layer 1: WHAT

Block 1: count by the top value z, so $f(n) = \sum_{z \leq n} R(z,k)R(z,m)$ with R a rising factorial; assume $k \leq m$. Block 2: replace f by the polynomial F solving $F(x) - F(x-1) = R(x,k)R(x,m)$, $F(0) = 0$. Block 3: harvest the roots $0, -1, \ldots, -m$ of F from the zeros of $R(x,m)$; factor $F = x(x+1)\cdots(x+m)Q$. Block 4: divide the difference equation by the common factor to get $(x+m)Q(x) - (x-1)Q(x-1) = R(x,k)/m!$, and evaluate at the zeros $0, \ldots, -(k-1)$ of $R(x,k)$. Block 5: sign alternation of $Q(0), \ldots, Q(-k)$, intermediate value theorem, k real roots in $(-k, 0)$. Block 6: positive leading coefficient and a product of factors $(x+s)$, $s \geq 0$, so nonnegative coefficients.

Nominal route: expand, sum with Faulhaber or the hockey stick, and stare at an alternating formula hoping to see positivity. Ideal route: treat "nonnegative coefficients" as a statement about roots, and use the difference equation as a root detector. The bifurcation point is Block 2: the zombie tries to compute F; you decide to locate the roots of F without computing it.

Layer 2: HOW

Block 1. **Cue.** Two chains with a common cap $z \leq n$.

Why natural. Conditioning on the cap decouples the chains: each is a multiset from $\{1, \ldots, z\}$ and the multiset count is the rising factorial $R(z,j)$. Writing R as a polynomial $\frac{x(x+1)\cdots(x+j-1)}{j!}$ rather than a binomial coefficient is deliberate: it displays the zeros at $0, -1, \ldots, -(j-1)$, which is the only property you will use.

Link to the next block. A sum from 1 to n of a polynomial is the unique polynomial solution of a difference equation with $F(0) = 0$; pass to that polynomial.

Block 2. **Cue.** "Can be expressed as a polynomial in n" asks you to leave the positive integers.

Why natural. The coefficients of a polynomial are properties of the polynomial on all of $\mathbb{R}$; the difference equation $F(x) - F(x-1) = g(x)$ holds identically, so you may evaluate it at negative and non-integer points. That is the step that unlocks everything: the values of f at positive integers say nothing about signs of coefficients, the values of F at nonpositive integers say everything.

Link to the next block. Evaluate the difference equation where the right side vanishes.

Block 3. **Cue.** $R(x,m)$ vanishes at $0, -1, \ldots, -(m-1)$ and $F(0) = 0$.

Why natural. Each vanishing of g propagates the zero of F one step to the left: $F(-j) = F(-j+1) - g(-j+1)$. So $m+1$ roots of F come for free, which is more than half of its $k+m+1$ roots (as $k \leq m$). Factoring them out leaves a degree-k cofactor Q whose difference equation is simpler.

Link to the next block. Divide the difference equation through by the common polynomial factor; Q inherits a two-term relation.

Block 4. **Cue.** $(x+m)Q(x) - (x-1)Q(x-1) = R(x,k)/m!$, whose right side still has k known zeros.

Why natural. The zeros $0, \ldots, -(k-1)$ of $R(x,k)$ are where the inhomogeneous term disappears, so at those points the relation is homogeneous and two-term, linking $Q(-j)$ to $Q(-j-1)$ with coefficients of known signs. This is the same move as Block 3 applied one level down; no new idea, the same idea twice.

Link to the next block. A two-term relation with a negative ratio is sign alternation, and sign alternation plus continuity is roots.

Block 5. **Cue.** $Q(-j) = -\frac{j+1}{m-j}Q(-j-1)$ with positive ratio magnitudes.

Why natural. Nonvanishing must be checked (otherwise all zero, degree contradiction); then consecutive values alternate in sign and the intermediate value theorem plants a root in each unit interval. Degree k with k roots found means you have found all of them, and all are real and negative. This is the standard way real-rootedness is proved for combinatorial polynomials: exhibit enough sign changes.

Link to the next block. Real nonpositive roots and a positive leading coefficient give the factorised form, and the factorised form has visible signs.

Block 6. **Cue.** $F = q\,x(x+1)\cdots(x+m)\prod(x+s_j)$, $q > 0$, $s_j > 0$.

Why natural. A product of polynomials with nonnegative coefficients has nonnegative coefficients (every coefficient of the product is a sum of products of coefficients of the factors). This is why real-rootedness with nonpositive roots is the mechanism behind positivity of coefficients.

Link to the next block. Done; the answer is a structure, not a formula.

Layer 3: WHY

The central truth: a polynomial with positive leading coefficient and all roots real and nonpositive has nonnegative coefficients, and this is the only general mechanism that produces nonnegative coefficients from structure rather than from computation. The converse is false ($x^2 + x + 1$), but in combinatorics the polynomials whose coefficient positivity is asked for are very often real-rooted, and the examiners know it: this problem's polynomial has roots exactly at $0, -1, \ldots, -m$ and one in each of $(-1,0), (-2,-1), \ldots, (-k,-k+1)$, an interlacing pattern that is the fingerprint of a rising-factorial construction.

The second truth is that the summation operator $g \mapsto F$ (with $F(x) - F(x-1) = g(x)$, $F(0) = 0$) interacts cleanly with zeros of g at consecutive integers: a run of zeros of g at $0, -1, \ldots, -(m-1)$ gives a run of zeros of F at $0, \ldots, -m$, one longer. That is why the rising factorial, whose zeros are a run of consecutive integers, is the right building block, and why the problem posed the count with weak inequalities (multisets, rising factorials) rather than strict ones (sets, falling factorials with zeros at $0, 1, \ldots$, which would put the free roots at positive integers, the wrong side).

The discernment mechanism: when asked for nonnegative coefficients of a polynomial that is defined by counting, do not compute the polynomial; ask where its roots are. Cheap roots come from evaluating a defining identity at points where one side vanishes. Expensive roots come from sign changes at consecutive integers. Train it by taking the order polynomials of small posets (chains, antichains, the Λ shape of this problem) and locating their roots by hand; you will find the pattern of roots at nonpositive integers and the sign alternation at the remaining ones recurring.

What was the examiners' nudge? The phrase "nonnegative coefficients" itself, which is never a numerical statement, plus the symmetric design in (k, m) that makes "assume $k \le m$" available, plus a right-hand side with $k + m$ known zeros. Everything you needed was planted at $x \le 0$.

Revolving concepts

Multiset count and rising factorial. The number of weakly increasing j-sequences from $\{1,\dots,z\}$ is $\binom{z+j-1}{j} = R(z,j)$, the rising factorial $z^{\bar{j}}/j!$, with zeros at $0,-1,\dots,-(j-1)$ and the identities $R(z,j) - R(z-1,j) = R(z,j-1)$ and $\sum_{z=1}^{n} R(z,j) = R(n,j+1)$. Contrast the falling factorial $\binom{z}{j}$ with zeros at $0,1,\dots,j-1$. See Book 1, field: Combinatorics, topic: stars and bars, rising and falling factorials.

The summation operator and difference equations. For a polynomial g of degree d there is a unique polynomial F of degree $d+1$ with $F(x) - F(x-1) = g(x)$ and $F(0) = 0$, and $F(n) = \sum_{z=1}^{n} g(z)$. Generalised recursion: any linear recurrence $F(x) = F(x-1) + g(x)$ has solution $F(x) = F(x_0) + \sum g$, and its evaluation at zeros of g transports zeros of F; more generally for $a(x)F(x) = b(x)F(x-1) + g(x)$ the zeros of g give two-term relations whose signs are read from a and b. See Book 1, field: Polynomials, topic: difference operators on polynomials.

Real-rooted polynomials and coefficient positivity. If p has positive leading coefficient and all roots real and in $(-\infty, 0]$ then $p = c\prod(x+s_i)$ has nonnegative coefficients; moreover the coefficient sequence is then log-concave and unimodal (Newton's inequalities). Knowledge gap, beyond A-level: install the statement, the proof by expanding the product, and the standard method of proving real-rootedness by sign changes at $k+1$ points. See Book 1, field: Polynomials, topic: real-rootedness, interlacing, Newton's inequalities.

Order polynomials. For a finite poset P the number $\Omega_P(n)$ of order-preserving maps $P \to \{1,\dots,n\}$ is a polynomial in n of degree $|P|$ with leading coefficient $e(P)/|P|!$, $e(P)$ the number of linear extensions; here P is the Λ-shaped tree with $k+m+1$ elements and $e(P) = \binom{k+m}{k}$, matching the leading coefficient $\frac{1}{k!\,m!\,(k+m+1)}$ of f. Beyond A-level; know it exists. See Book 1, field: Discrete structures and graphs, topic: posets and order polynomials.

Circuit Bank

- **WHEN** "polynomial with nonnegative coefficients" **DO** try to prove all roots are real and nonpositive with positive leading coefficient **BECAUSE** a product of factors $(x+s)$, $s \geq 0$, has nonnegative coefficients, and this is the structural mechanism
- **WHEN** a polynomial defined as $\sum_{z=1}^{n} g(z)$ **DO** pass to the polynomial F with $F(x) - F(x-1) = g(x)$, $F(0) = 0$, and evaluate this identity at the zeros of g **BECAUSE** the identity holds on all of $\mathbb{R}$, and zeros of g propagate to zeros of F
- **WHEN** a two-term relation $a_j Q(-j) = -b_j Q(-j-1)$ with $a_j, b_j > 0$ **DO** check nonvanishing by a degree count, then apply the intermediate value theorem on each unit interval **BECAUSE** sign alternation at $k+1$ consecutive points gives k real roots
- **WHEN** a count symmetric in two parameters k, m where one step needs $k \leq m$ **DO** say "by symmetry assume $k \leq m$" at the start and point to the line that uses it **BECAUSE** unstated assumptions lose marks; stated ones cost one sentence
- **WHEN** weak inequalities in a counting problem **DO** write the count as a rising factorial $R(z,j)$ with its zeros at $0,-1,\dots$ **BECAUSE** the sign pattern of the answer lives at nonpositive integers

Backtesting

1. First useful cue: the two capped chains are multisets, so the summand is a product of rising factorials with zeros at $0,-1,\dots$.
2. Method the expression suggested: root location through the difference equation, then real-rootedness implies nonnegative coefficients.

3. Where you would hesitate, and the thought to reinforce: after finding the roots $0, \ldots, -m$, wondering how to find the other k. The thought: repeat the same move one level down; evaluate the reduced difference equation at the zeros of $R(x, k)$.
4. The trap the question sets: proving polynomiality and then computing coefficients through Faulhaber or the hockey stick, which produces alternating expressions and no sign conclusion.
5. What makes you recognise it faster next time: "nonnegative coefficients" is a root statement; the design $k \leq m$ by symmetry and a right-hand side with $k + m$ known zeros is the fingerprint of the intended proof.
6. The reusable decision rule: for a counting polynomial, coefficient positivity is proved by locating all roots on the nonpositive real axis; find the cheap roots at the zeros of the defining identity and the remaining ones by sign alternation.

Mirror drills

1. Show that $\sum_{z=1}^{n} z^4$, as a polynomial in n, has a negative coefficient, so "partial sums of polynomials with nonnegative coefficients" is not the mechanism at work in this problem. *Answer:* $\frac{n(n+1)(2n+1)(3n^2+3n-1)}{30} = \frac{6n^5+15n^4+10n^3-n}{30}$; its roots are all real but one of them, $\frac{-3+\sqrt{21}}{6}$, is positive, which is exactly what a negative coefficient forces.
2. Prove that a polynomial with positive leading coefficient and all roots real and nonpositive has nonnegative coefficients, and give an example showing the converse fails. *Answer:* $p = c\prod(x + s_i)$ with $c > 0$, $s_i \geq 0$, expand; converse fails for $x^2 + x + 1$.
3. For $k = m = 2$ verify the prediction of the proof: $f(n) = \frac{n(n+1)(n+2)(3n^2+6n+1)}{60}$, and the roots of $3x^2 + 6x + 1$ are $-1 \pm \sqrt{2/3}$, one in $(-1, 0)$ and one in $(-2, -1)$. *Hint:* $R(z, 2)^2 = \frac{z^2(z+1)^2}{4}$; sum with the formulas for $\sum z^2, \sum z^3, \sum z^4$ and factor.

2.12 B6. Complete the square and find the Gaussian peak

For a real number a, let $F_a(x) = \sum_{n\geq 1} n^a e^{2n} x^{n^2}$ for $0 \leq x < 1$. Find a real number c such that

$$\lim_{x\to 1^-} F_a(x)e^{-1/(1-x)} = 0 \qquad \text{for all } a < c, \text{ and}$$
$$\lim_{x\to 1^-} F_a(x)e^{-1/(1-x)} = \infty \qquad \text{for all } a > c.$$

Read it out loud

A power series in x with only square exponents, a partial theta series, weighted by e^{2n} and a power n^a, and you are asked how fast it blows up as $x \to 1^-$, measured against $e^{1/(1-x)}$. So the question is an asymptotic one: the series is a sum of positive terms, and its size near $x = 1$ is governed by its largest terms. The answer c is a threshold exponent: below it the series is $o(e^{1/(1-x)})$, above it the series dominates. The two limits together say $F_a(x) \approx e^{1/(1-x)} \cdot (1-x)^{-(a-c)} \cdot (\text{something bounded})$, and your job is to find c and prove the two one-sided statements.

The fields are real analysis (asymptotics of series, comparison of sums with integrals) and the single most important reflex of analytic estimation, Laplace's method: locate the maximum of the summand, measure its height and its width, multiply. What is really being tested is whether you can complete a square in the exponent. Write the summand as $n^a \exp(2n + n^2 \ln x)$. Near $x = 1$, $\ln x \approx -(1-x)$; put $t = \frac{1}{1-x}$ so that $\ln x \approx -\frac{1}{t}$ and the exponent is $2n - \frac{n^2}{t} = t - \frac{(n-t)^2}{t}$. There it is: the peak is at $n = t$, the peak height is $e^t = e^{1/(1-x)}$, exactly the normalising factor in the problem, and the width of the peak is $\sqrt{t}$. So after normalising, the sum is roughly $t^a \cdot \sqrt{t} \cdot \sqrt{\pi}$, and the threshold is $a + \frac{1}{2} = 0$, that is $c = -\frac{1}{2}$.

The first useful cue is the pair e^{2n} and x^{n^2} in the same term, a linear and a quadratic exponent in n which together form a square. Within thirty seconds you should have written $t = \frac{1}{1-x}$ and $2n - \frac{n^2}{t} = t - \frac{(n-t)^2}{t}$, and guessed $c = -\frac{1}{2}$. The rest of the arena time is rigour: two-sided bounds on $\ln x$, a lower bound from a window of width $\sqrt{t}$, and an upper bound from a split of the sum.

Approaches, ranked worst to best

1. **Closed form for the theta-type sum.** *Cue:* square exponents x^{n^2}. *Circuit:* Jacobi theta functions and their modular transformation $\vartheta(1/\tau)$. (the sum runs over $n \geq 1$ only and carries the weight $n^a e^{2n}$, so no transformation formula applies; even for the pure theta function the modular relation is a knowledge gap you cannot prove in the arena; stalls)

2. **Replace the sum by an integral.** *Cue:* a sum of a smooth, unimodal function of n. *Circuit:* $\int_0^\infty u^a e^{2u} x^{u^2}\, du$ by Laplace's method. (gives the correct heuristic instantly, but the rigorous sum-to-integral comparison must be done on monotone pieces on either side of the peak, and the peak is at a non-integer; more bookkeeping than the direct estimate, so it ranks below it, though it is the right way to *guess*)

3. **Peak window with ε-widths.** *Cue:* after completing the square, the summand is a discrete Gaussian around $n = t$. *Circuit:* split into $|n - t| < t^{1/2+\varepsilon}$ and the two tails; bound each. (the official route; correct, and needs an ε for the upper bound because it bounds the window by its width times its maximum; slightly more bookkeeping than needed)

4. **Complete the square, then window for the lower bound and a half-line split plus integral comparison for the upper bound.** *Cue:* $e^{2n}x^{n^2}$ and the factor $e^{-1/(1-x)}$. *Circuit:* $t = \frac{1}{1-x}$, $-\frac{1}{t} - \frac{1}{t^2} \leq \ln x \leq -\frac{1}{t}$; lower bound from $t \leq n \leq t + \sqrt{t}$; upper bound from $n < \frac{t}{2}$ (negligible) and $n \geq \frac{t}{2}$ (Gaussian sum $\leq 4\sqrt{t}$). (half a page, every constant explicit, no ε; the ideal)

The ideal solution

The answer is $c = -\dfrac{1}{2}$.

Step 1: the substitution and the logarithm bounds. For $x \in [0,1)$ put $t = \frac{1}{1-x} \in [1,\infty)$, so $x = 1 - \frac{1}{t}$ and $x \to 1^-$ is $t \to \infty$; the factor $e^{-1/(1-x)}$ is e^{-t}. For $t \geq 2$, with $u = \frac{1}{t} \in (0, \frac{1}{2}]$,

$$\ln x = \ln(1-u) = -\sum_{j\geq 1} \frac{u^j}{j} \leq -u, \qquad \ln x \geq -u - \frac{1}{2}\sum_{j\geq 2} u^j = -u - \frac{u^2}{2(1-u)} \geq -u - u^2,$$

using $1 - u \geq \frac{1}{2}$. Hence, for $t \geq 2$,

$$-\frac{1}{t} - \frac{1}{t^2} \leq \ln x \leq -\frac{1}{t}.$$

Step 2: completing the square. The nth term of $F_a(x)e^{-t}$ is $n^a \exp(2n - t + n^2 \ln x)$. Since $2n - t - \frac{n^2}{t} = -\frac{(n-t)^2}{t}$, Step 1 gives, for all $n \geq 1$ and $t \geq 2$,

$$n^a\, e^{-(n-t)^2/t}\, e^{-n^2/t^2} \;\leq\; n^a e^{2n-t} x^{n^2} \;\leq\; n^a\, e^{-(n-t)^2/t}.$$

Step 3: $a > -\frac{1}{2}$ forces the limit ∞. Let $t \geq 4$ and let N be the set of integers n with $t \leq n \leq t + \sqrt{t}$. An interval of length L contains at least $\lfloor L \rfloor$ integers, so $|N| \geq \lfloor \sqrt{t} \rfloor \geq \sqrt{t} - 1 \geq \frac{\sqrt{t}}{2}$. For $n \in N$: $\frac{(n-t)^2}{t} \leq 1$; $\frac{n^2}{t^2} \leq \left(1 + t^{-1/2}\right)^2 \leq \frac{9}{4}$; and $n^a \geq \frac{t^a}{\sqrt{2}}$, because if $a \geq 0$ then $n^a \geq t^a$, while if $-\frac{1}{2} < a < 0$ then $n^a \geq (2t)^a = 2^a t^a \geq 2^{-1/2} t^a$. Keeping only the terms $n \in N$ in the lower bound of Step 2,

$$F_a(x)e^{-t} \;\geq\; |N| \cdot \frac{t^a}{\sqrt{2}}\, e^{-1} e^{-9/4} \;\geq\; \frac{e^{-13/4}}{2\sqrt{2}}\, t^{a+\frac{1}{2}},$$

which tends to ∞ as $t \to \infty$ since $a + \frac{1}{2} > 0$.

Step 4: $a < -\frac{1}{2}$ forces the limit 0. Let $t \geq 2$ and use the upper bound of Step 2, splitting the sum at $\frac{t}{2}$.

For $1 \leq n < \frac{t}{2}$: $n^a \leq 1$ (as $a < 0$) and $(n-t)^2 > \frac{t^2}{4}$, so each term is at most $e^{-t/4}$; there are fewer than $\frac{t}{2}$ such n, so this part is at most $\frac{t}{2} e^{-t/4}$.

For $n \geq \frac{t}{2}$: $n^a \leq \left(\frac{t}{2}\right)^a = 2^{-a} t^a$ (as $a < 0$), so this part is at most $2^{-a} t^a \sum_{n\in\mathbb{Z}} e^{-(n-t)^2/t}$. To bound the Gaussian sum, note that the integers n with $|n - t| < 1$ number at most 2 and each contributes at most 1. The function $u \mapsto e^{-(u-t)^2/t}$ is decreasing on $[t,\infty)$, so for each integer $n \geq t+1$ we have $e^{-(n-t)^2/t} \leq \int_{n-1}^{n} e^{-(u-t)^2/t}\, du$, and the intervals $[n-1, n]$ for these n are non-overlapping subsets of $[t,\infty)$; hence $\sum_{n\geq t+1} e^{-(n-t)^2/t} \leq \int_t^\infty e^{-(u-t)^2/t}\, du = \frac{\sqrt{\pi t}}{2}$. Symmetrically $\sum_{n\leq t-1} e^{-(n-t)^2/t} \leq \frac{\sqrt{\pi t}}{2}$. Therefore

$$\sum_{n\in\mathbb{Z}} e^{-(n-t)^2/t} \leq 2 + \sqrt{\pi t} \leq 4\sqrt{t} \qquad (t \geq 1),$$

and the part $n \geq \frac{t}{2}$ is at most $4 \cdot 2^{-a}\, t^{a+\frac{1}{2}}$.

Altogether, for $t \geq 2$,

$$0 \leq F_a(x)e^{-t} \leq \frac{t}{2} e^{-t/4} + 4 \cdot 2^{-a}\, t^{a+\frac{1}{2}} \longrightarrow 0 \qquad (t \to \infty),$$

since $a + \frac{1}{2} < 0$.

Conclusion. With $c = -\frac{1}{2}$, the limit is 0 for every $a < c$ and ∞ for every $a > c$:

$$\boxed{c = -\tfrac{1}{2}}.$$

(Any other value c' fails: for a strictly between c' and $-\frac{1}{2}$ one of the two requirements is violated by Steps 3 and 4, so the answer is unique.) $\square$

Layer 1: WHAT

Block 1: substitute $t = \frac{1}{1-x}$ and bound $\ln x$ between $-\frac{1}{t} - \frac{1}{t^2}$ and $-\frac{1}{t}$. Block 2: complete the square: $2n - t - \frac{n^2}{t} = -\frac{(n-t)^2}{t}$, so each normalised term is a discrete Gaussian of centre t and width $\sqrt{t}$, times n^a, up to a bounded factor e^{-n^2/t^2} near the centre. Block 3: lower bound for $a > -\frac{1}{2}$: keep only the $\sim \sqrt{t}$ terms with $t \le n \le t + \sqrt{t}$, each of size $\asymp t^a$. Block 4: upper bound for $a < -\frac{1}{2}$: the terms with $n < \frac{t}{2}$ are exponentially small; for $n \ge \frac{t}{2}$ bound n^a by its largest value and the Gaussian sum by $4\sqrt{t}$ via integral comparison. Block 5: read off $c = -\frac{1}{2}$ from the exponent $a + \frac{1}{2}$ common to both bounds.

Nominal route: try to evaluate or transform the series, or expand $x^{n^2} = e^{n^2 \ln x}$ and lose the structure in a double sum. Ideal route: identify the largest terms and estimate the sum by "height times width". The bifurcation point is Block 2: the zombie sees a series and wants a formula for it; you see a sum of positive terms and want its peak.

Layer 2: HOW

Block 1. **Cue.** The normalising factor $e^{-1/(1-x)}$ and the behaviour $\ln x \approx -(1-x)$ as $x \to 1$.

Why natural. The problem names the quantity $\frac{1}{1-x}$, so it is the natural large parameter; and you need $\ln x$ in the exponent because $x^{n^2} = e^{n^2 \ln x}$. A two-sided bound on $\ln(1 - \frac{1}{t})$ by the first one or two terms of its series is the standard way to make "$\approx$" rigorous, and the second-order term $\frac{1}{t^2}$ is kept because it multiplies $n^2 \approx t^2$ at the peak and so contributes a bounded, not negligible, factor.

Link to the next block. With $\ln x$ replaced by $-\frac{1}{t}$ the exponent is a quadratic in n, and a quadratic exponent is completed as a square, always.

Block 2. **Cue.** $2n + n^2 \ln x$: linear plus quadratic in n with a negative quadratic coefficient.

Why natural. Completing the square is the definition-level move for a quadratic; it exposes the vertex $n = t$ and the value at the vertex, t, which is exactly $\frac{1}{1-x}$. This is the moment you know the examiners built the problem backwards from $e^{1/(1-x)}$: the normalisation removes the peak height, leaving only the peak width and the weight n^a at the peak. Guess $c = -\frac{1}{2}$ here, before any rigour.

Link to the next block. A Gaussian of width $\sqrt{t}$ has about $\sqrt{t}$ terms of size comparable to the maximum; the lower bound counts them and the upper bound must show the rest do not matter.

Block 3. **Cue.** You need a lower bound tending to infinity and you only need finitely many terms of a positive series.

Why natural. Dropping terms from a series of positive terms gives a lower bound; the window $[t, t + \sqrt{t}]$ is chosen because on it every factor is bounded below by an explicit constant times t^a (the Gaussian factor by e^{-1}, the correction e^{-n^2/t^2} by $e^{-9/4}$, the weight n^a by $t^a/\sqrt{2}$). The count of integers in an interval of length $\sqrt{t}$ supplies the factor $\sqrt{t}$.

Link to the next block. The upper bound is harder because you cannot drop terms; you must control all of them.

Block 4. **Cue.** Terms far from the peak are exponentially small; near the peak n^a is at most its value at the left end of the range because $a < 0$.

Why natural. Splitting at $\frac{t}{2}$ is the coarsest split that works: below it the Gaussian factor is at most $e^{-t/4}$ and the number of terms is polynomial, so the product is negligible; above it $n^a \le (\frac{t}{2})^a$ is uniform, and what remains is a pure Gaussian sum, which is compared with the Gaussian integral on the two monotone sides of the peak. The bound $4\sqrt{t}$ is crude and sufficient; precision is not the goal, the exponent of t is.

Link to the next block. Both bounds carry $t^{a+\frac{1}{2}}$; the sign of $a + \frac{1}{2}$ decides which limit you get, so $c = -\frac{1}{2}$.

Block 5. Cue. Two one-sided statements with the same exponent.

Why natural. The threshold is where the exponent $a + \frac{1}{2}$ changes sign; both statements must be proved, since the problem defines c by both, and uniqueness is a one-line remark.

Link to the next block. End.

Layer 3: WHY

The truth beneath the route is Laplace's method for sums: if a sum of positive terms has a summand of the form $h(n)e^{\phi(n)}$ with ϕ concave and peaked at n_0 with $\phi''(n_0) \approx -\frac{1}{\sigma^2}$, then the sum is approximately $h(n_0)e^{\phi(n_0)}\sigma\sqrt{2\pi}$, provided h varies slowly on the scale σ and $\sigma \gg 1$ so that the sum behaves like an integral. Here $\phi(n) = 2n - \frac{n^2}{t}$, $n_0 = t$, $\phi(n_0) = t$, $\sigma = \sqrt{t/2}$, $h(n) = n^a$. Everything in the problem is a special case of that sentence, and the examiners chose e^{2n} rather than e^n so that the vertex value $\frac{b^2t}{4}$ with $b = 2$ equals t exactly, making the normalising factor the clean $e^{1/(1-x)}$.

The second truth is about what "lim $= 0$ for $a < c$ and lim $= \infty$ for $a > c$" really asks: it is a statement that the normalised sum is $t^{a+\frac{1}{2}}$ times something bounded above and below by positive constants. You are not asked to find that constant (it is $\sqrt{\pi}e^{-1/2}$ at $a = -\frac{1}{2}$, from the second-order term of the logarithm), and you should not try; the arena rewards the exponent, and every estimate in the ideal solution is deliberately crude in the constant and sharp in the exponent.

The discernment mechanism is a fixed protocol for any series of positive terms near a singular point: (1) name the large parameter (here t); (2) write the summand as e^{exponent} times a slowly varying weight; (3) find the maximum of the exponent and its second derivative there, giving the peak location, height and width; (4) guess the answer as height times width times weight at the peak; (5) prove a lower bound by a window and an upper bound by a split. Train it on $\sum x^{n^2}$, $\sum x^n/n$, $\sum n^a x^n$, and $\sum e^{bn}x^{n^2}$ until step (3) is reflex.

Knowledge gaps, stated with brutal honesty. First, Laplace's method itself, both for integrals and for sums, is not in A-level or Further Mathematics; you must install the heuristic and the two standard rigorous devices (window for the lower bound, split and integral comparison for the upper bound). Second, the comparison of a monotone sum with an integral, including the Gaussian integral $\int_{-\infty}^{\infty} e^{-u^2/t}\,du = \sqrt{\pi t}$, must be automatic. Third, the two-sided series bounds for $\ln(1-u)$, with the reason the second-order term matters when it multiplies $n^2 \approx t^2$. Fourth, the vocabulary: partial theta series, and the fact that for the full theta function $\sum_{n\in\mathbb{Z}} x^{n^2}$ the growth $\sqrt{\pi/(1-x)}$ is a special case of the Jacobi transformation; you should know this exists so that you do not waste arena time trying to derive a closed form that does not exist for the weighted, one-sided sum. Without the first two of these, the problem is not approachable; with them it is a B6 only because of the bookkeeping.

Revolving concepts

Completing the square in an exponent. $bn - \frac{n^2}{t} = \frac{b^2t}{4} - \frac{(n-\frac{bt}{2})^2}{t}$: peak at $n = \frac{bt}{2}$, height $e^{b^2t/4}$, width $\sqrt{t}$. This is the whole content of the Gaussian shape of $e^{bn}x^{n^2}$ near $x = 1$. See Book 1, field: Calculus and integrals, topic: Laplace's method and Gaussian peaks.

Laplace's method (sums and integrals). For $\int h(u)e^{\lambda\phi(u)}\,du$ with ϕ having a unique nondegenerate maximum at u_0: $\sim h(u_0)e^{\lambda\phi(u_0)}\sqrt{\frac{2\pi}{\lambda|\phi''(u_0)|}}$. For sums, the same when the width is large compared with 1. Rigorous versions: lower bound by restricting to a window, upper bound by splitting and comparing monotone pieces with integrals. Beyond A-level. See Book 1, field: Real analysis, topic: asymptotic analysis, Laplace's method.

Sum-to-integral comparison. If ψ is decreasing on $[A, \infty)$ then $\sum_{n\geq A+1}\psi(n) \leq \int_A^{\infty}\psi$; if increasing on $(-\infty, B]$ then $\sum_{n\leq B-1}\psi(n) \leq \int_{-\infty}^{B}\psi$; a unimodal function is handled by splitting at its mode and adding a bounded number of terms near the mode. The Gaussian integral $\int_{\mathbb{R}} e^{-u^2/t}\,du = \sqrt{\pi t}$. See Book 1, field: Real analysis, topic: integral test and monotone comparison.

Two-sided logarithm bounds. For $0 < u \leq \frac{1}{2}$: $-u - u^2 \leq \ln(1-u) \leq -u$; more generally $\ln(1-u) = -u - \frac{u^2}{2} + O(u^3)$. The second-order term is retained whenever it is multiplied by a quantity of size u^{-2}. See Book 1, field: Inequalities, topic: logarithm and exponential bounds.

Theta series. $\vartheta(x) = \sum_{n\in\mathbb{Z}} x^{n^2}$ satisfies $\vartheta(x) \sim \sqrt{\frac{\pi}{1-x}}$ as $x \to 1^-$, a consequence of the Jacobi transformation (Poisson summation). The problem's series is a one-sided, weighted partial theta series with no transformation law; the growth must be found by peak analysis. Beyond A-level; know the statement, not the proof. See Book 1, field: Complex numbers, topic: theta functions and modular transformation (reference only).

Recursion, generalised. There is no recursion, but there is a generalised family: $G_{a,b}(x) = \sum n^a e^{bn} x^{n^2}$ satisfies $G_{a,b}(x)e^{-b^2/(4(1-x))} \asymp (1-x)^{-(a+\frac{1}{2})}$ for every $b > 0$, by the identical argument with the window $[\frac{bt}{2}, \frac{bt}{2} + \sqrt{t}]$ and the split at $\frac{bt}{4}$; the threshold $c = -\frac{1}{2}$ does not depend on b, and the constant does. With $b = 0$ the peak sits at $n = 0$ and the analysis changes character: $\sum_{n\geq 1} n^a x^{n^2}$ has a finite limit if and only if $a < -1$, and grows like $t^{(a+1)/2}$ for $a > -1$.

Circuit Bank

- **WHEN** a series of positive terms and a question about its size near a singular point **DO** name the large parameter, write the summand as a weight times e^{exponent}, and locate the maximum of the exponent **BECAUSE** a positive series is dominated by its largest terms, and Laplace's method estimates them as height times width
- **WHEN** e^{bn} and x^{n^2} in the same term **DO** substitute $t = \frac{1}{1-x}$, bound $\ln x$ two-sidedly, and complete the square $bn - \frac{n^2}{t}$ **BECAUSE** a quadratic exponent is a Gaussian, with centre $\frac{bt}{2}$, height $e^{b^2t/4}$ and width $\sqrt{t}$
- **WHEN** a normalising factor like $e^{-1/(1-x)}$ in the question **DO** expect it to equal the peak height exactly and read the remaining question as "what power of t survives" **BECAUSE** examiners build such problems backwards from the peak
- **WHEN** you need a lower bound on a positive sum **DO** keep only a window of terms around the peak, of length equal to the width, and bound each term below by a constant times the peak value **BECAUSE** dropping positive terms only decreases the sum
- **WHEN** you need an upper bound on a Gaussian-type sum **DO** split into the far tail (exponentially small times polynomially many) and the bulk (uniform weight times a Gaussian sum compared with its integral on each monotone side) **BECAUSE** the two devices together cost one paragraph and no ε

Backtesting

1. First useful cue: $e^{2n}x^{n^2}$, a linear and a quadratic exponent in the same term, together with the normalising factor $e^{-1/(1-x)}$.
2. Method the expression suggested: $t = \frac{1}{1-x}$, complete the square, Laplace's method for sums.
3. Where you would hesitate, and the thought to reinforce: when writing the upper bound, the temptation to bound the window by width times maximum and then to need an ε. The thought: bound n^a uniformly on $n \geq \frac{t}{2}$ and compare the remaining Gaussian sum with the Gaussian integral; no ε is needed.
4. The trap the question sets: trying to sum the series, or dropping the second-order term of $\ln x$ in the lower bound without noticing it multiplies $n^2 \approx t^2$; the factor e^{-n^2/t^2} is bounded, but you must say so.

5. What makes you recognise it faster next time: any x^{n^2} near $x = 1$ is a Gaussian in n of width $(1-x)^{-1/2}$; any extra e^{bn} just moves the centre to $\frac{b}{2(1-x)}$ and the height to $e^{b^2/(4(1-x))}$.

6. The reusable decision rule: for $\sum n^a e^{bn} x^{n^2}$ the normalised growth exponent is $a + \frac{1}{2}$; the threshold in a is $-\frac{1}{2}$, independent of $b > 0$, because the width $\sqrt{t}$ contributes $\frac{1}{2}$ and the weight at the peak contributes a.

Mirror drills

1. Show that $\sqrt{1-x}\sum_{n\geq 0} x^{n^2} \to \frac{\sqrt{\pi}}{2}$ as $x \to 1^-$. *Hint:* with $t = \frac{1}{1-x}$, the summand is $e^{n^2 \ln x}$ with $-\frac{1}{t} - \frac{1}{t^2} \leq \ln x \leq -\frac{1}{t}$; compare $\sum_{n\geq 0} e^{-n^2/t}$ with $\int_0^\infty e^{-u^2/t}\, du = \frac{\sqrt{\pi t}}{2}$ from both sides (the sum lies between the integral and the integral plus 1), and show the correction e^{-n^2/t^2} is $1 + o(1)$ uniformly for $n \leq t^{3/4}$ while the terms with $n > t^{3/4}$ are negligible.

2. For $b > 0$ fixed, find the threshold c such that $\sum n^a e^{bn} x^{n^2} \cdot e^{-b^2/(4(1-x))}$ tends to 0 for $a < c$ and to ∞ for $a > c$. *Answer:* $c = -\frac{1}{2}$ for every $b > 0$; complete the square $bn - \frac{n^2}{t} = \frac{b^2 t}{4} - \frac{(n - bt/2)^2}{t}$ and repeat the two bounds with the window $[\frac{bt}{2}, \frac{bt}{2} + \sqrt{t}]$.

3. Show that $\lim_{x\to 1^-} \sum_{n\geq 1} n^a x^{n^2}$ is finite if and only if $a < -1$. *Hint:* for $a < -1$ the series is dominated by $\sum n^a < \infty$ (monotone convergence); for $a \geq -1$ compare with $\int_1^{\sqrt{t}} u^a\, du$, which is $\asymp t^{(a+1)/2}$ for $a > -1$ and $\asymp \ln t$ for $a = -1$, using $x^{n^2} \geq e^{-2}$ for $n \leq \sqrt{t}$ and $t \geq 2$.

Chapter 3

Putnam 2023

3.1 A1. Second derivative of a cosine product at zero

For a positive integer n, let $f_n(x) = \cos(x)\cos(2x)\cos(3x)\cdots\cos(nx)$. Find the smallest n such that $|f_n''(0)| > 2023$.

Read it out loud

A product of n cosines whose frequencies are $1, 2, \ldots, n$; the second derivative of that product; evaluated at the single point 0; compared with a threshold. Say it that way and the structure is already talking to you. Nothing about f_n away from 0 matters. Only one number matters: the second Taylor coefficient of f_n at 0, because $f_n''(0) = 2\,[x^2]f_n(x)$ by definition of the Taylor coefficients.

Fields wired in: single-variable calculus (Taylor expansion, the product rule as a fallback), a closed form for $1^2 + 2^2 + \cdots + n^2$, and one line of monotonicity. Knowledge base: the expansion $\cos(mx) = 1 - \frac{m^2x^2}{2} + O(x^4)$, the fact that truncated power series multiply like polynomials, and $\sum_{m=1}^{n} m^2 = \frac{n(n+1)(2n+1)}{6}$. All of it is A-level; what is being tested is whether you differentiate what you were asked to differentiate (zombie) or read off the coefficient (ideal).

The first useful cue is "at 0" sitting next to a product of even functions each equal to 1 at 0. Within thirty seconds you should have written: $\cos(mx) = 1 - \frac{m^2}{2}x^2 + \ldots$, no x^1 term, and asked yourself: what is the x^2 coefficient of a product of factors of the form $1 + c_m x^2 + \ldots$? The answer is $\sum c_m$, because a cross term needs two non-constant factors and the cheapest non-constant term is already x^2. That single sentence is the whole problem. The number 2023 then forces an exact evaluation of the sum of squares, not an asymptotic; it was chosen so that $n = 18$ is the first crossing and so that a sloppy candidate who writes $n^3/3 > 2023$ gets $n = 19$ and loses the mark.

Approaches, ranked worst to best

1. **Product rule, twice.** *Cue:* the words "second derivative". *Circuit:* differentiate what you are asked to differentiate. (This is the nominal route. f_n'' is a sum of n terms in which one factor is differentiated twice plus $\binom{n}{2}$ terms in which two distinct factors are differentiated once each. At $x = 0$ every term of the second type contains a factor $\sin(0) = 0$; every term of the first type is $-m^2$ times a product of ones. The answer falls out, but you must write a paragraph classifying the terms, and the classification is exactly where a tired candidate miscounts. It is correct and it is the official write-up; it is still the most ink for the least structure.)

2. **Logarithmic derivative.** *Cue:* a product of factors that are positive near 0. *Circuit:* turn a product into a sum with log. (Near 0, $f_n > 0$, so $(\log f_n)' = f_n'/f_n = -\sum_{m=1}^{n} m\tan(mx)$. Differentiate once more: $f_n''/f_n = (\log f_n)'' + \big((\log f_n)'\big)^2 = -\sum m^2\sec^2(mx) + \big(\sum m\tan(mx)\big)^2$. At 0: $f_n(0) = 1$, $\tan 0 = 0$, $\sec 0 = 1$, so $f_n''(0) = -\sum m^2$. Two lines, fully rigorous, and it generalises to any product. It costs you the identity $f'' = f\,[(\log f)'' + ((\log f)')^2]$, which you must be able to reproduce cold.)

3. **Taylor coefficient extraction.** *Cue:* "at 0" next to a product of series with no linear term. *Circuit:* the k-th derivative at a point is $k!$ times the x^k coefficient; multiply truncated series. (The ideal route. Expand each factor to order 2, multiply, and note that the x^2 coefficient of the product is the sum of the individual x^2 coefficients because there are no x^1 terms to cross-multiply. No differentiation is performed at all. This is the laziest correct route and it is also the one that scales: the same move gives $f_n^{(4)}(0)$ in one more line.)

The ideal solution

For each m, the cosine series gives $\cos(mx) = 1 - \frac{m^2}{2}x^2 + x^4R_m(x)$, where R_m is an everywhere convergent power series. Multiply the n factors. Any term of the expanded product that uses at

least one $x^4 R_m(x)$, or at least two of the factors $-\frac{m^2}{2}x^2$, is divisible by x^4. The remaining terms are the product of all the ones, which is 1, and the terms with exactly one factor $-\frac{m^2}{2}x^2$ and ones elsewhere. Hence

$$f_n(x) = 1 - \frac{x^2}{2}\sum_{m=1}^{n} m^2 + x^4 R(x)$$

with R a power series convergent everywhere. By uniqueness of Taylor coefficients, $f_n''(0) = 2! \cdot \left(-\frac{1}{2}\sum_{m=1}^{n} m^2\right)$, thus

$$|f_n''(0)| = \sum_{m=1}^{n} m^2 = \frac{n(n+1)(2n+1)}{6} =: g(n).$$

The sequence $g(n)$ is strictly increasing, since $g(n+1) - g(n) = (n+1)^2 > 0$. Now $g(17) = \frac{17\cdot 18\cdot 35}{6} = 17 \cdot 3 \cdot 35 = 1785 \le 2023$ and $g(18) = \frac{18\cdot 19\cdot 37}{6} = 3 \cdot 19 \cdot 37 = 2109 > 2023$. By monotonicity, $g(n) \le 1785$ for all $n \le 17$ and $g(n) \ge 2109$ for all $n \ge 18$. The smallest n with $|f_n''(0)| > 2023$ is therefore

$$\boxed{n = 18}.$$

Layer 1: WHAT

Block 1. Translate "$f_n''(0)$" into "twice the x^2 coefficient of f_n at 0".

Block 2. Expand each factor to order two: $\cos(mx) = 1 - \frac{m^2}{2}x^2 + O(x^4)$; record that there is no x^1 term.

Block 3. Multiply: the x^2 coefficient of the product is the sum of the x^2 coefficients of the factors, because the cheapest cross term is $x^2 \cdot x^2 = x^4$.

Block 4. Sum of squares in closed form, one line of monotonicity, two evaluations bracketing 2023.

Juxtaposition. The nominal route reads "second derivative" and starts differentiating: product rule, n factors, then product rule again on each of the n resulting products, then evaluation. It arrives at the same $-\sum m^2$, after a page. The ideal route never differentiates. The bifurcation point is the first pen stroke: do you write $f_n'(x) =$ (zombie) or do you write $\cos(mx) = 1 - \frac{m^2}{2}x^2 + \ldots$ (ideal)? Everything downstream is decided there.

Layer 2: HOW

Block 1. Cue. The derivative is requested at one point, 0, and the function is a finite product of entire functions. **Why natural.** A derivative at a point is a local object; the local object at 0 is the Taylor series, and $f''(0)/2!$ is by definition its x^2 coefficient. Asking for $f_n''(0)$ is asking for one coefficient. It is worth repeating: when a question evaluates a derivative at a specific point, the question is about a coefficient, not about a function. **Link to the next block.** Once the target is a coefficient of a product, the natural question is how coefficients of products are built from coefficients of factors.

Block 2. Cue. Each factor is $\cos(mx)$, an even function with value 1 at 0. **Why natural.** Even functions have no odd Taylor terms, so the expansion of each factor starts $1 + c_m x^2$ with $c_m = -m^2/2$. The absence of an x^1 term is the structural fact that makes the next block a one-liner; you note it explicitly because it is the reason, not a coincidence. **Link to the next block.** With every factor of the shape $1 + c_m x^2 + O(x^4)$, the product's x^2 coefficient can be read off without writing the product.

Block 3. **Cue.** A product of n series of the form $1 + c_m x^2 + O(x^4)$. **Why natural.** To produce an x^2 term from the product you must pick a non-constant term from at least one factor, and the smallest non-constant degree available is 2; picking non-constant terms from two factors already gives degree at least 4. So the x^2 coefficient is exactly $\sum c_m$. This is the "log-linearisation" of a product: $\prod(1+\epsilon_m) = 1 + \sum \epsilon_m + (\text{terms of order } \epsilon^2)$, and here the ϵ_m are already of order x^2. **Link to the next block.** $|f_n''(0)| = \sum m^2$; the calculus is over and a finite-sum problem remains.

Block 4. **Cue.** "Smallest n such that [quantity] > 2023". **Why natural.** A smallest-n question needs two facts: the quantity is monotone in n (so that "smallest" is meaningful and the answer is a single crossing), and the two consecutive values straddling the threshold. Monotonicity is one line, $g(n+1) - g(n) = (n+1)^2 > 0$. The evaluations at 17 and 18 are chosen by the estimate $n^3/3 \approx 2023$, so $n \approx 18$; then you check the neighbours exactly, because the estimate is not a proof. **Link to the next block.** The answer is 18, with a complete justification that no smaller n works and that 18 does.

Layer 3: WHY

The truth beneath the route is that truncation is compatible with multiplication: the map sending a power series to its remainder modulo x^k is a ring homomorphism, so to know a product modulo x^4 you only need each factor modulo x^4. That is why "multiply the truncated series" is a proof and not a heuristic. The second truth is additivity to second order: a product of factors $1 + \epsilon_m$ with $\epsilon_m = O(x^2)$ equals $1 + \sum \epsilon_m$ modulo x^4. There is a probabilistic reading that makes this feel inevitable. Let $X = \epsilon_1 \cdot 1 + \epsilon_2 \cdot 2 + \cdots + \epsilon_n \cdot n$ with independent fair signs $\epsilon_m = \pm 1$. Then $\mathbb{E}[e^{iXx}] = \prod_m \mathbb{E}[e^{i\epsilon_m m x}] = \prod_m \cos(mx) = f_n(x)$, and the second derivative of a characteristic function at 0 is $-\mathbb{E}[X^2]$. Variances of independent summands add, so $-f_n''(0) = \sum m^2$. The additivity you exploited in Block 3 is the additivity of variance.

The discernment mechanism is a fixed question you ask of every derivative-at-a-point problem: which coefficient is being requested, and which coefficients of the ingredients feed it? For a product, the answer is a convolution of coefficient sequences, and low-order coefficients of the product depend only on low-order coefficients of the factors. For a composition, the same principle holds with Faà di Bruno replacing convolution. You train the discernment by refusing, for one month, to differentiate any product at a point; you expand instead, every time, until the reflex is installed.

What the examiners nudged toward: they put the evaluation at 0, where sin vanishes and cos is 1, so that the product rule collapses; they used frequencies $1, \ldots, n$ so that the answer is a textbook sum; and they chose 2023 so that the crossing is at 18 rather than at a round number, which forces an exact evaluation and punishes the approximation $n^3/3$.

Revolving concepts

Taylor coefficient extraction. Definition: if f is k times differentiable at a, then $f^{(k)}(a) = k!\,[(x-a)^k]f$ where the bracket denotes the coefficient in the Taylor polynomial; for a function given by a convergent power series the Taylor coefficients are the series coefficients (uniqueness of power series). Orbiting facts: truncation modulo $(x-a)^k$ is a ring homomorphism; even functions have zero odd coefficients at 0; $[x^2]\prod_m(1 + a_m x + b_m x^2 + \ldots) = \sum_m b_m + \sum_{i<j} a_i a_j$, which is the general form of Block 3 with the elementary symmetric function e_2 of the linear coefficients appearing as soon as linear terms exist. See Book 1, field: Calculus and integrals, topic: Taylor expansion of products.

The recursion generalised. Coefficients of a product obey the Cauchy convolution $[x^k]\prod_{m=1}^n g_m = \sum_{k_1+\cdots+k_n=k} \prod_m [x^{k_m}] g_m$. Two general solution methods: (i) generating functions, where the product is the object itself; (ii) logarithms, where $\log \prod g_m = \sum \log g_m$ turns the multiplicative recursion into an additive one, and exponentiating back is the standard way to compute power sums from

elementary symmetric functions (Newton's identities live here). The logarithmic-derivative route of Approach 2 is this second method applied to two coefficients only. See Book 1, field: Generating functions, topic: products and logarithmic derivatives.

Characteristic functions. Definition: $\varphi_X(x) = \mathbb{E}[e^{iXx}]$. Orbiting theorems: $\varphi_{X+Y} = \varphi_X \varphi_Y$ for independent X, Y; $\varphi_X^{(k)}(0) = i^k \mathbb{E}[X^k]$ when the moment exists; a fair sign times m has characteristic function $\cos(mx)$. This is the reason products of cosines appear in counting problems about signed sums and in the theory of the Rademacher functions. See Book 1, field: Probability, topic: characteristic functions of sums.

Sum of squares. $\sum_{m=1}^{n} m^2 = \frac{n(n+1)(2n+1)}{6}$, proved by telescoping $(m+1)^3 - m^3 = 3m^2 + 3m + 1$; the same telescoping gives every $\sum m^k$ recursively, which is the recursion behind Faulhaber's formulas. See Book 1, field: Sequences and recurrences, topic: power sums by telescoping.

Circuit Bank

- **WHEN** you see a derivative of a product (or composition) evaluated at one specific point **DO** write the Taylor expansion of every factor at that point to the required order and multiply the truncations **BECAUSE** because $f^{(k)}(a)$ is $k!$ times one coefficient, and truncation commutes with multiplication, so nothing outside those few coefficients can matter
- **WHEN** you see a product of factors each of the form $1 +$ (something of order x^2) **DO** write the x^2 coefficient as the plain sum of the individual x^2 coefficients **BECAUSE** because a cross term needs two non-constant factors and is therefore of order at least x^4; this is additivity of variance in disguise
- **WHEN** you see a product of cosines with different frequencies **DO** read it as the characteristic function of $\sum \pm m$ with independent fair signs **BECAUSE** because $\cos(mx) = \mathbb{E}[e^{i\epsilon mx}]$, so derivatives at 0 are moments and independence makes second moments add
- **WHEN** you see "smallest n such that [expression in n] exceeds a threshold" **DO** prove monotonicity in one line, estimate the crossing, then evaluate exactly at the two neighbouring integers **BECAUSE** because monotonicity plus two exact values is a complete proof, and an estimate alone is not

Backtesting

1. First useful cue: "$f_n''(0)$", a derivative at one point, next to a product of even functions equal to 1 at that point.
2. Method the expression suggested: expand each $\cos(mx)$ to order two, multiply truncations, read the x^2 coefficient; never apply the product rule.
3. Where you would hesitate, and the thought to reinforce: whether multiplying truncated series is legitimate. It is, because truncation modulo x^4 is a ring homomorphism; say that sentence and move on.
4. The trap the question sets: the threshold 2023 invites the approximation $\sum m^2 \approx n^3/3$, which suggests $n \approx 18.2$ and tempts you to answer 19; the exact values 1785 and 2109 settle it at 18.
5. What makes you recognise it faster next time: any "evaluate a derivative at a point" is a "read one Taylor coefficient" problem; any product of series with no linear terms has additive second coefficients.
6. The reusable decision rule: derivative at a point means coefficient; product of series means truncated multiplication; smallest n means monotonicity plus two exact evaluations.

Mirror drills

1. (drill) Let $g_n(x) = \prod_{m=1}^{n} \cosh(mx)$. Find $g_n''(0)$. *Answer:* $\cosh(mx) = 1 + \frac{m^2}{2}x^2 + O(x^4)$, so $g_n''(0) = \sum_{m=1}^{n} m^2 = \frac{n(n+1)(2n+1)}{6}$; only the sign changes.
2. (drill) Let $h_n(x) = \prod_{m=1}^{n}(1+mx)$. Find $h_n''(0)$. *Answer:* now the factors have linear terms, so $[x^2]h_n = e_2(1,\dots,n) = \sum_{i<j} ij = \frac{1}{2}\left[(\sum m)^2 - \sum m^2\right]$ and $h_n''(0) = (\sum m)^2 - \sum m^2$. This is the drill that shows why "no linear term" mattered in A1.
3. (drill) Express $f_n^{(4)}(0)$ for the A1 function in terms of $S_2 = \sum m^2$ and $S_4 = \sum m^4$. *Answer:* $[x^4]f_n = \sum_m \frac{m^4}{24} + \sum_{i<j} \frac{i^2 j^2}{4}$, so $f_n^{(4)}(0) = S_4 + 6\sum_{i<j} i^2 j^2 = 3S_2^2 - 2S_4$; check $n = 1$ gives 1, as $\cos^{(4)}(0) = 1$. Probabilistically this is $\mathbb{E}[X^4]$ for $X = \sum \epsilon_m m$.

3.2 A2. Reversing a polynomial to expose two missing roots

Let n be an even positive integer. Let p be a monic, real polynomial of degree $2n$; that is to say, $p(x) = x^{2n} + a_{2n-1}x^{2n-1} + \cdots + a_1x + a_0$ for some real coefficients $a_0, \ldots, a_{2n-1}$. Suppose that $p(1/k) = k^2$ for all integers k such that $1 \leq |k| \leq n$. Find all other real numbers x for which $p(1/x) = x^2$.

Read it out loud

A monic polynomial of degree $2n$; you are told its value at $2n$ specified points, namely the reciprocals $\pm 1, \pm\frac{1}{2}, \ldots, \pm\frac{1}{n}$; and the values are prescribed by the rule $p(1/k) = k^2$. Then you are asked for the other solutions of the same equation. Say that out loud and the arithmetic of degrees of freedom is already audible: p has exactly $2n$ unknown coefficients and you are handed exactly $2n$ conditions, so p is pinned down completely. A weak reading concludes "so I must find p". The correct reading is the opposite: the question asks only for the extra solutions, so the design of the problem is telling you that the extra solutions can be named without ever computing a single a_i.

Fields wired in: polynomials, the factor theorem and root counting, the reversal (reciprocal) operation on a polynomial, and Vieta's relations at the two ends of the coefficient list. The knowledge base needed is small and entirely nameable: a polynomial of degree d has exactly d roots in $\mathbb{C}$ with multiplicity; if $r_1, \ldots, r_d$ are those roots of a monic polynomial then the sum is minus the coefficient of x^{d-1} and the product is $(-1)^d$ times the constant term; and multiplying by a power of x converts an expression in $1/x$ into a polynomial in x.

The first useful cue is that the phrase "$p(1/x) = x^2$" is an equation, not a value, and you are told it holds at $2n$ named points. Any time a question hands you many points where two things agree, the object you should build is the single polynomial that vanishes at all of them. Within thirty seconds you should have written

$$q(x) := x^{2n+2} - x^{2n}p(1/x),$$

and then checked three things about it: it is a genuine polynomial, it is monic of degree $2n + 2$, and its roots are exactly the solutions of the equation you were asked about. Everything after that is bookkeeping at the two ends of q.

The second cue is the hypothesis "n is even". Competition hypotheses of that shape are never decoration. Somewhere a $(-1)^n$ is going to appear, and the parity is inserted to fix its sign. Hunt for that sign as you go; it is the difference between two real answers and no real answer at all.

Approaches, ranked worst to best

1. **Interpolate p explicitly, then solve.** *Cue:* "$2n$ conditions on $2n$ unknown coefficients". *Circuit:* when a linear system is determined, solve it. (This is the nominal route and it is a swamp. You would set up a $2n$ by $2n$ Vandermonde-type system in the a_i with entries k^{-j}, invert it symbolically for general even n, and then attempt to solve a degree $2n + 2$ equation with the resulting coefficients. Even for $n = 4$ the coefficients are ratios such as $83149/144$, and no pattern in n is visible from them. The route never terminates in the arena.)

2. **Clear the fraction on the other side.** *Cue:* "$p(1/k) = k^2$ says $p(y) = 1/y^2$ at $y = \pm 1/k$". *Circuit:* multiply through by the offending denominator to get a polynomial equation. (Set $P(y) = y^2p(y) - 1$. It is monic of degree $2n + 2$ and vanishes at the $2n$ points $y = \pm 1/k$, so $P(y) = \prod_{k=1}^{n}\left(y^2 - \frac{1}{k^2}\right) \cdot (y^2 + cy + d)$. Comparing the coefficients of y^1 and y^0, which are 0 and -1, gives $c = 0$ and $d = -(n!)^2$, so the extra roots are $y = \pm n!$ and hence $x = 1/y = \pm 1/n!$. This is correct and costs little. It ranks below the reversal for two reasons: the two coefficients you can read off are the two lowest, so the monic normalisation at the top is wasted, and you

finish in the variable y and must remember to invert at the end, which is exactly the sort of last-line slip that costs a point.)

3. **Reversal, then long division by the known factor.** *Cue:* "$p(1/x)$ next to x^2". *Circuit:* form the polynomial whose roots are the solutions, then divide out what you know. (Build $q(x) = x^{2n+2} - x^{2n}p(1/x)$, divide by $\prod_{k=1}^{n}(x^2 - k^2)$, and read the quotient. Correct, but polynomial division by a product of n quadratics is a page of ink for information that lives in two coefficients.)

4. **Reversal, then Vieta at the two ends.** *Cue:* a monic polynomial with all but two of its roots known, and both extreme coefficients visible. *Circuit:* sum and product of roots are free; everything in the middle costs ink. (The ideal route. The reversed polynomial q is monic, has no x^{2n+1} term and has constant term -1; those two facts say the roots sum to 0 and multiply to -1. The $2n$ known roots sum to 0 and multiply to $(n!)^2$, so the two unknown roots sum to 0 and multiply to $-1/(n!)^2$. Two lines, no division, and the parity hypothesis announces itself exactly where it is used.)

The ideal solution

Since n is an even positive integer, $n \geq 2$.

Write $p(x) = x^{2n} + a_{2n-1}x^{2n-1} + \cdots + a_0$ and set

$$q(x) := x^{2n+2} - x^{2n}p(1/x).$$

Because $x^{2n}p(1/x) = 1 + a_{2n-1}x + a_{2n-2}x^2 + \cdots + a_0x^{2n}$, the function q is a polynomial. It is monic of degree $2n+2$, its coefficient of x^{2n+1} is 0, and $q(0) = -1$.

For $x \neq 0$ we have $q(x) = x^{2n}\big(x^2 - p(1/x)\big)$, so $q(x) = 0$ if and only if $p(1/x) = x^2$. Also $q(0) = -1 \neq 0$. Hence the real numbers x with $p(1/x) = x^2$ are precisely the real roots of q.

By hypothesis the $2n$ distinct numbers $\pm1, \pm2, \ldots, \pm n$ are roots of q, so

$$q(x) = \Big(\prod_{k=1}^{n}(x^2 - k^2)\Big)(x^2 + ax + b)$$

for some real a, b: the quotient of the monic real polynomial q by the monic real polynomial $\prod_{k=1}^{n}(x^2 - k^2)$ is monic, real and of degree 2.

Let r and s be the two roots of $x^2 + ax + b$ in $\mathbb{C}$. The full root multiset of q is $\{\pm1, \ldots, \pm n, r, s\}$. Vieta's relations for the monic polynomial q of degree $2n+2$ give

$$\sum \text{roots} = -[x^{2n+1}]q = 0, \qquad \prod \text{roots} = (-1)^{2n+2}q(0) = -1.$$

The known roots contribute $\sum_{k=1}^{n}\big(k + (-k)\big) = 0$ to the sum and $\prod_{k=1}^{n} k(-k) = (-1)^n(n!)^2 = (n!)^2$ to the product, the last equality because n is even. Therefore

$$r + s = 0, \qquad (n!)^2\, rs = -1.$$

From the first, $s = -r$; substituting into the second gives $-r^2 = -1/(n!)^2$, that is $r^2 = 1/(n!)^2$, so $r = \pm 1/n!$ and $\{r, s\} = \{1/n!, -1/n!\}$. Both are real.

Finally, these are new solutions: $n \geq 2$ forces $0 < 1/n! \leq \frac{1}{2} < 1$, so $\pm 1/n!$ is none of $\pm1, \ldots, \pm n$. The other real numbers x with $p(1/x) = x^2$ are therefore

$$\boxed{x = \pm\frac{1}{n!}}.$$

Two remarks a grader will not demand but which cost one line each. First, such a p does exist and is unique: reading the argument backwards, $q(x) = \big(\prod_{k=1}^{n}(x^2 - k^2)\big)\big(x^2 - (n!)^{-2}\big)$ is even, so

it has no x^{2n+1} term, and its constant term is $(-1)^n(n!)^2 \cdot \big(-(n!)^{-2}\big) = -1$; hence $x^{2n+2} - q(x)$ has degree at most $2n$ and constant term 1, which is exactly a reversed monic p of degree $2n$. Second, the hypothesis that n is even is load-bearing and not cosmetic: for odd n the product of the known roots is $-(n!)^2$, the same computation gives $r^2 = -1/(n!)^2$, and the two extra roots are the non-real numbers $\pm i/n!$, so an odd n would have the answer "there are no other real solutions".

Layer 1: WHAT

Block 1. Read "$p(1/k) = k^2$ for $2n$ values of k" as "one equation with $2n$ known solutions", not as "$2n$ linear conditions on the a_i".

Block 2. Build the polynomial whose roots are the solutions: multiply by x^{2n} to clear the reciprocals and move everything to one side, giving $q(x) = x^{2n+2} - x^{2n}p(1/x)$, monic of degree $2n+2$.

Block 3. Record the two free facts about q: no x^{2n+1} term (because subtracting a polynomial of degree at most $2n$ cannot disturb the top two coefficients of x^{2n+2}) and constant term -1 (because the reversal of a monic p has constant term 1).

Block 4. Count roots: $2n+2$ in total, $2n$ known, so exactly two unknown.

Block 5. Apply Vieta at the two ends: the unknown pair sums to 0 and multiplies to $-1/(n!)^2$; the parity of n enters here and only here.

Block 6. Solve the two-by-two system, get $\pm 1/n!$, and check they are new.

Juxtaposition. The nominal route reads "$2n$ conditions, $2n$ unknowns" and starts inverting a matrix; it computes p, which the question never asked for, and then faces a degree $2n+2$ equation with unpleasant coefficients. The ideal route never learns a single a_i; it learns only that the top-but-one coefficient of q is 0 and the bottom coefficient is -1, which is all the information the answer depends on. The bifurcation point is the first pen stroke after reading the hypothesis: do you write "$a_0 + a_1k^{-1} + \cdots = k^2$" (zombie) or "$q(x) := x^{2n+2} - x^{2n}p(1/x)$" (ideal)?

Layer 2: HOW

Block 1. Cue. An equation, $p(1/x) = x^2$, stated to hold at a list of $2n$ specific points, with the question asking for the rest of the solution set. **Why natural.** A list of points where an equation holds is a list of roots of the difference of the two sides. That is the factor theorem read in reverse, and it is the only way to convert "many conditions" into "a known factor", which is the currency you can actually compute with. It is worth repeating: values at many points are never data about coefficients, they are data about roots. **Link to the next block.** Once you want roots, you need a polynomial; the expression $p(1/x) - x^2$ is not one, so the next move is forced.

Block 2. Cue. The variable appears as $1/x$ inside p, and p has degree $2n$. **Why natural.** Multiplying by x^{2n} is the smallest power that clears every denominator, since the worst denominator in $p(1/x)$ is x^{-2n}. The resulting object $x^{2n}p(1/x)$ is the reversal of p: its coefficient list is that of p read backwards. Reversal is the standard dictionary between a polynomial's roots and their reciprocals, and it turns the hypothesis "monic" into the fact "constant term 1", which is a fact at the end of the polynomial where Vieta is cheap. **Link to the next block.** Now you have a polynomial identity; the next question is what its degree and its extreme coefficients are, because those are the only things you get for free.

Block 3. Cue. q is a difference of x^{2n+2} and something of degree at most $2n$. **Why natural.** A subtraction cannot disturb coefficients above the degree of what is subtracted. So the coefficients of x^{2n+2} and x^{2n+1} in q are those of x^{2n+2} itself, namely 1 and 0. The gap of two between $2n+2$ and $2n$ is the whole reason the problem works, and it is the reason the exponent in "$p(1/x) = x^2$" is a 2: it

creates exactly one free coefficient at the top to pair with the free coefficient at the bottom. **Link to the next block.** Two free coefficients at the two ends is exactly enough to pin two unknown roots.

Block 4. **Cue.** $2n$ distinct known roots inside a degree $2n+2$ polynomial. **Why natural.** The factor theorem plus distinctness gives divisibility by $\prod(x-k)$ over all $2n$ known roots, which is $\prod_{k=1}^{n}(x^2-k^2)$; the quotient is monic real of degree 2 by comparing degrees and leading coefficients. Note that you never need to know what the quotient is, only that it exists. **Link to the next block.** A monic quadratic has two unknowns, and you have two coefficient facts, so the system is square and you should not compute the quotient at all.

Block 5. **Cue.** A monic polynomial with all roots known but two, and its two extreme coefficients known. **Why natural.** Vieta at the ends is free information: the sum of all roots is minus the second coefficient and the product of all roots is $(-1)^{\deg}$ times the constant term. Every other elementary symmetric function sits in the middle of the coefficient list, where you do not know anything. So the lazy move is to use only e_1 and e_{2n+2}, and the problem has been built so that these suffice. The known roots come in $\pm$ pairs, which annihilates them in e_1 and turns them into $(-1)^n(n!)^2$ in the product, and this is the unique place where the parity of n acts. **Link to the next block.** Two symmetric equations in r and s; the first makes $s=-r$, so the second becomes a single quadratic in r.

Block 6. **Cue.** $r+s=0$ and $rs=-1/(n!)^2$. **Why natural.** A pair with zero sum is $\{r,-r\}$, and its product is $-r^2$, so the second equation reads $r^2=1/(n!)^2$: positive, hence two real roots. Had the right-hand side been negative you would have concluded that there are no further real solutions, which is precisely the odd-n situation. Finish by verifying the new roots are not old ones, because the question said "other". **Link to the next block.** Nothing left; the answer is $\pm 1/n!$.

Layer 3: WHY

Three mathematical truths carry this route. The first is that a polynomial identity is determined by its roots and its leading coefficient, so information about where two expressions agree is structural information, whereas information about coefficients is arithmetic information. Structural information composes; arithmetic information has to be carried. The second is that reversal, $p \mapsto p^*(x) = x^{\deg p}p(1/x)$, is an involution on polynomials with nonzero constant term that inverts every root and reverses the coefficient list. Any hypothesis phrased in terms of $1/x$ is an invitation to apply it, and after applying it a normalisation you were given at one end of the polynomial reappears at the other end, where it may be more useful. Here "monic" becomes "constant term 1", and the constant term is one half of Vieta's cheap pair. The third is that the elementary symmetric functions of the roots are the coefficients, so partial knowledge of the roots plus partial knowledge of the coefficients is a solvable system whenever the counts match; the designer of this problem matched them deliberately.

The discernment mechanism is a counting question you should ask before writing anything: how many unknowns does the answer actually depend on, and where in the polynomial do they live? Here the answer depends on two numbers, a and b in the quotient, and q offers exactly two coefficients you can name without work. If instead the exponent in the problem had been 3, so that q had degree $2n+3$ and a cubic quotient, you would need three cheap coefficients, and you would look for a third: the coefficients of x^{2n+2} and x^{2n+1} are both 0 and the constant is -1, so it still closes. If the exponent had been 1, the quotient would be linear and the top gap would vanish; you would need a different pairing. Training this is a matter of always writing the degree of the constructed polynomial and the degree of the known factor on the same line, then subtracting.

What the examiners nudged toward and how they nudged: they wrote the conditions symmetrically in $\pm k$, which is the signal that the extra roots will be a $\pm$ pair and that the sum of the known

roots is zero; they made p monic, which is the signal that the reversed polynomial has a known constant term; and they specified that n is even, which is the signal that a $(-1)^n$ will decide reality of the answer. Three planted cues, three used facts, no accidents.

Revolving concepts

Factor theorem and the root count. Definition and statement: for a field F and $p \in F[x]$ of degree $d \geq 1$, $p(r) = 0$ if and only if $(x - r) \mid p$; distinct roots give coprime linear factors, so d distinct roots force $\prod(x - r_i) \mid p$; over $\mathbb{C}$ there are exactly d roots with multiplicity. Corollary used constantly on the Putnam: if two polynomials of degree at most d agree at $d + 1$ points they are identical. See Book 1, field: Polynomials, topic: factor theorem and degree bounds.

Reciprocal (reversed) polynomial. Definition: $p^*(x) = x^d p(1/x)$ where $d = \deg p$; its coefficient sequence is that of p reversed, its roots are the reciprocals of the roots of p, and p is called palindromic when $p^* = p$. Orbiting facts: p monic if and only if $p^*(0) = 1$; a palindromic polynomial of even degree $2m$ can be reduced to degree m by the substitution $u = x + 1/x$, which is the standard route into problems about roots on the unit circle. Here reversal is the move that makes the whole problem two lines. See Book 1, field: Polynomials, topic: reciprocal and palindromic polynomials.

Vieta's relations and the symmetric functions. For monic q of degree d with roots $r_1, \ldots, r_d$, the coefficient of x^{d-j} is $(-1)^j e_j(r_1, \ldots, r_d)$, where e_j is the j-th elementary symmetric function. The two cheap ones are e_1 (from the second coefficient) and e_d (from the constant term). The general principle: knowing all roots but m of them, plus m coefficients, determines the missing ones, because the e_j of the whole set are polynomial in the e_j of the two parts. See Book 1, field: Polynomials, topic: Vieta and symmetric functions.

The recursion generalised. The factorial in the answer is the only recursion in sight, and it enters through the product of the known roots: $R_n := \prod_{k=1}^{n} k(-k) = (-1)^n (n!)^2$ satisfies $R_n = -n^2 R_{n-1}$ with $R_0 = 1$. The general statement worth installing is the parametrised version of this problem. Suppose p is monic of degree D and $p(1/x) = x^m$ at N prescribed nonzero points; then $q(x) = x^{D+m} - x^D p(1/x)$ is monic of degree $D + m$ with the top $m - 1$ coefficients after the leading one equal to zero and constant term -1, and the unknown factor has degree $D + m - N$. The missing factor is determined as soon as $D + m - N$ of its symmetric functions can be read off, and the products of the known roots enter through the same telescoping product R. Solving that general form is the same two-step method: build q, then match counts. See Book 1, field: Polynomials, topic: constructed polynomials with prescribed roots.

Degrees of freedom counting. Definition of the habit: before solving, count unknowns and independent conditions and ask what the answer depends on. Here p has $2n$ unknowns and there are $2n$ conditions, so p is determined, yet the answer depends only on two symmetric functions. Recognising that gap is what stops you from computing p. See Book 1, field: Logic and set theory, topic: counting constraints before solving.

Circuit Bank

- **WHEN** you are told an equation holds at more named points than you have unknowns, and asked where else it holds **DO** form the single polynomial whose roots are all solutions and factor out the known ones **BECAUSE** because the factor theorem is the only mechanism that converts a list of values into an algebraic factor, and the leftover factor has small degree, which is exactly what the question is asking for
- **WHEN** the unknown appears as $1/x$ inside a polynomial of degree d **DO** multiply by x^d to form the reversal $x^d p(1/x)$ **BECAUSE** because reversal turns reciprocal roots into ordinary roots and moves a normalisation such as monicity from the top of the coefficient list to the bottom, where Vieta is cheap

- **WHEN** a monic polynomial has all its roots known except a few, and you know the extreme coefficients **DO** use the sum and the product of the roots rather than dividing polynomials **BECAUSE** because e_1 and e_d are readable off the two ends for free, whereas the middle coefficients cost a long division that you will not need
- **WHEN** a hypothesis fixes a parity, such as "n is even" **DO** find the single step where $(-1)^n$ appears and mark it **BECAUSE** because such hypotheses are inserted to fix a sign, and the sign usually decides whether the answer is real, positive, or empty

Backtesting

1. First useful cue: an equation asserted at $2n$ named points, with the question asking for the other solutions, next to the reciprocal argument $1/x$ and the word "monic".
2. Method the expression suggested: build $q(x) = x^{2n+2} - x^{2n}p(1/x)$, note that it is monic of degree $2n+2$ with zero x^{2n+1} coefficient and constant term -1, divide off the $2n$ known roots in principle, and pin the remaining monic quadratic by the sum and product of all roots.
3. Where you would hesitate, and the thought to reinforce: at the moment you realise p is uniquely determined by the data, since the instinct is to find it. Reinforce this sentence: the question asks for solutions, not for p, and solutions are roots, so build the polynomial whose roots they are.
4. The trap the question sets: two traps. Computing p by interpolation, which burns the whole session; and forgetting that "other" requires checking $\pm 1/n!$ is not already in the list $\pm 1, \ldots, \pm n$, which is where a one-line justification ($n \geq 2$ so $1/n! < 1$) earns the last mark.
5. What makes you recognise it faster next time: the pair of cues "value conditions at many points" and "argument $1/x$" together mean "reversed polynomial with known roots"; the phrase "monic" is then a statement about the constant term of that reversed object.
6. The reusable decision rule: many prescribed values means known roots; $1/x$ means reverse; all-but-two roots known means Vieta at the two ends; a parity hypothesis means a sign is about to be decided.

Mirror drills

1. (drill) Take $n = 2$: p is monic of degree 4 with $p(1) = p(-1) = 1$ and $p(1/2) = p(-1/2) = 4$. Find all other real x with $p(1/x) = x^2$, and find p itself as a check. *Answer:* $x = \pm 1/2! = \pm\frac{1}{2}$. Solving the system confirms $p(z) = z^4 - \frac{21}{4}z^2 + \frac{21}{4}$, and indeed $p(2) = 16 - 21 + \frac{21}{4} = \frac{1}{4}$, as required by $p(1/x) = x^2$ at $x = \frac{1}{2}$.
2. (drill) Same hypotheses but with n odd. What changes? *Answer:* only the sign in $\prod_{k=1}^{n} k(-k) = (-1)^n(n!)^2$. Now $(n!)^2 rs = -1$ with $r + s = 0$ gives $r^2 = -1/(n!)^2$, so the two extra roots are $\pm i/n!$ and there are no other real solutions. This is exactly why the problem says n is even.
3. (drill) With n even, compute $p(0) = a_0$ without solving any linear system. *Answer:* $q(x) = \prod_{k=1}^{n}(x^2 - k^2) \cdot \left(x^2 - (n!)^{-2}\right)$, and $[x^{2n}]q = -a_0$. Writing $u = x^2$, the coefficient of u^n in $\prod_{k=1}^{n}(u - k^2) \cdot (u - (n!)^{-2})$ is minus the sum of the roots in u, so $a_0 = \sum_{k=1}^{n} k^2 + \frac{1}{(n!)^2} = \frac{n(n+1)(2n+1)}{6} + \frac{1}{(n!)^2}$. For $n = 2$ this is $5 + \frac{1}{4} = \frac{21}{4}$, matching drill 1.

3.3 A3. Nothing in the plane turns faster than one radian

Determine the smallest positive real number r such that there exist differentiable functions $f\colon \mathbb{R} \to \mathbb{R}$ and $g\colon \mathbb{R} \to \mathbb{R}$ satisfying

(a) $f(0) > 0$,

(b) $g(0) = 0$,

(c) $|f'(x)| \leq |g(x)|$ *for all* x,

(d) $|g'(x)| \leq |f(x)|$ *for all* x, *and*

(e) $f(r) = 0$.

Read it out loud

Two real functions, coupled so that each one's growth rate is controlled by the other one's size, started at a point where the first is positive and the second is zero, and you are asked how soon the first can vanish. Read the pair as a single object and the problem changes character: put $w(x) = (f(x), g(x))$, a point moving in the plane. Condition (c) and condition (d) together say

$$|w'(x)|^2 = f'(x)^2 + g'(x)^2 \leq g(x)^2 + f(x)^2 = |w(x)|^2,$$

that is, the speed of the moving point never exceeds its distance from the origin. Conditions (a) and (b) say the point starts on the positive horizontal axis, and condition (e) says that at time r it is on the vertical axis. So the question is: how quickly can a plane curve get from one axis to the other if its speed is bounded by its radius?

Fields wired in: differential inequalities (Gronwall and integrating factors), plane curves in polar coordinates, and the comparison theory of second order oscillation, which is the grown-up name for what is happening here. The knowledge base is three items: the equality case $f' = -g$, $g' = f$ is uniform rotation; for a curve avoiding the origin the velocity splits as $|w'|^2 = \rho'^2 + \rho^2(\theta')^2$ in polar coordinates; and a bound on a derivative plus a starting value bounds the function, by the mean value theorem.

The first useful cue is the perfect symmetry of (c) and (d) in f and g, together with the absolute values. Absolute values destroy all sign information, so nothing is being said about direction; only about magnitude. The only thing a magnitude bound can control is speed. Within thirty seconds you should have written $f = \cos$, $g = \sin$, which satisfies (c) and (d) with equality and gives $f(\pi/2) = 0$, and next to it the sentence "so $r \leq \pi/2$, and the whole problem is the lower bound". Then you should have written $|w'| \leq |w|$, because the moment the two conditions are added in squares, the mixed nature of the coupling disappears and a single geometric statement remains.

The last cue is the shape of the answer to expect. Speed bounded by radius is a scale-invariant hypothesis: if (f, g) works then so does (cf, cg). So the answer cannot involve any length, and it cannot involve $f(0)$. It must be a pure angle. The quarter turn from one axis to the other is $\pi/2$, and the equality case turns at exactly one radian per unit time.

Approaches, ranked worst to best

1. **Produce the example and stop.** *Cue:* "determine the smallest r". *Circuit:* exhibit, then assert minimality. (Writing $f = \cos$, $g = \sin$ and asserting that $\pi/2$ is optimal is worth almost nothing: the entire content of the problem is that no smaller r is possible. On the Putnam ten point scale this is one or two points. Notice the shape of the question: "smallest such that there exist" always splits into a construction and a bound, and the bound is where the marks are.)

2. **Bound the amplitude and hope.** *Cue:* the coupled inequalities look like Gronwall. *Circuit:* differentiate $f^2 + g^2$. (Set $k = f^2 + g^2$; then $|k'| \leq 4|fg| \leq 2k$, so $k(0)e^{-2x} \leq k(x) \leq k(0)e^{2x}$.

This is true, useful, and by itself powerless: it proves the pair never reaches the origin, but exponential envelopes contain no information about angles, and the answer is an angle. Rank it as a necessary lemma that is not a solution.)

3. **Iterate the integral form.** *Cue:* the fundamental theorem of calculus turns derivative bounds into integral bounds. *Circuit:* Picard iteration and comparison with cos. (From $|f'(x)| \le |g(x)| \le \int_0^x |g'| \le \int_0^x |f|$ one gets $f'(x) + F(x) \ge 0$ where $F(x) = \int_0^x f$. Multiplying by $\cos x$, integrating, then multiplying by $\sec^2 y$ and integrating again produces $F(r)\sin^2 r \ge F(r)$, which is impossible for $0 < r < \pi/2$. This is the published second solution and it is fully rigorous. It ranks below the angle argument because the two integrating factors $\cos x$ and $\sec^2 y$ are pulled from the answer rather than from the structure: you can only guess them once you already believe the answer is $\pi/2$. It also costs three integrations instead of one differentiation.)

4. **Polar angle: bound the angular speed.** *Cue:* speed bounded by radius, start on one axis, finish on another. *Circuit:* in polar coordinates a bound of speed by radius is exactly a bound of angular speed by one. (The ideal route. The hypothesis says the point cannot turn faster than one radian per unit time; the conclusion demands a quarter turn; so at least $\pi/2$ units of time are needed. Implemented with $\theta = \arctan(g/f)$ up to the first zero of f, it is half a page and every line is forced by the geometry.)

The ideal solution

The answer is $\boxed{r = \dfrac{\pi}{2}}$.

Attainment. Take $f(x) = \cos x$ and $g(x) = \sin x$. Then $f(0) = 1 > 0$, $g(0) = 0$, $|f'| = |\sin| = |g|$, $|g'| = |\cos| = |f|$, and $f(\pi/2) = 0$. So $r = \pi/2$ is achieved.

No smaller r works. Suppose, for contradiction, that f and g are differentiable and satisfy (a) to (e) for some r with $0 < r < \pi/2$.

Step 1 (cut at the first zero). The set $Z = \{x \in [0, r] : f(x) = 0\}$ is nonempty, since $r \in Z$, and closed and bounded, since f is continuous; hence it has a least element ρ. As $f(0) > 0$ we have $\rho > 0$, and by minimality $f(x) \ne 0$ for $x \in [0, \rho)$. Note $0 < \rho \le r < \pi/2$. Replacing r by ρ, we may and do assume from now on that $f(x) \ne 0$ on $[0, r)$ and $f(r) = 0$.

Step 2 (the pair never reaches the origin). Put $k = f^2 + g^2$, which is differentiable. Then

$$|k'| = |2ff' + 2gg'| \le 2|f||g| + 2|g||f| = 4|f||g| \le 2(f^2 + g^2) = 2k,$$

the last step by $2|f||g| \le f^2 + g^2$. In particular $k' + 2k \ge 0$, so $\big(e^{2x}k(x)\big)' = e^{2x}\big(k'(x) + 2k(x)\big) \ge 0$, so $e^{2x}k(x)$ is non-decreasing on $[0, \infty)$ and therefore

$$k(x) \ge e^{-2x}k(0) = e^{-2x}f(0)^2 > 0 \qquad (x \ge 0).$$

At $x = r$ this gives $g(r)^2 = k(r) > 0$, so $g(r) \ne 0$.

Step 3 (angular speed at most one). On $[0, r)$ the function f does not vanish, so

$$\theta(x) := \arctan\big(g(x)/f(x)\big)$$

is differentiable there, with $\theta(0) = \arctan(0) = 0$ and

$$\theta'(x) = \frac{f(x)g'(x) - g(x)f'(x)}{f(x)^2 + g(x)^2}.$$

Using (c) and (d),

$$|\theta'(x)| \le \frac{|f||g'| + |g||f'|}{f^2 + g^2} \le \frac{|f|\,|f| + |g|\,|g|}{f^2 + g^2} = 1.$$

By the mean value theorem, for each $x \in [0, r)$ there is $c \in (0, x)$ with $|\theta(x)| = |\theta(x) - \theta(0)| = |\theta'(c)|\, x \le x < r$.

Step 4 (contradiction). Since $|\theta(x)| < r < \pi/2$ for all $x \in [0, r)$ and tan is increasing on $(-\pi/2, \pi/2)$,

$$\left|\frac{g(x)}{f(x)}\right| = |\tan\theta(x)| \le \tan r \qquad (x \in [0, r)),$$

a fixed finite bound. But f and g are continuous with $f(r) = 0$, $g(r) \neq 0$ and $f(x) \neq 0$ on $[0, r)$, so $|g(x)/f(x)| \to \infty$ as $x \to r^-$. These two statements are incompatible, and the contradiction shows that no $r < \pi/2$ admits such a pair.

Hence the smallest possible r is $\pi/2$.

A remark on Step 2. The published solution divides by k and bounds the derivative of $\log k$, which presumes what is being proved, namely that k does not vanish, and then repairs the gap by a continuity argument. The integrating factor e^{2x} avoids the issue: $k' + 2k \ge 0$ is a statement about a differentiable function that is valid whether or not k vanishes, and it delivers a positive lower bound directly. Prefer it in the arena, since it removes an edge case rather than patching one.

Layer 1: WHAT

Block 1. Take the equality case seriously: $f' = -g$, $g' = f$ is uniform rotation, so $(\cos, \sin)$ is the candidate and $r \le \pi/2$.

Block 2. Add the two hypotheses in squares: $f'^2 + g'^2 \le f^2 + g^2$, that is, the plane curve $w = (f, g)$ has speed at most its radius.

Block 3. Replace r by the first zero of f, so that f is nonzero on $[0, r)$ and the angle is defined by a single branch of arctan.

Block 4. Show the curve avoids the origin, by the differential inequality $k' + 2k \ge 0$ and the integrating factor e^{2x}. Deduce $g(r) \neq 0$.

Block 5. Compute the angular speed and bound it by one.

Block 6. The angle starts at 0 and, by continuity of the picture, is forced to $\pm\pi/2$ at $x = r$; travelling $\pi/2$ radians at angular speed at most one takes time at least $\pi/2$, so $r < \pi/2$ is impossible.

Juxtaposition. The nominal route stays inside the inequalities: substitute one into the other, integrate, produce exponential envelopes, and then wonder why no exponential bound ever produces a π. The ideal route leaves the algebra and names the geometric object the hypotheses describe. The bifurcation point is the line right after you write down cos and sin: do you start bounding $|f|$ and $|g|$ separately (zombie) or do you write $w = (f, g)$ and ask what the hypotheses say about w (ideal)? Everything downstream is decided there, because the answer $\pi/2$ is an angle and no argument that never mentions an angle can produce it.

Layer 2: HOW

Block 1. Cue. Two inequalities that become equalities for a familiar pair; the phrase "smallest r such that there exist". **Why natural.** An extremal problem with an inequality hypothesis is solved by its equality case, so the first thing to do is to write down the equality case as a differential system: $f' = \pm g$, $g' = \pm f$. The sign choice $f' = -g$, $g' = f$ gives $f'' = -f$, the rotation, and its first zero is at $\pi/2$. Constructing the extremal object converts half the problem into a verification and, more importantly, tells you the number you must prove is a lower bound. **Link to the next block.** Now you know the target is $\pi/2$; a bare number cannot come out of algebra alone, so you look for what in the problem measures a quarter turn.

Block 2. Cue. Absolute values on all four quantities, and perfect symmetry between f and g. **Why natural.** Absolute values keep magnitudes and discard directions, and a hypothesis about magnitudes of derivatives is a hypothesis about speed. Adding the squares of (c) and (d) is the

only way to combine them without choosing signs, and it produces $|w'| \le |w|$, a single statement about one object. It is worth repeating: when two hypotheses are symmetric under swapping the objects, combine them into one statement about the pair rather than reasoning about each separately. **Link to the next block.** A statement about speed and radius is a statement in polar coordinates, so decompose the velocity.

Block 3. **Cue.** The conclusion is about the first time f vanishes, and the angle formula $\arctan(g/f)$ needs $f \neq 0$. **Why natural.** If f has an earlier zero, that earlier zero is also an admissible r, so passing to it costs nothing and buys the non-vanishing you need. This is the standard "replace the given object by the extremal one" move: minimal counterexample, first zero, largest interval. The set of zeros is closed and bounded, so a least element exists; that sentence is the entire justification and it must be written, because "let r be the first zero" without it is an assumption. **Link to the next block.** With $f \neq 0$ on $[0, r)$, a single branch of arctan works and no lifting theory is needed.

Block 4. **Cue.** The angle is undefined at the origin, so you must rule out $(f, g) = (0, 0)$. **Why natural.** The quantity $k = f^2 + g^2$ is the natural test, and its derivative is controlled by the same two hypotheses through $2|f||g| \le f^2 + g^2$. Once $|k'| \le 2k$, the one-sided version $k' + 2k \ge 0$ is what you need, and multiplying by the integrating factor e^{2x} turns it into the monotonicity of a single function. That is the general recipe for every differential inequality: never divide, always multiply by the integrating factor. **Link to the next block.** The pair is nonzero at $x = r$ where f vanishes, so $g(r) \neq 0$: the curve arrives on the vertical axis at a genuine point, not at the origin. That is what makes the angle blow up to a right angle instead of dribbling out.

Block 5. **Cue.** A quotient g/f whose derivative you are about to take, with $f^2 + g^2$ in the denominator. **Why natural.** The derivative of $\arctan(g/f)$ is $(fg' - gf')/(f^2 + g^2)$, and the numerator is exactly the cross product of position and velocity, which is what measures rotation. Bounding it with (c) and (d) gives $|f||f| + |g||g|$ on top, which cancels the denominator exactly. The cancellation is not a coincidence: it is the statement $|w'| \le |w|$ read in polar coordinates, since $|w'|^2 = \rho'^2 + \rho^2\theta'^2 \ge \rho^2\theta'^2$ forces $|\theta'| \le |w'|/\rho \le 1$. **Link to the next block.** Angular speed at most one plus the mean value theorem gives $|\theta(x)| \le x$: the total turn by time x is at most x radians.

Block 6. **Cue.** $f(r) = 0$ with $g(r) \neq 0$: the curve is on the vertical axis at time r. **Why natural.** Being on the vertical axis is being at angle $\pm\pi/2$, and the total turn available in time $r < \pi/2$ is less than $\pi/2$ radians. Written without limits of angles, the same fact is that $|g/f|$ stays bounded by $\tan r$ while it must blow up: that is the cleanest way to state the contradiction, since it avoids discussing the limit of θ at the endpoint. **Link to the next block.** Contradiction; the minimum is $\pi/2$.

Layer 3: WHY

The mathematical truth beneath the route is the polar decomposition of velocity. For a differentiable plane curve avoiding the origin, $w = \rho(\cos\theta, \sin\theta)$ with $|w'|^2 = \rho'^2 + \rho^2(\theta')^2$. A hypothesis bounding $|w'|$ by ρ therefore says two things at once: the radius can grow or decay at rate at most ρ, which is exponential and harmless, and the angle can change at rate at most 1, which is the only rigid constraint in the problem. The conclusion $f(r) = 0$ is purely angular. So the amplitude is a red herring by design, and every route that only tracks amplitude must fail. That is the real reason the answer is $\pi/2$ and not something involving $f(0)$ or e.

The discernment mechanism is scale invariance. Test the hypotheses against the substitution $(f, g) \mapsto (cf, cg)$: they are invariant, and so is the conclusion. Therefore the answer is a function of nothing at all, a pure number, and it must be produced by an invariant quantity. The invariants

of a plane curve under scaling are angles, so look for the angle. Train the reflex like this: for every extremal problem, list the transformations that preserve the hypotheses, and only then choose a quantity to track, insisting that it be invariant under all of them.

There is a second, deeper reading. Differentiating the extremal system gives $f'' = -f$, and the general problem "how far apart can the zeros of $y'' + q(x)y = 0$ be when $0 < q \leq 1$" is Sturm comparison. The standard proof of Sturm comparison is the Prüfer substitution: write $y = \rho \sin\theta$ and $y' = \rho\cos\theta$, and compute $\theta' = \cos^2\theta + q\sin^2\theta \leq 1$; consecutive zeros of y are consecutive multiples of π for θ, so they are at least π apart. That is exactly Step 3 of the solution, with the pair (y', y) playing the role of (f, g). In other words this problem is a quarter of the Sturm comparison theorem, dressed as an inequality about two unknown functions. Recognising the dressing is what makes the route obvious rather than inspired.

What the examiners nudged toward and how: they used absolute values so that no sign information survives, leaving only speed; they made the hypotheses symmetric so that adding the squares is the natural combination; they placed the start exactly on one axis, $g(0) = 0$, so that the required turn is a full quarter and not less; and they demanded $f(r) = 0$ rather than $f(r) = g(r) = 0$, since the latter is impossible by Step 2 and would have given the game away.

Revolving concepts

Polar coordinates for a moving point. Definition: for a differentiable $w\colon I \to \mathbb{R}^2 \setminus \{0\}$, write $\rho = |w|$ and let θ be a continuous choice of argument; then ρ is differentiable, a differentiable θ exists locally, and $|w'|^2 = \rho'^2 + \rho^2(\theta')^2$. Orbiting facts: the cross product $fg' - gf'$ equals $\rho^2\theta'$ and is the signed area rate swept out (Kepler's second law is the statement that it is constant); a local branch is given by $\arctan(g/f)$ where $f \neq 0$ and by $\operatorname{arccot}(f/g)$ where $g \neq 0$, and the two agree up to a constant on overlaps, which is the elementary form of the lifting theorem for the covering $\mathbb{R} \to S^1$. See Book 1, field: Geometry, topic: plane curves in polar form.

Differential inequalities and Gronwall. Statement: if u is differentiable and $u' \leq au + b$ on an interval, then multiplying by e^{-ax} makes $\left(e^{-ax}u\right)' \leq be^{-ax}$ and integration gives the explicit bound; the one-sided reverse version with $u' \geq -au$ gives $u(x) \geq u(0)e^{-ax}$. The rule to install: never divide by u to take log, always multiply by the integrating factor, because the integrating factor argument never needs $u \neq 0$. See Book 1, field: Real analysis, topic: Gronwall and integrating factors.

Sturm comparison and the Prüfer angle. Statement: if $y'' + q(x)y = 0$ with $0 < q(x) \leq Q$ then consecutive zeros of a nontrivial solution are at least $\pi/\sqrt{Q}$ apart; if $q \geq Q$ they are at most $\pi/\sqrt{Q}$ apart. Proof mechanism: the Prüfer substitution $y = \rho\sin\theta$, $y' = \rho\cos\theta$ turns the second order equation into the first order angle equation $\theta' = \cos^2\theta + q\sin^2\theta$, and zeros of y are the times when θ crosses a multiple of π. This problem is the case $Q = 1$ over a quarter period. See Book 1, field: Real analysis, topic: oscillation and comparison theorems.

The recursion generalised. The integral route is Picard iteration, and the iteration is a genuine recursion worth stating in general: define $u_0 = c$ and $u_{m+1}(x) = \int_0^x u_m(t)\,dt$; then $u_m(x) = cx^m/m!$ and $\sum_m u_m = ce^x$. Feeding $|f'| \leq |g|$ and $|g'| \leq |f|$ into each other repeatedly produces exactly these terms with alternating signs, which is why the extremal pair is $(\cos, \sin)$ and not some exotic function: the alternation comes from the two applications needed to return to f, giving $f'' = -f$. The general lesson is that iterating a pair of first order bounds converges to the solution of the corresponding second order equation, and comparison with that solution is where sharp constants such as $\pi/2$ come from. See Book 1, field: Sequences and recurrences, topic: Picard iteration and exponential bounds.

Extremal problems of the form "smallest r such that there exist". Definition of the shape: the answer set is an interval $[r_0, \infty)$ or (r_0, ∞), and a complete solution has two halves, a construction achieving r_0 and a proof that nothing smaller works. Here the construction is one line and the bound is the problem; recognise the split before starting and allocate your ink accordingly. Note also that every $r \geq \pi/2$ is achievable, by $f(x) = \cos(\lambda x)$ and $g(x) = \sin(\lambda x)$ with $\lambda = \pi/(2r) \leq 1$,

so the admissible set really is $[\pi/2, \infty)$. See Book 1, field: Inequalities, topic: extremal existence problems.

Circuit Bank

- **WHEN** two functions satisfy coupled bounds of the form $|f'| \le |g|$ and $|g'| \le |f|$ **DO** write $w = (f, g)$, add the squares to get $|w'| \le |w|$, and read it as speed at most radius **BECAUSE** because absolute values carry only magnitude, and the only invariant meaning of a magnitude bound on a derivative is a bound on speed, which in polar coordinates is a bound on angular speed by one
- **WHEN** an extremal problem has an inequality hypothesis with a visible equality case **DO** solve the equality case first as a differential system and let it name the answer **BECAUSE** because the extremal trajectory is the unique candidate for optimality, and knowing the target number tells you which invariant you must bound
- **WHEN** you need a pair (f, g) never to vanish simultaneously **DO** bound $|(f^2 + g^2)'|$ by a multiple of $f^2 + g^2$ and multiply by the integrating factor **BECAUSE** because the integrating factor turns the inequality into monotonicity of one function and never requires dividing by a quantity you have not yet shown to be nonzero
- **WHEN** an angle argument needs a branch of arctan **DO** pass to the first zero of the denominator and work on the half-open interval before it **BECAUSE** because the first zero exists (the zero set is closed and bounded), it is still an admissible endpoint, and on the interval before it a single branch is differentiable, so no lifting theorem is needed
- **WHEN** the hypotheses are invariant under scaling the unknowns **DO** conclude the answer is a pure number and hunt for a scale-invariant quantity **BECAUSE** because a scale-invariant problem cannot have an answer depending on any length, and in the plane the scale-invariant quantities are angles

Backtesting

1. First useful cue: the symmetric pair of absolute-value bounds, which becomes $f'^2 + g'^2 \le f^2 + g^2$, together with a start on one axis and a finish on the other.
2. Method the expression suggested: build the extremal pair $(\cos, \sin)$ from the equality case to get $r \le \pi/2$, then bound the angular speed of the plane curve (f, g) by one and observe that a quarter turn is required.
3. Where you would hesitate, and the thought to reinforce: at the definition of the angle, because $\arctan(g/f)$ needs $f \neq 0$ and the origin must be excluded. Reinforce these two sentences: pass to the first zero of f, and control $f^2 + g^2$ from below with an integrating factor.
4. The trap the question sets: producing the example and calling the problem finished. The construction is worth little; the lower bound is the problem. A second, smaller trap is asserting that $g(r) \neq 0$ without proof, which is exactly the step that makes the quotient blow up.
5. What makes you recognise it faster next time: any hypothesis of the shape "derivative of each bounded by the other" is a rotation speed limit; any question about the first zero under such a hypothesis is a quarter or half period question, and the answer will be $\pi/2$ or π times a scale factor.
6. The reusable decision rule: pair the functions into a vector, convert the magnitude hypothesis into an angular speed bound, and measure the required rotation.

Mirror drills

1. (drill) Suppose f, g are differentiable with $|f'| \le |g|$, $|g'| \le |f|$ and $f(0) = g(0) = 0$. Show $f \equiv g \equiv 0$. *Answer:* with $k = f^2 + g^2$ we have $k' \le 2k$, so $\left(e^{-2x}k\right)' \le 0$ and $k(x) \le k(0)e^{2x} = 0$ for $x \ge 0$; the same argument in the reversed variable $x \mapsto -x$ handles $x \le 0$. This is the uniqueness half of the same circuit.

2. (drill) Same hypotheses (c) and (d), but now $f(0) = g(0) > 0$. What is the smallest r with $f(r) = 0$? *Answer:* $\pi/4$. The starting angle is $\pi/4$ and the nearest axis crossing is a further $\pi/4$ of turn; angular speed at most one gives $r \ge \pi/4$, and $f(x) = \cos(x + \pi/4)$, $g(x) = \sin(x + \pi/4)$ attains it.

3. (drill) Let y be a nontrivial solution of $y'' + q(x)y = 0$ with $0 < q(x) \le 1$ and $y(0) = 0$. Show that the next zero of y is at least π away. *Answer:* the pair (y', y) never vanishes at the same point (uniqueness for the linear equation), so set $\theta = \arctan(y/y')$; then $\theta' = \left(y'^2 + qy^2\right)/\left(y^2 + y'^2\right) = \cos^2\theta + q\sin^2\theta \le 1$, and zeros of y are the times θ hits a multiple of π, so consecutive zeros are at least π apart. This is A3 with the training wheels removed.

3.4 A4. Icosahedral vectors generate a dense subgroup

Let $v_1, \ldots, v_{12}$ be unit vectors in $\mathbb{R}^3$ from the origin to the vertices of a regular icosahedron. Show that for every vector $v \in \mathbb{R}^3$ and every $\varepsilon > 0$, there exist integers $a_1, \ldots, a_{12}$ such that $\|a_1 v_1 + \cdots + a_{12} v_{12} - v\| < \varepsilon$.

Read it out loud

Twelve fixed vectors; integer coefficients, positive and negative and zero; and the demand that the resulting set comes arbitrarily close to every point of space. The set of all such integer combinations is precisely the subgroup of $(\mathbb{R}^3, +)$ generated by $v_1, \ldots, v_{12}$, so the problem, stripped of its epsilon, reads: prove that the subgroup generated by the twelve vertex vectors of a regular icosahedron is dense in $\mathbb{R}^3$. Say it that way and you have already discarded the analysis and turned the question into algebra.

Fields wired in: the structure of subgroups of $(\mathbb{R}, +)$, Diophantine approximation in its simplest form (a subgroup generated by 1 and an irrational number is dense), and the coordinate geometry of the icosahedron. The knowledge base is exactly three items: every subgroup of $\mathbb{R}$ is either $c\mathbb{Z}$ or dense; the golden ratio $\phi = \frac{1+\sqrt{5}}{2}$ is irrational and satisfies $\phi^2 = \phi + 1$; and the twelve vertices of a regular icosahedron can be placed at the cyclic permutations of $(\pm 1, \pm\phi, 0)$.

The first useful cue is the word "integers" next to "for every ε". That pairing is the signature of a density-of-a-subgroup question, and it should immediately raise the counter-question: when would this be false? Run the same statement for the eight vertices of a cube, $(\pm 1, \pm 1, \pm 1)/\sqrt{3}$. Every integer combination lands in $\frac{1}{\sqrt{3}}\mathbb{Z}^3$, which is discrete, so the cube version is false. So the statement is not about "twelve vectors spanning space"; something specific to the icosahedron is doing the work. Within thirty seconds you should have written the cube counterexample and the question it forces: what does the icosahedron have that the cube does not?

The answer is the golden ratio, and behind the golden ratio is the five-fold symmetry. A lattice cannot have a five-fold rotational symmetry (this is the crystallographic restriction), so a solid with five-fold symmetry cannot have its vertices sitting in a discrete subgroup that its own symmetry group preserves. The icosahedron is therefore forced to be dense, and the coordinates make that visible: they contain the irrational number ϕ in an essential way, and $\mathbb{Z} + \phi\mathbb{Z}$ is dense in $\mathbb{R}$.

Approaches, ranked worst to best

1. **Chase the approximation directly.** *Cue:* "for every v and every ε". *Circuit:* do what the epsilon asks. (Trying to build the integers a_i for a given v and ε by hand, coordinate by coordinate, is hopeless: there is no formula, and the choice of a_i is wildly discontinuous in v. The epsilon is a disguise, not an instruction. Any solution that never says the word "subgroup" is fighting the problem.)

2. **Descent by differences.** *Cue:* differences of vertices are in the group and some of them are short. *Circuit:* produce arbitrarily short elements, then translate them around. (You can take a vertex difference, apply the icosahedral rotations to it, take differences again, and try to prove the lengths tend to zero, a three dimensional continued fraction. It can be made to work, but controlling a descent in three dimensions costs pages and the required estimates are exactly the sort of thing that goes wrong under time pressure.)

3. **Closed subgroups and the trace obstruction.** *Cue:* the icosahedral rotation group preserves the generated subgroup. *Circuit:* a lattice invariant under an order five rotation cannot exist. (The closure of the subgroup is a closed subgroup of $\mathbb{R}^3$, hence of the form $V \oplus L$ with V a linear subspace and L discrete; the rotation group preserves V; the standard three dimensional representation of the icosahedral group is irreducible, so V is trivial or everything; and if

V were trivial the group would be a rank three lattice invariant under a rotation of order 5, forcing the integer matrix of that rotation to have integer trace, while the true trace is $1 + 2\cos(2\pi/5) = \phi$. Beautiful, coordinate-free and structurally the true reason, but it needs the structure theorem for closed subgroups and a representation-theoretic input. Worth knowing; too expensive as a first line of attack.)

4. **Coordinates plus the subgroup dichotomy.** *Cue:* the icosahedron has standard coordinates built from the golden ratio. *Circuit:* $\mathbb{Z} + \phi\mathbb{Z}$ is dense because ϕ is irrational. (The ideal route. Choose the standard coordinates, add and subtract two vertices to isolate $(2,0,0)$ and $(2\phi,0,0)$ and their cyclic images, conclude that the group contains $H \times H \times H$ with $H = 2\mathbb{Z} + 2\phi\mathbb{Z}$, then quote the dichotomy for subgroups of $\mathbb{R}$. Four lines once the coordinates are on the page.)

The ideal solution

Write $\Lambda = \{a_1v_1 + \cdots + a_{12}v_{12} : a_i \in \mathbb{Z}\}$, which is the subgroup of $(\mathbb{R}^3, +)$ generated by $v_1, \ldots, v_{12}$. The assertion to be proved is exactly that Λ is dense in $\mathbb{R}^3$.

Reduction to standard coordinates. All twelve vertices are at distance 1 from the origin, so the origin is the centre of the sphere circumscribing the icosahedron; since a sphere through the vertices is unique, the origin is the centre of the icosahedron. Hence the twelve vectors are obtained from the standard vertex set by a rotation together with a positive scaling. If R is an orthogonal map and $c > 0$, then Λ is dense if and only if $cR(\Lambda)$ is dense, because $x \mapsto cRx$ is a homeomorphism of $\mathbb{R}^3$ and a group automorphism. We may therefore assume that the twelve vertices are the cyclic permutations of

$$(\pm 1, \pm\phi, 0), \qquad \phi = \frac{1+\sqrt{5}}{2},$$

that is, the four vectors $(\pm 1, \pm\phi, 0)$, the four vectors $(0, \pm 1, \pm\phi)$ and the four vectors $(\pm\phi, 0, \pm 1)$. (That these twelve points are the vertices of a regular icosahedron is the standard construction from three mutually perpendicular golden rectangles; the verification is that all twelve have the same length $\sqrt{1+\phi^2}$ and that each one has exactly five others at distance 2, which uses $\phi^2 = \phi + 1$. For instance the five neighbours of $(1,\phi,0)$ are $(-1,\phi,0)$, $(0,\pm 1,\phi)$ and $(\phi,0,\pm 1)$, and $\|(1,\phi,0) - (0,1,\phi)\|^2 = 1 + (\phi-1)^2 + \phi^2 = 2(\phi^2 - \phi + 1) = 4$.)

Step 1: the group contains an explicit product. Adding and subtracting pairs of vertices,

$$\begin{aligned}
(1,\phi,0) + (1,-\phi,0) &= (2,0,0), & (1,\phi,0) - (1,-\phi,0) &= (0,2\phi,0),\\
(0,1,\phi) + (0,1,-\phi) &= (0,2,0), & (0,1,\phi) - (0,1,-\phi) &= (0,0,2\phi),\\
(\phi,0,1) + (\phi,0,-1) &= (2\phi,0,0), & (\phi,0,1) - (\phi,0,-1) &= (0,0,2).
\end{aligned}$$

So Λ contains the six vectors $(2,0,0), (2\phi,0,0), (0,2,0), (0,2\phi,0), (0,0,2), (0,0,2\phi)$, and therefore contains $H \times H \times H$, where

$$H := 2\mathbb{Z} + 2\phi\mathbb{Z} \leq (\mathbb{R}, +).$$

Step 2: the dichotomy for subgroups of $\mathbb{R}$.

Lemma 3.4.1. *Let H be a subgroup of $(\mathbb{R}, +)$ with $H \neq \{0\}$. Then either $H = c\mathbb{Z}$ for some $c > 0$, or H is dense in $\mathbb{R}$.*

Proof. Let $c = \inf\{h \in H : h > 0\}$, which is well defined since H contains a nonzero element and hence a positive one.

If $c = 0$, then for every $\varepsilon > 0$ there is $h \in H$ with $0 < h < \varepsilon$, and every real number is within $h < \varepsilon$ of an integer multiple of h, so H is dense.

If $c > 0$, first note $c \in H$. Otherwise choose $h_1 \in H$ with $c < h_1 < 2c$ and then $h_2 \in H$ with $c < h_2 < h_1$; then $h_1 - h_2 \in H$ and $0 < h_1 - h_2 < h_1 - c < c$, contradicting the definition of c. Now for any $h \in H$ the number $h - c\lfloor h/c \rfloor$ lies in $H \cap [0, c)$, hence is 0, so $H = c\mathbb{Z}$. □

Step 3: H is dense. Suppose $H = 2\mathbb{Z} + 2\phi\mathbb{Z}$ were equal to $c\mathbb{Z}$. Then $2 = mc$ and $2\phi = kc$ for some nonzero integers m, k, whence $\phi = k/m$ is rational. But $\phi = \frac{1+\sqrt{5}}{2}$ and $\sqrt{5}$ is irrational, so ϕ is irrational. Contradiction; by the lemma, H is dense in $\mathbb{R}$.

Step 4: conclusion. Let $v = (x, y, z) \in \mathbb{R}^3$ and $\varepsilon > 0$. By Step 3 choose $h_1, h_2, h_3 \in H$ with

$$|h_1 - x| < \frac{\varepsilon}{\sqrt{3}}, \qquad |h_2 - y| < \frac{\varepsilon}{\sqrt{3}}, \qquad |h_3 - z| < \frac{\varepsilon}{\sqrt{3}}.$$

Then $(h_1, h_2, h_3) \in H \times H \times H \subseteq \Lambda$ and $\|(h_1, h_2, h_3) - v\| < \varepsilon$. Since every element of Λ is of the form $a_1 v_1 + \cdots + a_{12} v_{12}$ with $a_i \in \mathbb{Z}$, this is exactly the required statement. ■

Layer 1: WHAT

Block 1. Translate the epsilon statement into "the subgroup generated by the twelve vectors is dense".

Block 2. Test the statement against the cube, where it is false, and identify that irrationality of the coordinate ratios, not spanning, is the active ingredient.

Block 3. Put the icosahedron in standard coordinates, which is legitimate because density is invariant under rotation and scaling.

Block 4. Add and subtract vertex pairs to isolate the six vectors $(2, 0, 0)$, $(2\phi, 0, 0)$ and their cyclic images, so that the group contains H^3 with $H = 2\mathbb{Z} + 2\phi\mathbb{Z}$.

Block 5. Prove or quote the dichotomy: a subgroup of $\mathbb{R}$ is cyclic or dense, and rule out cyclic using the irrationality of ϕ.

Block 6. Assemble: dense in each coordinate gives dense in the product.

Juxtaposition. The nominal route reads "for every v and every ε" and starts constructing coefficients, or reaches for a compactness or equidistribution theorem. The ideal route deletes the analysis in the first line and never returns to it: the only analytic content in the whole solution is the one-line lemma about subgroups of $\mathbb{R}$. The bifurcation point is the sentence you write immediately after reading the problem: "let Λ be the subgroup generated by the v_i; we must show Λ is dense" (ideal) versus "let v be given and $\varepsilon > 0$; we construct a_i" (zombie).

Layer 2: HOW

Block 1. Cue. Integer coefficients, all twelve of them free, with both signs allowed, and an arbitrarily small error. **Why natural.** A set closed under addition and negation is a group, and "comes arbitrarily close to every point" is the definition of dense. So the hypothesis and the conclusion are both statements about one object, the generated subgroup, and naming it removes both quantifiers from view. It is worth repeating: an epsilon in a problem about integer combinations is almost never an analysis cue, it is the definition of density wearing a disguise. **Link to the next block.** Once the object is a subgroup, the relevant classification is the classification of subgroups, so ask which subgroups of $\mathbb{R}^3$ are not dense.

Block 2. Cue. The statement would be false for other polyhedra; nothing so far has used any property of the icosahedron. **Why natural.** A subgroup that is not dense is, in the closed case, a lattice, and lattices are exactly what integer coordinates produce. The cube has vertex coordinates that are all equal up to sign, so its group sits inside a scaled copy of $\mathbb{Z}^3$ and is discrete. Running that test tells you what to look for in the icosahedron: a ratio of coordinates that is irrational. This is the single most useful habit in a "prove that" problem, namely to find the nearest false statement and see which hypothesis kills it. **Link to the next block.** The irrational ratio in the icosahedron is ϕ, so put the icosahedron in coordinates where ϕ is visible.

Block 3. **Cue.** "Regular icosahedron" with no coordinates given, and a conclusion invariant under rotations and scalings. **Why natural.** Density is preserved by any invertible linear map, in particular by rotations and by positive scalings, since such maps are homeomorphisms and group automorphisms. So you may normalise, and the normalisation to use is the standard golden rectangle construction, in which each vertex has one coordinate zero and the other two equal to 1 and ϕ up to sign. Note that the problem already fixes the centre at the origin for you: all twelve vectors are unit vectors, so the origin is equidistant from all twelve vertices, and the circumscribed sphere is unique. **Link to the next block.** With explicit coordinates, the group is explicit, and you can start producing convenient elements.

Block 4. **Cue.** Vertices come in $\pm$ pairs within each coordinate plane: $(1, \phi, 0)$ and $(1, -\phi, 0)$ differ only in one sign. **Why natural.** Adding a vector to its sign-flipped partner kills one coordinate and doubles the other; subtracting does the reverse. That is the cheapest way to extract axis-aligned elements from a symmetric generating set, and after doing it in all three cyclic planes you hold 2 and 2ϕ on each axis. Do not chase a minimal generating set or the exact group Λ; you only need a subgroup that is already dense, and a product of one dimensional groups is the easiest such object to handle. **Link to the next block.** The problem is now one dimensional: is $2\mathbb{Z} + 2\phi\mathbb{Z}$ dense in $\mathbb{R}$?

Block 5. **Cue.** A subgroup of $\mathbb{R}$ generated by two numbers with irrational ratio. **Why natural.** The infimum of the positive elements is the only possible generator, and the standard argument shows that either it is positive and attained, in which case the group is cyclic, or it is zero, in which case the group is dense. Ruling out the cyclic case is pure arithmetic: two generators of a cyclic group are integer multiples of the same c, so their ratio is rational. This is the elementary form of Kronecker's theorem and you should be able to write the lemma cold, in five lines. **Link to the next block.** Density in each coordinate gives density of the product.

Block 6. **Cue.** A product of dense subsets and a Euclidean norm. **Why natural.** Approximate each coordinate separately to within $\varepsilon/\sqrt{3}$ and the vector norm is below ε. This is the only place in the proof where the metric appears, and it is the only place it should appear. **Link to the next block.** The approximating point is an integer combination of the v_i by construction, so the required a_i exist.

Layer 3: WHY

The mathematical truth beneath this problem is the classification of closed subgroups: a closed subgroup of $\mathbb{R}^n$ is $V \oplus L$ with V a linear subspace and L a discrete lattice in a complement. Hence a finitely generated subgroup either is discrete or has dense directions, and there is nothing in between. So proving density is the same as ruling out discreteness, and discreteness for a group generated by a symmetric configuration is ruled out by symmetry alone. This is the crystallographic restriction: if a lattice L of rank n is invariant under a rotation σ of order m, then in a basis of L the matrix of σ has integer entries, so its trace is an integer; in $\mathbb{R}^3$ a rotation of order m has trace $1 + 2\cos(2\pi/m)$, so $2\cos(2\pi/m)$ must be an integer and $m \in \{1, 2, 3, 4, 6\}$. The icosahedral rotation group contains rotations of order 5, with trace $1 + 2\cos 72^\circ = 1 + (\phi - 1) = \phi$, which is irrational. Therefore no lattice can be invariant under the icosahedral group, the generated subgroup cannot be discrete, and since it spans, it is dense. The golden ratio in the coordinates is not a coincidence: it is the trace of the five-fold rotation, and it is irrational for exactly the reason the theorem says it must be.

The discernment mechanism is the false-neighbour test. Before proving a statement, find the nearest configuration for which it fails, and locate the hypothesis that separates them. Here the cube fails and the icosahedron succeeds, and the separating feature is five-fold symmetry, equivalently the appearance of ϕ. Once you have located the separating feature, the proof writes itself: use it. Train this by making yourself state, for every "show that" problem, one nearby false version.

There is a second, physical reading. A discrete group of translations is a crystal; a dense one, generated by finitely many vectors with irrational ratios, is a quasicrystal. The icosahedral vertex vectors generate a dense group precisely because icosahedral symmetry is incompatible with periodicity, which is why icosahedral quasicrystals exist and why five-fold diffraction patterns were considered impossible until they were observed. The Putnam problem is the two-line mathematical core of that story.

What the examiners nudged toward and how: they specified unit vectors, which silently centres the icosahedron at the origin and saves you from worrying about translations; they chose the icosahedron rather than any of the crystallographic solids, which is the entire content; and they phrased the conclusion with an epsilon, which is a small test of whether you can recognise density when it is written out in full.

Revolving concepts

Subgroups of $(\mathbb{R}, +)$. Statement: a nontrivial subgroup is either $c\mathbb{Z}$ for some $c > 0$ or is dense; the proof is the infimum argument given above. Orbiting facts: $\mathbb{Z} + \alpha\mathbb{Z}$ is dense if and only if α is irrational, which is Kronecker's theorem in one dimension and is equivalent to the equidistribution-free statement that the fractional parts $\{n\alpha\}$ are dense in $[0, 1)$; the pigeonhole proof of that is Dirichlet's approximation theorem, which gives infinitely many p/q with $|\alpha - p/q| < 1/q^2$. See Book 1, field: Number theory, topic: Diophantine approximation and dense subgroups.

Closed subgroups of $\mathbb{R}^n$ and lattices. Statement: every closed subgroup of $\mathbb{R}^n$ is $V \oplus L$, where V is a linear subspace and L is a lattice (a discrete subgroup) in a complementary subspace. Consequence used here: a finitely generated subgroup that spans and is not discrete has dense closure in the span of its non-discrete part; combined with irreducibility of the symmetry action, discreteness or density is the only alternative. See Book 1, field: Discrete structures and graphs, topic: lattices and closed subgroups.

The crystallographic restriction. Statement: a rotation of finite order m preserving a rank n lattice acts by an integer matrix in a lattice basis, so its trace is an integer; in the plane the trace is $2\cos(2\pi/m)$ and in three dimensions it is $1 + 2\cos(2\pi/m)$, forcing $m \in \{1, 2, 3, 4, 6\}$. Orbiting facts: this is why crystals have no five-fold axes, why the Penrose tiling is aperiodic, and why the icosahedron is the natural source of a dense vector group. See Book 1, field: Geometry, topic: symmetry groups and lattices.

The golden ratio and icosahedral coordinates. Definition: $\phi = \frac{1+\sqrt{5}}{2}$ is the positive root of $\phi^2 = \phi + 1$, so $\phi - 1 = 1/\phi$ and $2\cos 36^\circ = \phi$, $2\cos 72^\circ = \phi - 1$. Standard construction: the twelve points obtained as the cyclic permutations of $(\pm 1, \pm\phi, 0)$ are the vertices of a regular icosahedron; equivalently three mutually perpendicular 1 by ϕ rectangles have as their twelve corners exactly this vertex set. This construction is a named knowledge gap: you must install it, since re-deriving it in the arena would cost more time than the rest of the problem. See Book 1, field: Geometry, topic: coordinates for the Platonic solids.

The recursion generalised. The golden ratio is the fixed point of the recursion $x_{k+1} = 1 + 1/x_k$, equivalently the limit of F_{k+1}/F_k for the Fibonacci recursion $F_{k+1} = F_k + F_{k-1}$. The general fact worth carrying: for a linear recursion $x_{k+1} = px_k + qx_{k-1}$ with characteristic roots α, β of different modulus, the ratios x_{k+1}/x_k converge to the dominant root, and $\mathbb{Z} + \alpha\mathbb{Z}$ is dense exactly when that root is irrational. In the icosahedral setting the Fibonacci recursion is visible directly: the powers $\phi^k = F_k\phi + F_{k-1}$ all lie in H, so the group elements grow along the Fibonacci sequence, and the small elements $|\phi^{-k}| = |F_{k-1} - F_k(\phi - 1)|$ tending to zero give an explicit proof that H is dense without the infimum lemma. See Book 1, field: Sequences and recurrences, topic: linear recurrences and their dominant roots.

Circuit Bank

- **WHEN** a problem asks for integer combinations of fixed vectors to approximate every point **DO** rename the set as the subgroup generated by those vectors and prove it is dense **BECAUSE** because integer combinations form a group and approximation of every point is density, so both quantifiers vanish and the classification of subgroups becomes available
- **WHEN** you must show a finitely generated subgroup of $\mathbb{R}$ is dense **DO** show it is not cyclic, by exhibiting two generators with irrational ratio **BECAUSE** because a nontrivial subgroup of $\mathbb{R}$ is either $c\mathbb{Z}$ or dense, and two elements of $c\mathbb{Z}$ always have rational ratio
- **WHEN** you are proving a statement about a symmetric configuration and have not yet used the symmetry **DO** find the nearest configuration where the statement is false and isolate the separating feature **BECAUSE** because that feature is what the proof must use, and here it is the five-fold symmetry that forces an irrational coordinate ratio
- **WHEN** a conclusion is invariant under rotations and scalings **DO** normalise the configuration to standard coordinates before computing anything **BECAUSE** because the invariance is free and standard coordinates convert a synthetic object into arithmetic you can add and subtract
- **WHEN** you need density in $\mathbb{R}^n$ and have density in each coordinate **DO** approximate each coordinate to within $\varepsilon/\sqrt{n}$ **BECAUSE** because the Euclidean norm of a vector with entries below $\varepsilon/\sqrt{n}$ is below ε, and a product of dense subgroups is dense in the product

Backtesting

1. First useful cue: integer coefficients plus an arbitrary epsilon, which together mean "the generated subgroup is dense".
2. Method the expression suggested: normalise to golden ratio coordinates, extract axis-aligned elements 2 and 2ϕ by adding and subtracting vertex pairs, and apply the cyclic-or-dense dichotomy for subgroups of $\mathbb{R}$.
3. Where you would hesitate, and the thought to reinforce: at "may we choose coordinates?". Reinforce the sentence: density is preserved by rotations and positive scalings because they are homeomorphisms and group automorphisms, and the unit length hypothesis already centres the solid at the origin.
4. The trap the question sets: treating the epsilon as an analysis problem and trying to build the coefficients, or assuming that twelve spanning vectors are automatically enough, which the cube disproves in one line.
5. What makes you recognise it faster next time: five-fold symmetry means no invariant lattice, so any group generated by a symmetric five-fold configuration that spans is dense; the golden ratio is the trace of the five-fold rotation and its irrationality is the whole engine.
6. The reusable decision rule: integer combinations means subgroup; density means "not cyclic" in one dimension; symmetry that is incompatible with a lattice means density is forced.

Mirror drills

1. (drill) Show that the same statement for the eight vertex vectors of a cube is false. *Answer:* take the vertices to be $(\pm 1, \pm 1, \pm 1)/\sqrt{3}$; every integer combination lies in $\frac{1}{\sqrt{3}}\mathbb{Z}^3$, which is a discrete set, so points of $\mathbb{R}^3$ at distance more than $\frac{1}{2\sqrt{3}}$ from that set are not approximated at all. The same argument kills the tetrahedron and the octahedron.

2. (drill) Prove that $\{n\alpha \bmod 1 : n \in \mathbb{Z}\}$ is dense in $[0,1)$ for irrational α, without the infimum lemma. *Answer:* by pigeonhole, among the $N+1$ numbers $\{k\alpha\}$ for $k = 0,\dots,N$ two lie in the same interval of length $1/N$, so some $\{m\alpha\}$ with $m \neq 0$ is within $1/N$ of an integer; the multiples of that number are $1/N$-dense, and N was arbitrary. This is Dirichlet's approximation theorem doing the same job.

3. (drill) For which of the five Platonic solids is the A4 statement true? *Answer:* exactly the icosahedron and the dodecahedron, the two with five-fold symmetry. The dodecahedron has vertices $(\pm 1, \pm 1, \pm 1)$ together with the cyclic permutations of $(0, \pm\phi^{-1}, \pm\phi)$, and the same adding and subtracting gives 2 and $2\phi^{-1}$ on each axis, so the group contains a dense subgroup of each coordinate line. The tetrahedron, cube and octahedron all have rational coordinates after scaling, so their groups are lattices.

3.5 A5. Base three weights collapse a shift operator

For a nonnegative integer k, let $f(k)$ be the number of ones in the base 3 representation of k. Find all complex numbers z such that

$$\sum_{k=0}^{3^{1010}-1} (-2)^{f(k)}(z+k)^{2023} = 0.$$

Read it out loud

A weighted sum of 3^{1010} translates of one fixed polynomial, z^{2023}, where the weight attached to the translate by k depends only on the base 3 digits of k. Two structures are being handed to you at once. First, the weight is multiplicative across digits: $(-2)^{f(k)}$ is the product over digit positions of 1, -2 or 1 according as the digit is 0, 1 or 2, and k runs over every digit string of length 1010. Anything defined as a product over independent coordinates, summed over the full product of ranges, factorises. Second, "sum of shifted copies" is not an arithmetic object at all, it is a linear operator applied to one polynomial, and the operator is built out of the single shift $S\colon p(z) \mapsto p(z+1)$.

Before anything else, write $n = 1010$ and stare at the exponent: $2023 = 2 \cdot 1010 + 3 = 2n + 3$. That is not a coincidence and it is the whole design of the problem. The generating polynomial of the weights will turn out to have a zero of order exactly $2n$ at $x = 1$, an operator whose symbol vanishes to order $2n$ drops the degree of any polynomial by exactly $2n$, and $2n + 3$ drops to 3. A cubic has three roots; the question asks you to find them.

Fields wired in: generating functions over digit expansions, the finite difference and shift calculus (the umbral or symbol calculus, with $S = e^{\partial}$), and elementary root finding for a depressed cubic. The knowledge base is: digit-multiplicative weights factorise; $\Delta = S - I$ lowers polynomial degree by exactly one; a formal power series in ∂ acts on polynomials because ∂ is nilpotent on each one; and sinh has an even Taylor series.

The third cue is the palindrome. The digits of $3^n - 1 - k$ are $2 - d_j$ where d_j are the digits of k, and $2 - d = 1$ exactly when $d = 1$, so $f(3^n - 1 - k) = f(k)$ and the weight sequence is a palindrome. A palindromic weight makes the whole sum symmetric about the centre $k = \frac{3^n-1}{2}$, so you should predict, before computing anything, that the answers are symmetric about $z = -\frac{3^n-1}{2}$ and that this centre is itself a root, because 2023 is odd.

Approaches, ranked worst to best

1. **Binomial expansion and moments.** *Cue:* "$(z+k)^{2023}$". *Circuit:* expand and collect powers of z. (Writing the sum as $\sum_i \binom{2023}{i} z^{2023-i} M_i$ with $M_i = \sum_k (-2)^{f(k)} k^i$ leaves you needing 2024 moment sums over 3^{1010} terms. It is not wrong, and in fact the truth "$M_i = 0$ for $i < 2020$" is exactly the degree collapse in disguise, but as a plan it has no way to compute a single one of those moments. Dead on the page.)

2. **Recursion on n with an explicit two-term ansatz.** *Cue:* the digit structure gives a recursion between n and $n-1$. *Circuit:* induct on the number of digits. (This is the published route: prove by induction on i that the product of the first i symmetric second difference operators applied to z^{2n+3} equals $C_i(z^{2n+3-2i} + \alpha_i z^{2n+1-2i}) + O(z^{2n-1-2i})$. It is correct and complete, but you must carry an unknown constant C_i, an explicit α_i and an error term through an induction, and the bookkeeping is where marks are lost.)

3. **Symmetry plus degree count plus one moment.** *Cue:* palindromic weights and a huge exponent. *Circuit:* centre the variable, use parity, then pin the single remaining constant. (Centre at $z_0 = -\frac{3^n-1}{2}$; the sum becomes an odd polynomial in $w = z - z_0$; the degree collapse says it is a cubic; so it is $C(w^3 + \beta w)$ and only β is unknown, computable from one coefficient.

Efficient, and it explains the shape of the answer. It ranks second only because computing β still needs the operator expansion of the next route.)

4. **Shift operator with the exponential symbol.** *Cue:* a sum of translates with digit-defined weights. *Circuit:* $\sum_k c_k p(z+k) = C(S)p$ with $S = e^{\partial}$. (The ideal route. Factor $C(x) = \sum_k c_k x^k = \prod_{j=0}^{n-1}(x^{3^j}-1)^2$; substitute $x = S = e^{\partial}$; use $(e^t-1)^2 = e^t \cdot 4\sinh^2(t/2)$ to split off the shift by $\frac{3^n-1}{2}$ and leave an even symbol; expand that symbol to two terms in ∂; apply to z^{2n+3}. No induction, no error terms, and the centre of symmetry appears automatically as the factored-out shift.)

The ideal solution

Write $n = 1010$, so the exponent is $2n+3 = 2023$, and set $c_k = (-2)^{f(k)}$ and

$$P(z) = \sum_{k=0}^{3^n-1} c_k (z+k)^{2n+3}.$$

Step 1: the weights factorise. Every k with $0 \le k < 3^n$ has a unique base 3 expansion $k = \sum_{j=0}^{n-1} d_j 3^j$ with $d_j \in \{0,1,2\}$, and this is a bijection between digit strings and the range of k. Since $f(k) = \#\{j : d_j = 1\}$ we have $c_k = \prod_j w_{d_j}$ with $w_0 = w_2 = 1$ and $w_1 = -2$. Hence, for a commuting indeterminate x,

$$C(x) := \sum_{k=0}^{3^n-1} c_k x^k = \prod_{j=0}^{n-1} \left(1 - 2x^{3^j} + x^{2\cdot 3^j}\right) = \prod_{j=0}^{n-1} \left(x^{3^j}-1\right)^2.$$

Step 2: the sum is an operator applied to a monomial. Let S be the shift on $\mathbb{C}[z]$, $(Sp)(z) = p(z+1)$, so that $(S^k p)(z) = p(z+k)$. The map $x \mapsto S$ is a ring homomorphism from $\mathbb{C}[x]$ to the (commutative) ring of operators generated by S, so Step 1 gives

$$P(z) = C(S)\, z^{2n+3} = \prod_{j=0}^{n-1} \left(S^{3^j} - I\right)^2 z^{2n+3}.$$

Step 3: the symbol. For a polynomial p, Taylor's theorem is exact and the sum is finite: $p(z+t) = \sum_{i \ge 0} \frac{t^i}{i!} p^{(i)}(z)$. Hence $S^t = e^{t\partial}$ as operators on $\mathbb{C}[z]$, where $\partial = d/dz$.

Lemma 3.5.1. *Formal power series in ∂ act on $\mathbb{C}[z]$, and the action is a ring homomorphism: if $F(\partial) = \sum_{i \ge 0} \gamma_i \partial^i$ and p has degree d, then $F(\partial)p := \sum_{i=0}^{d} \gamma_i p^{(i)}$ is well defined, and $(FG)(\partial)p = F(\partial)\big(G(\partial)p\big)$.*

Proof. Only finitely many terms act nontrivially on a given p, since $\partial^i p = 0$ for $i > d$, so each series acts. Both sides of the homomorphism identity depend only on the coefficients of F and G up to index d, where the identity is the usual polynomial one. □

Since $(e^t-1)^2 = e^t\left(e^{t/2} - e^{-t/2}\right)^2 = e^t \cdot 4\sinh^2(t/2)$, applying this with $t = 3^j\partial$ and multiplying over j gives

$$C(S) = e^{m\partial} \prod_{j=0}^{n-1} 4\sinh^2\Big(\frac{3^j\partial}{2}\Big), \qquad m = \sum_{j=0}^{n-1} 3^j = \frac{3^n-1}{2},$$

and $e^{m\partial} = S^m$ is the shift $p(z) \mapsto p(z+m)$.

Step 4: two terms of the even symbol. From $\sinh u = u + \frac{u^3}{6} + O(u^5)$ we get $4\sinh^2(u/2) = u^2 + \frac{u^4}{12} + O(u^6)$, so with $u = 3^j\partial$,

$$4\sinh^2\Big(\frac{3^j\partial}{2}\Big) = 9^j\partial^2\Big(1 + \frac{9^j\partial^2}{12} + O(\partial^4)\Big),$$

and multiplying over $j = 0, \dots, n-1$,

$$\prod_{j=0}^{n-1} 4\sinh^2\Big(\frac{3^j\partial}{2}\Big) = A\,\partial^{2n}\Big(1 + \frac{\partial^2}{12}\sum_{j=0}^{n-1} 9^j + O(\partial^4)\Big), \qquad A = \prod_{j=0}^{n-1} 9^j = 9^{n(n-1)/2} \neq 0.$$

Now apply this to z^{2n+3}, using $\partial^{2n} z^{2n+3} = \frac{(2n+3)!}{3!} z^3$, $\partial^{2n+2} z^{2n+3} = (2n+3)!\, z$ and $\partial^i z^{2n+3} = 0$ for $i > 2n+3$, so the $O(\partial^4)$ tail contributes nothing:

$$\prod_{j=0}^{n-1} 4\sinh^2\Big(\frac{3^j\partial}{2}\Big) z^{2n+3} = A(2n+3)!\left(\frac{z^3}{6} + \frac{1}{12}\cdot\frac{9^n-1}{8}\,z\right) = \frac{A(2n+3)!}{6}\left(z^3 + \frac{9^n-1}{16}z\right),$$

where $\sum_{j=0}^{n-1} 9^j = \frac{9^n-1}{8}$.

Step 5: undo the shift and solve. Applying S^m replaces z by $z+m$, so

$$P(z) = \frac{A(2n+3)!}{6}\left((z+m)^3 + \frac{9^n-1}{16}(z+m)\right), \qquad m = \frac{3^n-1}{2}.$$

The leading constant is nonzero, so $P(z) = 0$ if and only if $(z+m)\big((z+m)^2 + \frac{9^n-1}{16}\big) = 0$, that is $z = -m$ or $(z+m)^2 = -\frac{9^n-1}{16}$. With $n = 1010$ the complete solution set is

$$\boxed{z = -\frac{3^{1010}-1}{2} \quad \text{and} \quad z = -\frac{3^{1010}-1}{2} \pm \frac{\sqrt{9^{1010}-1}}{4}\,i}$$

Two checks worth one line each. The case $n = 1$ of the formula reads $z^5 - 2(z+1)^5 + (z+2)^5 = 20\big((z+1)^3 + \frac{1}{2}(z+1)\big)$, and substituting $w = z+1$ makes the left side $(w-1)^5 - 2w^5 + (w+1)^5 = 2\binom{5}{2}w^3 + 2\binom{5}{4}w = 20w^3 + 10w$, which agrees. And the symmetry predicted in advance is visible: $c_k = c_{3^n-1-k}$ gives $P(-(3^n-1) - z) = -P(z)$ because the exponent 2023 is odd, so P is an odd function of $z+m$ and its roots are symmetric about $-m$, with $-m$ itself a root.

Layer 1: WHAT

Block 1. Set $n = 1010$ and notice $2023 = 2n+3$; predict a degree drop of $2n$ and a cubic answer.

Block 2. Factor the weights across base 3 digits: $C(x) = \prod_{j<n}(x^{3^j}-1)^2$, which has a zero of order $2n$ at $x = 1$.

Block 3. Recognise the sum as $C(S)z^{2n+3}$ for the shift operator S, so the factorisation of C becomes a factorisation of the operator.

Block 4. Substitute $S = e^{\partial}$ and split each factor as $e^{3^j\partial}\cdot 4\sinh^2(3^j\partial/2)$, collecting all the exponentials into the single shift by $m = \frac{3^n-1}{2}$.

Block 5. Expand the remaining even symbol to two terms in ∂ and apply it to z^{2n+3}; the result is $z^3 + \frac{9^n-1}{16}z$ up to a nonzero constant.

Block 6. Shift back and solve the depressed cubic.

Juxtaposition. The nominal route expands $(z+k)^{2023}$ and tries to evaluate moments; it never gets past writing M_i. A slightly better zombie route sets up the recursion in n and grinds an induction with an unknown constant and an error term. The ideal route treats the entire sum as one operator and computes only the first two terms of its symbol. The bifurcation point is the very first line: do you expand the bracket $(z+k)^{2023}$ (zombie) or do you write $\sum_k c_k x^k$ and factor it (ideal)? Every later economy follows from having a product instead of a sum.

Layer 2: HOW

Block 1. Cue. Two large numbers, 3^{1010} and 2023, both chosen by the setter. **Why natural.** On the Putnam the specific constants are always tuned so that the answer is finite and clean. Naming

$n = 1010$ turns two mysterious numbers into one relation, $2023 = 2n + 3$, and a relation is something you can use. It is worth repeating: never carry a competition's year in your algebra; parametrise it and find its relation to the other parameter. **Link to the next block.** A relation between the size of the sum and the exponent suggests that the sum will annihilate most of the degree, so ask exactly how much.

Block 2. Cue. The weight depends only on the base 3 digits of k, and k runs over every value in a complete digit range. **Why natural.** Digits are independent coordinates, and $x^k = \prod_j x^{d_j 3^j}$ turns the sum over the product set into a product of sums, one per digit position. Each digit contributes $1 - 2x^{3^j} + x^{2\cdot 3^j}$, which is a perfect square $(x^{3^j} - 1)^2$. Spotting the square is not decoration: it says the generating polynomial vanishes to order two at $x = 1$ for each digit, hence order $2n$ in total, and that number is exactly the degree drop you predicted. **Link to the next block.** Now you have a factored polynomial $C(x)$; the sum you want is what happens when x is replaced by the shift.

Block 3. Cue. The sum is $\sum_k c_k p(z + k)$: the same p, translated, with constant weights. **Why natural.** Translations commute and compose, so $p(z + k) = S^k p$, and a weighted sum of translates is $C(S)p$ for the very polynomial C from Step 1. This substitution is a ring homomorphism, so any factorisation of C transfers to a factorisation of the operator. This is the single most valuable reflex in problems about weighted sums of shifted values, and it converts a 3^{1010}-term sum into a product of $2n$ elementary factors. **Link to the next block.** Products of shift operators are easiest to expand through their symbols, so pass to e^{∂}.

Block 4. Cue. S is a translation, and Taylor's theorem for polynomials is a finite sum. **Why natural.** $S^t = e^{t\partial}$ is exact on $\mathbb{C}[z]$, not merely formal, because ∂ is nilpotent on each polynomial. Once the operator is written in terms of ∂, the factor $(e^t - 1)^2$ is best symmetrised: $(e^t - 1)^2 = e^t \cdot 4\sinh^2(t/2)$ separates a pure shift from an even function of t. The even part is what preserves parity, and collecting the shifts gives $\sum_j 3^j = \frac{3^n - 1}{2}$, which is precisely the centre of symmetry you predicted from the palindromic weights. Two independent arguments landing on the same centre is a strong sign you have not slipped. **Link to the next block.** The remaining operator is even in ∂, so applied to an odd monomial it gives an odd polynomial: only z^3 and z can survive.

Block 5. Cue. You need only a cubic, and ∂^i annihilates z^{2n+3} for $i > 2n + 3$. **Why natural.** Every extra factor of ∂^2 costs two degrees, so of the whole symbol only the coefficients of ∂^{2n} and ∂^{2n+2} can contribute; everything else either raises the order of vanishing beyond the degree or was already accounted for. Therefore expand each factor to two terms only. The arithmetic $\sum_j 9^j = \frac{9^n - 1}{8}$ is the only computation in the problem. **Link to the next block.** A constant multiple of $z^3 + \frac{9^n - 1}{16} z$; now restore the shift.

Block 6. Cue. A depressed cubic $w^3 + \beta w$ with $\beta > 0$. **Why natural.** It factors as $w(w^2 + \beta)$, so one real root and two purely imaginary ones; undoing $w = z + m$ translates all three by $-m$. Because the problem asked for complex numbers, all three count, and you must present all three. **Link to the next block.** Substituting $n = 1010$ gives the answer.

Layer 3: WHY

Three truths carry this solution. The first is independence: a weight that is a product over coordinates, summed over a full product of ranges, factorises. That is the same principle that makes the characteristic function of a sum of independent random variables a product, and it is why digit-defined sequences (the Thue and Morse sequence, digit sums, digit counts) always have product generating functions. The second is that the algebra of shift operators on polynomials is

just the algebra of polynomials, through $x \mapsto S$, and it embeds in formal power series in ∂ through $S = e^{\partial}$. Under that embedding, the order of vanishing of C at $x = 1$ becomes the order of vanishing of the symbol at $\partial = 0$, which is exactly the number of degrees that $C(S)$ removes. Stated cleanly: if $C(x) = (x-1)^m U(x)$ with $U(1) \neq 0$, then $C(S)$ annihilates every polynomial of degree less than m and reduces the degree of every other polynomial by exactly m. Here $m = 2n = 2020$ and $2023 - 2020 = 3$. The third is symmetry: palindromic weights make the functional invariant under reflecting k about the centre, so after centring the variable the answer is even or odd according to the parity of the exponent.

The discernment mechanism is a question to ask of any expression of the form $\sum_k c_k p(z+k)$: what is $C(x) = \sum_k c_k x^k$, and what is its order of vanishing at $x = 1$? That single number tells you the degree of the answer before you compute anything, and it tells you whether the problem is even well posed. If the exponent had been below $2n$ the sum would vanish identically and every complex z would be a solution; at exponent $2n$ it is a nonzero constant and no z works; at $2n+1$ there is one root; the setter chose $2n+3$ to get a genuine cubic with three distinct roots, two of them non-real, so that the phrase "all complex numbers" earns its place. Train the reflex by computing $\Delta^m p$ for small cases until "the difference operator eats one degree" is automatic.

What the examiners nudged toward and how: they used base 3 with the weight (-2) on the digit 1, which is exactly the combination making each digit factor a perfect square rather than a general quadratic; they made the range a complete block $0 \le k < 3^{1010}$, without which no factorisation exists; they made the exponent odd, so that the centre is itself a root; and they tuned the exponent to $2n+3$ so that the surviving polynomial is a cubic.

Revolving concepts

Digit-multiplicative sequences. Definition: a sequence with $c_{bk+d} = w_d c_k$ for $0 \le d < b$ and $c_0 = 1$ is determined by the digit weights w_d, and $c_k = \prod_j w_{d_j}$ over the base b digits of k. Generating function: $\sum_{k=0}^{b^n-1} c_k x^k = \prod_{j=0}^{n-1} \left(\sum_{d=0}^{b-1} w_d x^{db^j} \right)$. Orbiting examples: the Thue and Morse sequence ($b = 2$, $w_0 = 1$, $w_1 = -1$) with $\prod_j (1 - x^{2^j})$; digit sums; the $(-2)^{f(k)}$ of this problem. See Book 1, field: Generating functions, topic: digit expansions and product formulas.

Finite difference and shift calculus. Definitions: $Sp(z) = p(z+1)$, $\Delta = S - I$, and Δ lowers the degree of a polynomial by exactly one, with $\Delta z^d = dz^{d-1} + \cdots$. Theorems: $\Delta^m p = \sum_i (-1)^{m-i} \binom{m}{i} p(z+i)$; $\Delta^m p = 0$ if and only if $\deg p < m$; Newton's forward difference formula $p(z) = \sum_m \binom{z}{m} \Delta^m p(0)$. The general annihilation lemma used here: for $C(x) = (x-1)^m U(x)$ with $U(1) \neq 0$, the operator $C(S)$ kills polynomials of degree below m and drops all others by exactly m. See Book 1, field: Sequences and recurrences, topic: finite differences.

Symbol calculus, $S = e^{\partial}$. Statement: on $\mathbb{C}[z]$ the shift equals e^{∂} exactly, since Taylor's theorem is a finite identity for polynomials; consequently formal power series in ∂ act, and act as a commutative ring. Orbiting identities: $\Delta = e^{\partial} - 1$, so $\partial = \log(1 + \Delta)$, which is Newton's series; the symmetric second difference $S^{\ell} - 2I + S^{-\ell} = 4 \sinh^2(\ell \partial / 2)$; the Euler and Maclaurin operator $\partial / (e^{\partial} - 1)$ whose coefficients are the Bernoulli numbers. See Book 1, field: Generating functions, topic: umbral and operator calculus.

Palindromic weights and centring. Statement: if $c_k = c_{K-k}$ for all k in the range with $K = 3^n - 1$, then $\sum_k c_k (z+k)^N$ satisfies $P(-K - z) = (-1)^N P(z)$, so after substituting $w = z + K/2$ the polynomial is even or odd in w according to the parity of N. Consequence used here: half the coefficients of the cubic vanish for free, and the centre is a root when N is odd. See Book 1, field: Polynomials, topic: symmetry of coefficient sequences.

The recursion generalised. The weights obey $c_{3k} = c_k$, $c_{3k+1} = -2c_k$, $c_{3k+2} = c_k$, a digit recursion. Its general form and solution: if $c_{bk+d} = w_d c_k$ then, writing $C_n(x) = \sum_{k < b^n} c_k x^k$, one has the recursion $C_n(x) = C_{n-1}(x^b) \cdot \left(\sum_d w_d x^d \right)$ evaluated with the digit blocks in the right order, whose solution is the product formula above; the same telescoping product appears for every self-similar

(automatic) sequence. The operator consequence generalises too: $C_n(S)$ annihilates polynomials of degree less than $n \cdot \mathrm{ord}_{x=1}\left(\sum_d w_d x^d\right)$. See Book 1, field: Generating functions, topic: self-similar sequences and their products.

Circuit Bank

- **WHEN** you see $\sum_k c_k p(z+k)$, a weighted sum of translates of one polynomial **DO** write it as $C(S)p$ where $C(x) = \sum_k c_k x^k$ and S is the shift, then factor C **BECAUSE** because translations commute, so the sum is a polynomial in one operator, and any factorisation of C becomes a factorisation of the operator
- **WHEN** a weight depends only on the base b digits of the index and the index runs over a complete block $0 \le k < b^n$ **DO** factor the generating polynomial one digit at a time **BECAUSE** because digits are independent coordinates and a product weight summed over a product set always factorises
- **WHEN** a shift polynomial C has a zero of order m at $x = 1$ **DO** conclude the operator annihilates degrees below m and drops every other degree by exactly m **BECAUSE** because $C(S) = (S-I)^m U(S)$ with $U(I)$ invertible on each degree, and $S - I$ lowers degree by exactly one
- **WHEN** you need only the leading few coefficients of a complicated operator applied to a monomial **DO** expand the symbol in powers of ∂ and keep as many terms as the degree can support **BECAUSE** because ∂ is nilpotent on any fixed polynomial, so the symbol calculus is exact and the tail costs nothing
- **WHEN** the coefficient sequence is a palindrome **DO** centre the variable at the midpoint before expanding **BECAUSE** because the sum then becomes even or odd in the centred variable according to the parity of the exponent, and half the unknown coefficients vanish without computation

Backtesting

1. First useful cue: a weight defined by base 3 digits summed over the complete range $0 \le k < 3^{1010}$, next to the relation $2023 = 2 \cdot 1010 + 3$.
2. Method the expression suggested: factor the digit generating polynomial into $\prod(x^{3^j} - 1)^2$, replace x by the shift $S = e^{\partial}$, peel off the shift by $\frac{3^n-1}{2}$, expand the even symbol to two terms, apply to z^{2n+3}.
3. Where you would hesitate, and the thought to reinforce: at "may I substitute $S = e^{\partial}$ and multiply power series?". Reinforce: on polynomials ∂ is nilpotent, so every power series in ∂ acts through a finite sum and the algebra is exact; this is a theorem, not a formal manipulation.
4. The trap the question sets: expanding $(z+k)^{2023}$ by the binomial theorem, which produces 2024 moment sums and no route to any of them; and, at the end, giving only the real root when the question says "all complex numbers".
5. What makes you recognise it faster next time: any sum of translates is an operator; any digit-defined weight factorises; the order of vanishing at $x = 1$ of the weight generating polynomial is the number of degrees the operator removes.
6. The reusable decision rule: convert translate sums into $C(S)$, factor C, read the order of vanishing at 1 to get the degree of the answer, and expand the symbol only as far as that degree allows.

Mirror drills

1. (drill) Compute $z^5 - 2(z+1)^5 + (z+2)^5$ and identify its roots. *Answer:* substituting $w = z+1$ gives $(w-1)^5 - 2w^5 + (w+1)^5 = 2\binom{5}{2}w^3 + 2\binom{5}{4}w = 20w^3 + 10w$, so the roots are $z = -1$ and $z = -1 \pm \frac{i}{\sqrt{2}}$. This is the $n = 1$ case of A5, and it matches the general formula with $\frac{\sqrt{9-1}}{4} = \frac{1}{\sqrt{2}}$.

2. (drill) Show that $\sum_{i=0}^{m} (-1)^{m-i}\binom{m}{i} p(z+i) = 0$ for every polynomial p of degree less than m. *Answer:* the left side is $(S - I)^m p = \Delta^m p$, and Δ lowers degree by exactly one, so m applications annihilate anything of degree below m. Equivalently the weight generating polynomial $(x-1)^m$ vanishes to order m at $x = 1$.

3. (drill) In the A5 sum, replace the exponent 2023 by 2020, by 2021, and by 2019. What are the solution sets? *Answer:* the operator removes exactly 2020 degrees. At exponent 2019 the sum is identically zero, so every complex z works; at 2020 it is a nonzero constant, so no z works; at 2021 it is a nonzero multiple of $z + \frac{3^{1010}-1}{2}$, so the unique solution is the centre. This is why the setter chose $2n + 3$.

3.6 A6. Bob owns the parity of the fixed points

Alice and Bob play a game in which they take turns choosing integers from 1 *to* n*. Before any integers are chosen, Bob selects a goal of "odd" or "even". On the first turn, Alice chooses one of the* n *integers. On the second turn, Bob chooses one of the remaining integers. They continue alternately choosing one of the integers that has not yet been chosen, until the* n*th turn, which is forced and ends the game. Bob wins if the parity of* $\{k : \text{the number } k \text{ was chosen on the } k\text{th turn}\}$ *matches his goal. For which values of* n *does Bob have a winning strategy?*

Read it out loud

Two players alternately remove numbers from $\{1, \ldots, n\}$ until nothing is left. Assigning to each turn the number chosen on it produces a bijection π from turns to numbers, that is, a permutation of $\{1, \ldots, n\}$, and the set in the statement is exactly the fixed point set of π. So the game builds a random-looking permutation under adversarial control, and the payoff is one bit: the parity of the number of fixed points. Bob must nail that bit, and, worse, he must commit to which value of the bit he is chasing before a single move is made.

Fields wired in: permutations and their fixed points, parity arguments, and combinatorial game theory in its most elementary form, namely explicit strategies verified by induction on the size of the game. There is no clever counting here and no formula to derive; the entire content is the construction of a strategy that works against every line of play, plus the discipline to check it against every line of play.

The first useful cue is the alternation next to the indexing. Alice takes the odd turns $1, 3, 5, \ldots$ and Bob the even ones. A fixed point at k can be created only on turn k. Therefore odd numbers can be fixed only by Alice and even numbers only by Bob. Write that sentence down within thirty seconds, because it is the hinge of both halves of the solution: it tells Bob that pairing an odd number with the even number immediately after it locks the two of them together, and it tells him that occupying the number $t + 1$ on his turn t silently destroys Alice's only chance to score on her next turn.

The second cue is the phrase "the nth turn, which is forced". The setter is pointing at the last move. Who owns it? If n is even it is Bob's, and if n is odd it is Alice's. That single fact decides which goal Bob should choose, and it is also why the odd case is genuinely harder: Alice gets the last word, so Bob cannot simply mirror.

The third cue is what the answer is likely to be. A "for which n" question whose answer is "all n" is common when the underlying mechanism is a strategy rather than a numerical obstruction, and here Bob has two independent sources of power (he moves second, and he can occupy the number that would score for Alice next). Reconnaissance on $n = 1, 2, 3$ confirms it: for $n = 1$ Alice is forced to take 1 and there is one fixed point; for $n = 2$, either Alice takes 1 and Bob takes 2, giving two, or Alice takes 2 and Bob takes 1, giving zero, so Bob names "even" and wins.

Approaches, ranked worst to best

1. **Play small cases and assert the pattern.** *Cue:* "for which values of n". *Circuit:* compute, conjecture, stop. (Necessary reconnaissance, not a solution. Small cases give the answer, "all n", and the correct goal, matching the parity of n, but the question is a strategy question: without an explicit strategy proved against all of Alice's replies, you have nothing. Do the reconnaissance in two minutes and then throw it away.)

2. **Look for an invariant.** *Cue:* a parity payoff. *Circuit:* find a quantity neither player can change. (A natural instinct, and it fails here for a reason worth internalising: the parity of the fixed point count is genuinely contested, since Alice can create a fixed point by taking 1 on turn 1

and Bob can create one by taking 2 on turn 2. When both players can move the quantity, no invariant exists and you must build a strategy instead.)

3. **One global pairing for every n.** *Cue:* Bob moves second, so he can mirror. *Circuit:* answer inside a perfect matching of the ground set. (For even n this is the whole solution and it is beautiful: pair $\{1,2\},\{3,4\},\dots$ and always answer with the partner. For odd n the ground set has no perfect matching, and the naive repair, pairing $\{1,2\},\dots,\{n-2,n-1\}$ and leaving n over, loses. Concretely for $n=5$: Alice takes 3, Bob answers 4, Alice takes the unpaired 5, and Bob has no partner to play; whatever he does the count ends even. Rank this third: right for half the problem, and its failure tells you what the other half needs.)

4. **Pair for even n; for odd n bank one fixed point, then block, and reset by induction.** *Cue:* the last turn belongs to Alice exactly when n is odd. *Circuit:* a one-off parity adjustment plus a permanent shutdown, with strong induction to absorb the exceptional branch. (The ideal route. The key auxiliary result is a blocking lemma: from any of his turns, Bob can guarantee that no further fixed point ever occurs. Given that, all Bob needs is to reach an odd count while it is his move, and the whole odd case becomes an induction with one exceptional branch that resets to a smaller odd game.)

The ideal solution

Answer: Bob has a winning strategy for every positive integer n. He selects the goal "even" when n is even and "odd" when n is odd.

Set-up and notation. Each number is chosen exactly once, so the map π sending a turn t to the number chosen on turn t is a permutation of $\{1,\dots,n\}$, and "the number k was chosen on the kth turn" says $\pi(k)=k$. Call such a k a *hit*. Alice moves on the odd turns and Bob on the even ones. We use repeatedly the following remark.

Remark 3.6.1. A hit at k occurs on turn k. Hence every odd hit is made by Alice and every even hit is made by Bob. In particular, on his turn t Bob scores a hit if and only if he chooses the number t itself, and if the number $t+1$ has already been chosen then Alice cannot score a hit on turn $t+1$.

Part 1: n even. Bob forces an even number of hits.

Partition $\{1,\dots,n\}$ into the pairs $\{1,2\},\{3,4\},\dots,\{n-1,n\}$. Bob's strategy: whenever Alice chooses a number, Bob chooses its partner. This is always legal, because after each of Bob's moves the set of chosen numbers is a union of complete pairs, so when Alice next chooses a number its partner is still available.

Fix k with $1\le k\le n/2$; we claim $2k-1$ is a hit if and only if $2k$ is. If $2k-1$ is a hit it was chosen on the odd turn $2k-1$, hence by Alice, so Bob chose $2k$ on turn $2k$ and $2k$ is a hit. Conversely, if $2k$ is a hit it was chosen on the even turn $2k$, hence by Bob, and Bob only ever chooses the partner of the number Alice has just chosen, so Alice chose $2k-1$ on turn $2k-1$, making $2k-1$ a hit. Thus each pair contributes 0 or 2 hits, and the total is even. Bob's goal "even" is achieved.

Part 2: n odd. Bob forces an odd number of hits. We first isolate the shutdown mechanism.

Lemma 3.6.2 (Blocking)**.** *Let n be odd and let t be one of Bob's turns. Then Bob can play from turn t onwards so that no hit occurs on any turn $s\ge t$.*

Proof. Bob's rule at each of his turns $s\ge t$: if the number $s+1$ is still available, choose it; otherwise choose any available number other than s.

The rule is legal. Bob's turns are even and n is odd, so $s\le n-1$, and therefore at least $n-s+1\ge 2$ numbers are available; at most one of them equals s, so a choice other than s exists.

No hit occurs on Bob's turns from t on: if he chooses $s+1$ then $s+1\ne s$, and otherwise he chooses something other than s by construction. No hit occurs on Alice's turns from t on either: her turns after t are the turns $s+1$ for Bob's turns $s\ge t$, and in both branches of the rule the number

$s+1$ is unavailable when she moves, either because Bob has just taken it or because it was already gone. Since every turn after t is a turn of Bob's or a turn immediately following one, no hit occurs at any turn $s \geq t$. □

Theorem 3.6.3. *For every odd $n \geq 1$, Bob can force the number of hits to be odd.*

Proof. Strong induction on odd n.

Base $n = 1$. Alice is forced to choose 1 on turn 1, which is a hit, so the count is 1.

Induction step, $n \geq 3$. Let a be Alice's choice on turn 1.

Case (i): $a = 1$. This is a hit and the count is 1. Bob applies the Blocking Lemma from turn 2; no further hit occurs and the total is 1, odd.

Case (ii): $a = 2$. No hit on turn 1. Bob chooses 1 on turn 2, which is available and is not a hit since $1 \neq 2$. The remaining numbers are $\{3, \ldots, n\}$ and the remaining turns are $3, \ldots, n$, with Alice to move. Subtracting 2 from every number and every turn index identifies this position with the initial position of the whole game on $n-2$ numbers, and hits correspond to hits. Since $n-2$ is odd, the induction hypothesis lets Bob force an odd number of hits there, so the total is $0 +$ odd, odd.

Case (iii): $a = k$ with $k \geq 3$. No hit on turn 1. Bob chooses 2 on turn 2, which is available since $k \neq 2$ and is a hit, so the count is 1.

Bob now plays as follows on each later turn s of his. If Alice did not score a hit on turn $s-1$, he applies the Blocking Lemma from turn s and the game is over for our purposes. Otherwise he chooses s if it is available, and chooses 1 if it is not.

To see that this wins, observe that as long as Alice keeps scoring, an immediate induction on the turn number shows that just before Bob's turn s the chosen numbers are exactly $\{k\} \cup \{2, 3, \ldots, s-1\}$ and the hits are exactly the turns $2, 3, \ldots, s-1$, so the count is $s-2$, which is even. There are now three ways the play can go.

First, suppose Alice fails to score on some turn $j \geq 3$ of hers, either by choice or because $j = k$ is already gone. Just before turn j the chosen numbers are $\{k\} \cup \{2, \ldots, j-1\}$ and the count is $j-2$, which is odd since j is odd. No hit occurs on turn j, and Bob applies the Blocking Lemma from turn $j+1$, so the total is $j-2$, odd.

Second, suppose the run continues and Bob reaches a turn s with s unavailable. Since the chosen numbers are $\{k\} \cup \{2, \ldots, s-1\}$, this happens exactly when $s = k$, so k is even and $k \geq 4$. Bob chooses 1, which is available and is not a hit since $1 \neq k$. Now the chosen numbers are $\{1, 2, \ldots, k\}$, the remaining numbers are $\{k+1, \ldots, n\}$, the remaining turns are $k+1, \ldots, n$, and Alice is to move: subtracting k identifies this with the whole game on $n-k$ numbers, which is odd because n is odd and k is even, and nonempty because $k \neq n$ for the same parity reason. The count so far is $k-2$, even, and by the induction hypothesis Bob forces an odd number of hits from the sub-game, so the total is odd.

Third, suppose the run never breaks. Then Alice scores on every one of her turns and Bob on every one of his, so all of $2, 3, \ldots, n-1$ are chosen on their own turns, and together with Alice's first move this accounts for $n-1$ numbers, forcing $k = n$. The only number left for turn n is 1, which Alice must take, and $1 \neq n$, so it is not a hit. The count is $n-2$, odd.

In every line Bob forces an odd number of hits, completing the induction. □

Combining the two parts, Bob wins for every n, which is the answer: $\boxed{\text{all } n}$.

Why the goal must match the parity of n. The choice of goal is not free, and the reason is the same blocking mechanism run by the other player. For even n, Alice can force zero hits: on each of her turns t she chooses $t+1$ if available and otherwise anything other than t. This is legal because her turns are odd and n is even, so $t \leq n-1$ and at least two numbers remain; her own choice is never t, and Bob's turn $t+1$ can never be a hit because $t+1$ is gone. Every turn is one of hers or one immediately after, so no hit ever occurs. Hence for even n Bob could not have won with the goal "odd", and by the theorem he cannot lose with "even". For odd n, Alice's blocking breaks down at

her final turn n, which is forced, and the theorem shows Bob takes the odd parity. So for each n exactly one goal is winning, and it is the parity of n.

Layer 1: WHAT

Block 1. Name the object: the play is a permutation from turns to numbers, and the payoff is the parity of its fixed points.

Block 2. Extract the parity alignment: a number can be hit only on the turn equal to itself, so odd numbers are Alice's to hit and even numbers are Bob's.

Block 3. Even n: pair $\{2k-1, 2k\}$ and answer within the pair. The alignment makes the two members of a pair hit or miss together, so the count is even.

Block 4. Odd n: prove the Blocking Lemma, which says Bob can shut down all future hits from any of his turns.

Block 5. Odd n: Bob's job reduces to reaching an odd count on one of his turns. He banks the hit at 2 on turn 2 if Alice's opening leaves it available.

Block 6. Handle the two exceptional branches by induction: Alice opening with 2, and the run colliding with Alice's first number k, both of which reset the position to the same game on fewer numbers with Alice to move.

Juxtaposition. The nominal route computes small cases, guesses "all n", then tries to write one strategy that handles both parities and gets stuck because the odd case has no perfect matching. A second nominal route hunts for an invariant, which cannot exist because both players can change the count. The bifurcation point is the sentence after the reconnaissance: do you look for a formula or an invariant (zombie), or do you ask which numbers each player is even capable of hitting (ideal)? The parity alignment is the observation from which the pairing, the blocking and the induction all follow.

Layer 2: HOW

Block 1. **Cue.** "Choosing integers from 1 to n", each once, until all are gone, with the payoff indexed by turn number. **Why natural.** A sequence of distinct choices exhausting a finite set is a bijection, and naming it a permutation converts an unfamiliar game into a familiar object with a standard statistic, the fixed point count. Naming the object is not cosmetic; it is what lets you say "the two members of this pair are fixed together", a sentence you cannot even formulate while thinking about turns and choices. **Link to the next block.** With the object named, ask which player controls which part of the statistic.

Block 2. **Cue.** Alice takes odd turns, Bob even ones, and a hit at k can happen only on turn k. **Why natural.** The condition $\pi(k) = k$ ties the turn parity to the number parity. So the two players have disjoint scoring opportunities: Alice can only ever hit odd numbers, Bob only even ones. This is the structural asymmetry the setter built in, and everything Bob does exploits it. It also immediately suggests the pairing $\{2k-1, 2k\}$, since that is the unique matching for which the two members are hit on consecutive turns, one by each player. **Link to the next block.** If a pair can be arranged to score together or not at all, the total is automatically even.

Block 3. **Cue.** n even means a perfect matching of $\{1, \ldots, n\}$ exists and Bob moves second. **Why natural.** A second player can always answer inside a fixed perfect matching, since after each of his moves the taken set is a union of complete pairs. Choosing the matching $\{2k-1, 2k\}$ makes the alignment work: Alice hits $2k-1$ only on turn $2k-1$, and Bob's reply on turn $2k$ is then $2k$, a hit; conversely Bob hits $2k$ only if Alice has just hit $2k-1$. Note the "conversely" is a genuine step and not decoration: without it, Bob might hit $2k$ while $2k-1$ was missed, and the count would be odd.

Link to the next block. Even n is finished. For odd n the matching is imperfect, so the same idea fails and a new mechanism is needed.

Block 4. **Cue.** The failing line for odd n ends with Bob unable to reply, and with a count that is even rather than odd. **Why natural.** What Bob lacks in the odd case is not a way to score, but a way to stop scoring safely. So isolate that: can Bob guarantee that nothing more is ever scored? Yes, and by the cheapest possible device: on his turn s he takes the number $s+1$, which is the only number Alice could use to score on her next turn, and which cannot score for him. When $s+1$ is already gone, Alice cannot score anyway and he takes anything except s. It is worth repeating: a blocking move that also cannot help you is the perfect move, and here the alignment of parities supplies one for free. **Link to the next block.** With a permanent shutdown available, the whole odd case reduces to reaching an odd count while it is Bob's turn.

Block 5. **Cue.** Bob's only scoring move on turn 2 is the number 2, and it is available unless Alice took it. **Why natural.** Bob has to bank a hit at some point, and the earliest and cheapest is turn 2. If Alice opened with 1 she has already banked one for him, so he blocks at once; if she opened with 2 she has denied him the cheap hit but has also left the position looking exactly like a smaller game; and if she opened with anything else he takes 2 and is one ahead. **Link to the next block.** Now the count is odd on Bob's clock, and he needs only to preserve parity or shut the game down.

Block 6. **Cue.** Two branches do not close directly: Alice opening with 2, and the running sequence colliding with Alice's first number. **Why natural.** In both, the taken numbers form an initial block $\{1,\dots,m\}$ chosen during turns $1,\dots,m$, with Alice to move on turn $m+1$: the position is a shifted copy of the original game on $n-m$ numbers. That is precisely the situation strong induction was invented for. Check the parity of m each time: in case (ii) $m=2$, in the collision case $m=k$ is even, so the residual game has odd size and the banked count is even, and the induction hypothesis supplies the missing odd parity. **Link to the next block.** All branches close, so Bob wins for every odd n.

Layer 3: WHY

The mathematical truth underneath is that this is a game of scoring opportunities, not of counting. Each number k carries exactly one opportunity, at turn k, and that opportunity belongs to whichever player owns turn k. So the position is best pictured as n tokens, alternately coloured by owner, each of which can be cashed only at its own moment and only by its owner, and each of which can be destroyed by anyone who takes it early. Once you see the game that way, both mechanisms are forced: a pairing that couples one of Alice's tokens to the one of Bob's immediately after it (so they are cashed together), and a blocking move that destroys Alice's next token at no cost. Nothing else in the game matters.

The discernment mechanism is to ask, in any game with a parity payoff, three questions in order. Who can change the quantity at all? If both players can, no invariant exists and you need a strategy. Which player moves second, and does the ground set admit a matching that the second player can answer inside? If yes, the second player can control parity. And finally, is there a move that both denies the opponent and cannot help you? Such a move is a permanent shutdown, and a shutdown plus a single one-off adjustment is exactly what a parity target needs. Training this is a matter of running those three questions on every game problem you meet until they are reflex.

Two further remarks give the problem its shape. First, the last turn is the pivot: whoever owns it owns the final adjustment, which is why Bob's goal is forced to be the parity of n and why the even case is easy and the odd case needs induction. Second, this is a game, not a counting problem, and the distinction is worth stating plainly. If the permutation were chosen uniformly at random,

the number of fixed points would be asymptotically Poisson with mean 1 and the parity would be biased but not controllable; under adversarial play the parity is decided outright. Do not import intuition from the random model into a game.

Knowledge gaps, stated plainly, since this is an A6. First, combinatorial game theory vocabulary is not part of A-level: a strategy is a function assigning a legal move to every reachable position, not a single line of play, and a proof must verify the strategy against all replies. This is where the overwhelming majority of attempted solutions to this problem fail, by describing what happens if Alice cooperates. Second, induction on games: to induct you must exhibit a reachable position that is isomorphic to the initial position of a smaller instance, with the same player to move, and you must record the parity of what was banked before the reset. Third, permutations and fixed points as formal objects, including the fact that a sequence of distinct choices exhausting a finite set is a bijection. Install those three and this problem is a page of careful bookkeeping; skip them and it is unapproachable.

What the examiners nudged toward and how: they made Bob choose his goal in advance, which is the entire difficulty, since otherwise he could wait and see; they specified that the last turn is forced, which points at the parity of n; and they phrased the payoff as the parity of a set indexed by turn number, which is a nudge to identify the permutation and its fixed points.

Revolving concepts

Permutations and fixed points. Definitions: a permutation of $\{1, \dots, n\}$ is a bijection; k is a fixed point when $\pi(k) = k$; a permutation with no fixed points is a derangement. Orbiting facts: the number of derangements satisfies $D_n = nD_{n-1} + (-1)^n$ and also $D_n = (n-1)(D_{n-1} + D_{n-2})$, with solution $D_n = n! \sum_{i=0}^{n} \frac{(-1)^i}{i!}$; the number of permutations with exactly j fixed points is $\binom{n}{j} D_{n-j}$, so under the uniform distribution the fixed point count converges to a Poisson law of mean 1. See Book 1, field: Combinatorics, topic: derangements and fixed points.

Pairing (mirroring) strategies. Statement of the principle: if the ground set carries a perfect matching and the second player always answers with the partner of the first player's move, then after each of his moves the taken set is a union of complete pairs; hence any statistic that is constant on pairs is under his control. Orbiting examples: the second player forcing a draw by symmetry, Hackenbush and Nim style mirroring, and the classical result that in many combinatorial games a pairing strategy is the only known explicit strategy. The limitation to remember: pairing needs an even ground set, and the matching must be chosen so that the payoff statistic couples within a pair, which here forces the matching $\{2k-1, 2k\}$ rather than $\{2k, 2k+1\}$. See Book 1, field: Games and invariants, topic: pairing strategies.

Blocking and cost-free denial. Statement: a move that removes the opponent's only scoring option and cannot score for you is strictly dominant when your aim is to freeze the payoff. Here Bob's turn s move of taking $s+1$ denies Alice her unique chance on turn $s+1$ and can never be a hit for him. The general rule: when the payoff is a sum of one-shot opportunities, denial of the opponent's next opportunity is a complete defence provided you can repeat it every turn. See Book 1, field: Games and invariants, topic: blocking strategies and shutdown arguments.

Induction on game size, and the recursion generalised. The game recursion here is: from the initial position of the game on n numbers, Bob can reach, after m turns, a position that is a shifted copy of the initial position of the game on $n-m$ numbers with Alice to move, having banked a known parity $b(m)$. Writing $V(n)$ for the parity Bob can force, the recursion is $V(n) = b(m) + V(n-m)$ with m even, whose solution here is $V(n) \equiv n \pmod 2$. The general lesson is that a strategy proof for a game on n objects should always be arranged as a reduction to the same game on fewer objects with the same player to move, since only then is strong induction available; the residual parity $b(m)$ is the bookkeeping you must not lose. See Book 1, field: Games and invariants, topic: strategies by induction on size.

Parity arguments and when invariants do not exist. Statement: an invariant argument requires

that no legal move changes the quantity modulo the relevant number. Test it here: Alice taking 1 on turn 1 changes the count, and Bob taking 2 on turn 2 changes it again, so no invariant exists and no counting argument can decide the game. The habit worth installing is to run this test before hunting for an invariant, which takes ten seconds and saves twenty minutes. See Book 1, field: Games and invariants, topic: invariants versus strategies.

Circuit Bank

- **WHEN** a game builds a sequence of distinct choices that exhausts a finite set **DO** name the resulting bijection and rewrite the payoff as a statistic of that permutation **BECAUSE** because the standard statistics of permutations come with structure, and here the fixed point condition ties each number to one specific turn and therefore to one specific player
- **WHEN** a game has a parity payoff and both players can change the quantity **DO** stop looking for an invariant and build a strategy **BECAUSE** because an invariant exists only when no legal move changes the quantity, and ten seconds of testing settles it
- **WHEN** you move second and the ground set has even size **DO** fix a perfect matching whose pairs couple the payoff, and always answer with the partner **BECAUSE** because after each of your moves the taken set is a union of complete pairs, so any statistic constant on pairs is yours to control
- **WHEN** you want to stop your opponent scoring for the rest of the game **DO** on each of your turns take the item that is their only scoring option next turn, provided it cannot score for you **BECAUSE** because that is a permanent shutdown at zero cost, and it converts a parity target into a single one-off adjustment
- **WHEN** your strategy has an exceptional branch that you cannot close directly **DO** look for a position reachable in that branch which is a shifted copy of the whole game on fewer objects with the same player to move, and use strong induction **BECAUSE** because a game reduction plus a record of the parity banked so far closes the branch without inventing a new idea

Backtesting

1. First useful cue: alternation of turns next to a payoff indexed by turn number, which forces the parity alignment that Alice can hit only odd numbers and Bob only even ones.
2. Method the expression suggested: for even n, mirror inside the matching $\{2k-1, 2k\}$ so hits come in pairs; for odd n, bank one hit at 2 on turn 2, then shut the game down with the blocking rule, using strong induction for the two branches where the shutdown is not yet available.
3. Where you would hesitate, and the thought to reinforce: in the odd case, at the moment the running sequence collides with Alice's opening number. Reinforce the sentence: the taken numbers are an initial block $\{1, \ldots, m\}$ taken during turns $1, \ldots, m$, so the position is a shifted copy of a smaller game and induction applies.
4. The trap the question sets: describing a strategy only along the line where Alice cooperates. Bob must have a reply to every legal Alice move at every reachable position, and the two branches that look like edge cases (Alice opening with 2, and the collision at $s = k$) are exactly where the marks are.
5. What makes you recognise it faster next time: any game whose payoff is a sum of one-shot opportunities, each owned by a single player at a single moment, is decided by pairing and blocking; and the owner of the last turn decides which parity is forced.

6. The reusable decision rule: name the permutation, align turn parity with number parity, mirror when the ground set is even, and bank one plus block when it is odd.

Mirror drills

1. (drill) Show that for even n Alice can force zero hits, so that Bob's goal choice is forced. *Answer:* on each of her turns t, Alice takes $t+1$ if available, otherwise anything other than t; her turns are odd and n is even, so $t \leq n-1$ and at least two numbers remain. She never takes t, and Bob's turn $t+1$ can never be a hit because $t+1$ is gone. Every turn is one of hers or the one immediately after, so nothing is ever hit.
2. (drill) Play out $n = 3$ completely and check Bob's goal "odd" wins against all three openings. *Answer:* if Alice opens 1 (a hit), Bob takes 3 on turn 2, and Alice takes 2 on turn 3, total 1. If Alice opens 2, Bob takes 1, and Alice is forced to take 3 on turn 3, a hit, total 1. If Alice opens 3, Bob takes 2 on turn 2, a hit, and Alice is forced to take 1 on turn 3, total 1.
3. (drill) Can either player force the number of hits to be exactly zero? *Answer:* Bob never can, since Alice takes 1 on turn 1 and scores immediately. Alice can exactly when n is even, by drill 1; for odd n she cannot, because the theorem gives Bob an odd count, which is at least one. So the count itself is not controllable, only its parity, and only by the right player.

3.7 B1. Sliding coins and the staircase of holes

Consider an m-by-n grid of unit squares, indexed by (i, j) with $1 \leq i \leq m$ and $1 \leq j \leq n$. There are $(m-1)(n-1)$ coins, which are initially placed in the squares (i, j) with $1 \leq i \leq m-1$ and $1 \leq j \leq n-1$. If a coin occupies the square (i, j) with $i \leq m-1$ and $j \leq n-1$ and the squares $(i+1, j)$, $(i, j+1)$, and $(i+1, j+1)$ are unoccupied, then a legal move is to slide the coin from (i, j) to $(i+1, j+1)$. How many distinct configurations of coins can be reached starting from the initial configuration by a (possibly empty) sequence of legal moves?

Read it out loud

This is a reachability count on a state graph: a state is a set of occupied squares, a move is a local rewrite of that set, and you are asked how many states the initial state can reach. The fields wired in are combinatorics (lattice paths, binomial coefficients) and the invariant method (what does a move preserve, and is the preserved thing a complete description of the reachable states). Nothing about coins matters beyond their positions, because coins are indistinguishable and a configuration is a set.

What is really being tested is whether you count the right object. The coins are the wrong object: there are $(m-1)(n-1)$ of them, a big floppy set. The holes are the right object: there are exactly $mn-(m-1)(n-1) = m+n-1$ of them, the count never changes, and initially they form the last column together with the last row, an L shape. Read that L as a monotone lattice path from the top right corner $(1, n)$ down to (m, n) and then left to $(m, 1)$. The move needs three holes in the shape $(i, j+1), (i+1, j+1), (i+1, j)$, which is a corner of that path, and after the move the corner is replaced by $(i, j+1), (i, j), (i+1, j)$, the corner bent the other way.

Within thirty seconds you should have written: holes $= m+n-1$, initial holes form a path, a move flips one corner of the path. The rest is bookkeeping: the number of such paths is a binomial coefficient, and you must show every path is reached, which you do backwards.

Approaches, ranked worst to best

1. **Small cases and a guess.** *Cue:* the phrase "how many configurations" on a puzzle-shaped board. *Circuit:* tabulate, spot Pascal's triangle. (2×2 gives 2, 2×3 gives 3, 3×3 gives 6, 3×4 gives 10; the pattern $\binom{m+n-2}{m-1}$ is unmistakable, and a pattern earns the answer line and nothing else. Keep it only as a check on the real proof.)

2. **Track the coins.** *Cue:* every move is a diagonal slide of one coin. *Circuit:* monovariant on coin positions. (you can prove that each coin moves at most once and that the set of moved coins is closed under moving down and right, then count such sets. It is correct, but each of those statements is proved by looking at the holes anyway, so you pay for the same invariant twice.)

3. **Count the holes.** *Cue:* the complement has fixed size $m+n-1$ and starts as an L. *Circuit:* complement invariant plus a bijection. (the holes always form a monotone path; the map from reachable states to paths is injective by the invariant and surjective by undoing moves. Ideal: one invariant, one descent argument, one binomial coefficient.)

The ideal solution

A configuration is the set of occupied squares; write H for its complement, the set of holes. Every move keeps $|H| = mn-(m-1)(n-1) = m+n-1$.

Call H a *staircase* if $H = \{p_0, p_1, \ldots, p_{m+n-2}\}$ with $p_0 = (1, n)$, $p_{m+n-2} = (m, 1)$ and each difference $p_{s+1} - p_s$ equal to $(1, 0)$ (a step D) or $(0, -1)$ (a step L). A staircase is determined by its word in $\{D, L\}$, which has exactly $m-1$ letters D and $n-1$ letters L, and every such word gives a

staircase; so there are $\binom{m+n-2}{m-1}$ staircases. Along a staircase the first coordinate never decreases and the second never increases.

The initial hole set is the last column followed by the last row, the staircase with word $D^{m-1}L^{n-1}$.

Claim 3.7.1. *If H is a staircase and a legal move slides the coin at (i,j) to $(i+1,j+1)$, then the new hole set $H' = (H \setminus \{(i+1,j+1)\}) \cup \{(i,j)\}$ is a staircase, whose word is obtained from the word of H by replacing one adjacent pair DL by LD.*

Proof. The squares $(i,j+1)$, $(i+1,j+1)$, $(i+1,j)$ all lie in H. Let $p_s = (i,j+1)$. The next point p_{s+1} is $(i+1,j+1)$ or (i,j); if it were (i,j), every later point would have second coordinate at most j and every earlier point first coordinate at most i, so $(i+1,j+1)$ could not lie on the path at all. Hence $p_{s+1} = (i+1,j+1)$. Likewise p_{s+2} is $(i+2,j+1)$ or $(i+1,j)$; the first option would leave no room for $(i+1,j)$, whose second coordinate j is below everything before p_{s+1} and whose first coordinate $i+1$ is below everything after p_{s+2}. Hence $p_{s+2} = (i+1,j)$, so steps $s+1, s+2$ read DL. Replacing p_{s+1} by (i,j) turns them into LD, the endpoints are untouched because $0 < s+1 < m+n-2$, and the result is again a staircase. □

So every reachable hole set is a staircase, and distinct configurations have distinct hole sets: the reachable configurations inject into the $\binom{m+n-2}{m-1}$ staircases.

Claim 3.7.2. *Every staircase is the hole set of a reachable configuration.*

Proof. Induct on the number of inversions of the word, the number of pairs consisting of an L somewhere before a D. Zero inversions means the word $D^{m-1}L^{n-1}$, the initial configuration. Otherwise the word contains an adjacent LD: the path has $p_s = (i,j+1)$, $p_{s+1} = (i,j)$, $p_{s+2} = (i+1,j)$. Let H'' be the staircase with p_{s+1} replaced by $(i+1,j+1)$; its word has one inversion fewer, so by induction H'' is reachable. In that configuration the square (i,j) is occupied, it satisfies $i \le m-1$ and $j \le n-1$ because $(i+1,j)$ and $(i,j+1)$ are squares of the grid, and $(i+1,j)$, $(i,j+1)$, $(i+1,j+1)$ are holes. The slide from (i,j) to $(i+1,j+1)$ is therefore legal and produces exactly the hole set we started from. □

Reachable configurations and staircases are in bijection, so the number of reachable configurations is

$$\boxed{\binom{m+n-2}{m-1}}.$$

(When $m = 1$ or $n = 1$ there are no coins and the formula correctly gives 1.)

Layer 1: WHAT

Block 1: name the holes. They number $m+n-1$, the number is invariant, and the initial holes form an L, which is a monotone lattice path from $(1,n)$ to $(m,1)$.

Block 2: prove the invariant. A legal move needs three holes forming a corner of the path, and it flips that corner: DL becomes LD in the word.

Block 3: count. Words with $m-1$ letters D and $n-1$ letters L: $\binom{m+n-2}{m-1}$. This is an upper bound because the map from configurations to words is injective.

Block 4: surjectivity, backwards. Any word other than the initial one has an adjacent LD; un-flip it, apply induction on the inversion count, and check the forward move is legal.

Juxtaposition. The nominal route follows coins: which coins can move, in which order, and how far. You end up proving that each coin moves at most once and that moved coins form a down-right closed region, and both proofs secretly use the hole structure. The ideal route names the holes in the first line. The bifurcation point is the sentence in which you decide which set to describe: the $(m-1)(n-1)$ coins or the $m+n-1$ holes. The ideal solver picks the smaller, rigid set because invariants live in rigid objects.

Layer 2: HOW

Block 1. **Cue.** The move condition names three empty squares and one coin. Three quarters of the condition is about emptiness. **Why natural.** A configuration and its complement carry the same information, and the complement is tiny: $m+n-1$ against $(m-1)(n-1)$. Predicated on that, you describe the holes, and the initial holes are visibly an L, which is a lattice path. **Link to the next block.** Once holes are a path, the move must be read as an operation on the path.

Block 2. **Cue.** The three required holes $(i, j+1), (i+1, j+1), (i+1, j)$ are a down step followed by a left step. **Why natural.** On a monotone path the three squares can only be consecutive, so the move is exactly the local rewrite $DL \to LD$. This is the whole invariant: paths go to paths. **Link to the next block.** An injective map from states to words gives an upper bound; you now need the size of the target and surjectivity.

Block 3. **Cue.** Words with a fixed number of each letter. **Why natural.** Choosing the positions of the $m-1$ letters D among $m+n-2$ slots is a binomial coefficient by definition. **Link to the next block.** An upper bound is not an answer. Every word must be shown reachable, and forward simulation is clumsy, so go backwards.

Block 4. **Cue.** "Every word is reachable" plus a move that is an adjacent transposition. **Why natural.** Adjacent transpositions $LD \to DL$ sort any word to $D^{m-1}L^{n-1}$ and the inversion count strictly decreases, so induction on inversions terminates. The undo of a corner flip is a legal forward move because the three holes it needs are exactly the three squares of the corner, and (i, j) is occupied since it is not on the path. **Link to the next block.** Injective plus surjective is a bijection; write the boxed answer.

Layer 3: WHY

The mathematical truth beneath the route is that reachability questions decompose into two halves: an invariant (which states are possible) and a construction (which possible states are attained). A complete invariant is one where the two halves meet, and the count is then the count of invariant values. Here the invariant value is the staircase, the count of staircases is a binomial coefficient, and the construction is a sorting argument: adjacent transpositions of a two-letter word connect every arrangement to every other, with the inversion number as the monovariant that guarantees termination.

The second truth is the duality between a set and its complement. Every move is a swap of one square out of the occupied set and one into it; describing the swap on the side where the set is small and structured is always cheaper. The examiners nudged toward this by making three of the four squares in the move condition empty squares and by placing the coins so that the holes form the cleanest possible path.

The discernment mechanism: when you see "how many configurations can be reached", do not simulate. Ask what a move preserves, express the preserved thing as a standard combinatorial object (a path, a word, a subset), and only then ask whether every such object is reached. Train it by refusing, on every puzzle of this type, to write a single forward simulation before the invariant is on the page.

Revolving concepts

Monotone lattice paths. A path from one corner of an $a \times b$ box to the opposite corner using unit steps in two directions is a word with a letters of one kind and b of the other, so there are $\binom{a+b}{a}$ of them. The same word encodes a partition fitting inside the box (the region on one side of the path is

a Young diagram) and a subset of size a of $\{1, \ldots, a+b\}$. See Book 1, field: Combinatorics, topic: lattice paths.

The recursion, generalised. Writing $P(a,b)$ for the number of paths, the first step gives $P(a,b) = P(a-1,b) + P(a,b-1)$ with $P(a,0) = P(0,b) = 1$, Pascal's recursion, whose solution is the binomial coefficient. Every count of words by their first letter obeys a recursion of this shape; the general method is the two-variable generating function, here $\sum P(a,b)x^a y^b = 1/(1-x-y)$. Refining by area (the number of squares under the path) turns the recursion into $P_q(a,b) = P_q(a-1,b) + q^a P_q(a,b-1)$ and the solution into the Gaussian binomial coefficient; this is the natural next question once you know each coin moves at most once, because the area is the number of moves made.

Invariants and monovariants. An invariant restricts the reachable set; a monovariant (here the inversion number of the word) proves that a backward process terminates, hence that a forward process exists. Reachability counts on a state graph are always "invariant for the upper bound, construction for the lower bound". See Book 1, field: Games and invariants, topic: reachability and complete invariants.

Sorting by adjacent transpositions. Any arrangement of a multiset can be turned into any other by swapping adjacent letters, and the minimal number of swaps between two arrangements of a two-letter word is the difference of inversion counts. In B1 that says the longest legal play has exactly $(m-1)(n-1)$ moves, one per coin.

Circuit Bank

- **WHEN** you see "reachable configurations" of tokens with a local move **DO** write down the complement set, its size, and its initial shape before anything else **BECAUSE** the invariant lives in the smaller and more rigid of the two sets, and a move is a swap seen from either side
- **WHEN** you see a monotone lattice path with a local corner move **DO** encode the path as a two-letter word, the move as an adjacent transposition, and count words by a binomial coefficient **BECAUSE** adjacent transpositions connect all arrangements, and the inversion number is the monovariant that proves it
- **WHEN** you must show every object of some kind is reachable **DO** work backwards from the target with a potential that strictly decreases, and check that the undo step is a legal forward move **BECAUSE** forward simulation branches, backward descent terminates

Backtesting

1. First useful cue: three of the four squares named in the move condition are empty squares, and the empties number $m+n-1$.
2. Method the expression suggested: complement invariant, then lattice paths, then a backward descent for surjectivity.
3. Where you would hesitate, and the thought to reinforce: proving that the three holes are consecutive on the path. The thought is monotonicity: coordinates move one way only, so a square with a larger first coordinate cannot come earlier and a square with a smaller second coordinate cannot come later.
4. The trap the question sets: describing coins. You will try to prove "a coin moves at most once" from scratch and burn ten minutes proving a lemma the hole path gives for free.
5. What makes you recognise it faster next time: any move that requires an L-shaped cluster of empties is a corner flip of a boundary path.
6. The reusable decision rule: in a reachability count, name the invariant object as a standard combinatorial object, count that, then prove surjectivity backwards with a monovariant.

Mirror drills

1. (drill) n tokens sit on cells $1, \dots, n$ of a strip of $n + k$ cells; a token may move one cell to the right into an empty cell. How many configurations are reachable? *Answer:* every n-subset of the cells, $\binom{n+k}{n}$; the one-dimensional version of the same invariant (tokens keep their order) and the same backward descent (the rightmost token that is not yet in place can always be moved).
2. (drill) In B1, what is the length of the longest sequence of legal moves? *Answer:* $(m-1)(n-1)$; each move raises the inversion count of the hole word by exactly one, the maximum inversion count is $(m-1)(n-1)$, and the word $L^{n-1}D^{m-1}$ is reachable.
3. (drill) How many partitions have Young diagrams that fit inside an $a \times b$ box? *Answer:* $\binom{a+b}{a}$; the boundary of the diagram is a monotone lattice path across the box, and the correspondence is a bijection.

3.8 B2. Binary weight of the multiples of 2023

For each positive integer n, let $k(n)$ be the number of ones in the binary representation of $2023 \cdot n$. What is the minimum value of $k(n)$?

Read it out loud

You are asked for the smallest number of ones that any multiple of 2023 can have in binary. A number with k ones is a sum of k distinct powers of two, so the question is: what is the least k for which some sum of k distinct powers of two is divisible by 2023. That is a statement about the residues of $2, 4, 8, \ldots$ modulo 2023, and residues of powers are governed by multiplicative orders. The fields wired in are number theory (orders, Euler's theorem, the Chinese remainder theorem) and the arithmetic of binary representations; there is no combinatorics here, despite the counting language.

The first thing to write is the factorisation $2023 = 7 \cdot 17^2$. The second thing is to look at the two prime powers in binary: $7 = 111_2$ and $289 = 100100001_2$, both of weight three. That is a planted cue: each factor is, on its own, a weight-three number, so the only job on the construction side is to align exponents so that both divisibilities hold at once. On the obstruction side, weight one is out immediately (a power of two has no odd factor) and weight two means $2^c \equiv -1$ modulo 2023, hence modulo 7, and 2 has order 3 modulo 7, which is odd. The circuit that must fire: -1 is a power of g modulo a prime if and only if the order of g is even.

Within thirty seconds you should have: "$2023 = 7 \cdot 17^2$; weight 1 impossible; weight 2 needs $2^c \equiv -1 \pmod 7$, impossible since $2^c \in \{1, 2, 4\}$; so the answer is at least 3, and I now need $a \neq b$ with $2023 \mid 2^a + 2^b + 1$."

Approaches, ranked worst to best

1. **Search for a small multiple.** *Cue:* "minimum value" of a digit count. *Circuit:* compute $2023n$ for $n = 1, 2, 3, \ldots$ and count ones. (hopeless in the arena and silent about the lower bound; the smallest multiple of weight three is $2^{77} + 2^{16} + 1$, so a hand search never arrives.)

2. **Chase the residues of 2^c modulo 2023 directly.** *Cue:* binary digits are powers of two. *Circuit:* tabulate 2^c mod 2023 until two residues sum to 2022. (the period is $\operatorname{lcm}(3, 136) = 408$, so this is the search above in disguise.)

3. **Lower bound by an odd order, upper bound by aligning exponents with CRT.** *Cue:* $2023 = 7 \cdot 17^2$, and 7, 289 are both weight three in binary. *Circuit:* multiplicative order plus Chinese remainder theorem on the exponents. (mechanical: one obstruction modulo 7 rules out weight two, one congruence system on the exponents produces a weight-three multiple. Ideal.)

The official second solution finds the smaller witness $2^{77} + 2^{16} + 1$ from $2^{68} \equiv -1 \pmod{289}$ and $(2^8 - 1)^2 \equiv 0 \pmod{289}$; it is shorter on the page but needs an observation the CRT route does not, so it ranks as a variant of the ideal, not above it.

The ideal solution

The minimum is 3. Throughout, $2023 = 7 \cdot 17^2 = 7 \cdot 289$, and $k(n)$ is the number of distinct powers of two whose sum is $2023n$.

Lower bound. If $k(n) = 1$ then $2023n = 2^a$, impossible because 7 divides the left side and not the right. If $k(n) = 2$ then $2023n = 2^a + 2^b$ with $a > b \geq 0$, so 7 divides $2^b(2^{a-b} + 1)$, and as 7 is odd, 7 divides $2^c + 1$ with $c = a - b \geq 1$. But $2^3 = 8 \equiv 1 \pmod 7$, so $2^c \bmod 7$ is one of $1, 2, 4$ and never 6. Hence $k(n) \geq 3$ for every n.

Upper bound. It suffices to find distinct positive integers a, b with $2023 \mid 2^a + 2^b + 1$: then $n = (2^a + 2^b + 1)/2023$ is a positive integer and $2023n$ has exactly three ones in binary.

Modulo 7: $2^2 + 2^1 + 1 = 7$, and $2^3 \equiv 1 \pmod 7$, so $7 \mid 2^a + 2^b + 1$ whenever $a \equiv 2$ and $b \equiv 1 \pmod 3$.

Modulo 289: $2^8 + 2^5 + 1 = 256 + 32 + 1 = 289$, and $2^{272} \equiv 1 \pmod{289}$ by Euler's theorem because $\varphi(289) = 17 \cdot 16 = 272$ and $\gcd(2, 289) = 1$; so $289 \mid 2^a + 2^b + 1$ whenever $a \equiv 8$ and $b \equiv 5 \pmod{272}$.

Take $a = 8$ and $b = 277 = 272 + 5$. Then $a \equiv 2 \pmod 3$ and $b \equiv 1 \pmod 3$ (as $277 = 3 \cdot 92 + 1$), while $a \equiv 8$ and $b \equiv 5 \pmod{272}$. Both divisibilities hold, and $\gcd(7, 289) = 1$, so $2023 \mid 2^{277} + 2^8 + 1$. Thus $k(n) = 3$ for $n = (2^{277} + 2^8 + 1)/2023$, and the minimum value of $k(n)$ is

$$\boxed{3}.$$

A caveat worth clarifying. The choice $a = 8$, $b = 277$ came from solving $a \equiv 2 \pmod 3$, $a \equiv 8 \pmod{272}$ and $b \equiv 1 \pmod 3$, $b \equiv 5 \pmod{272}$; the Chinese remainder theorem guarantees solutions because $\gcd(3, 272) = 1$, and any solution pair with $a \neq b$ works. The smallest multiple of 2023 with three ones is in fact $2^{77} + 2^{16} + 1$, but the question asks for the minimum weight, not the minimum multiple, and you must not spend arena time on the latter.

Layer 1: WHAT

Block 1: factor $2023 = 7 \cdot 17^2$ and translate "$k(n) = k$" into "some sum of k distinct powers of two is divisible by 2023".

Block 2: kill weight one (odd factor) and weight two (it would force $2^c \equiv -1 \pmod 7$, but the order of 2 modulo 7 is 3, so -1 is not a power of 2 there).

Block 3: aim at weight three modulo each prime power separately, using the prime powers' own binary expansions as witnesses: $7 = 2^2 + 2^1 + 1$, $289 = 2^8 + 2^5 + 1$.

Block 4: convert each witness into congruence conditions on the exponents via the period of 2^c (period 3 modulo 7, period dividing 272 modulo 289), align them by CRT, write down $a = 8$, $b = 277$.

Juxtaposition. The zombie route multiplies 2023 by successive n and counts ones, or tabulates 2^c mod 2023. The ideal route never looks at a multiple of 2023 at all; it looks at the subgroup of $(\mathbb{Z}/2023)^\times$ generated by 2 and at its projections modulo 7 and modulo 289. The bifurcation point is Block 1: whether you read $k(n)$ as a property of the product $2023n$ or as a divisibility condition on a sum of powers of two.

Layer 2: HOW

Block 1. Cue. A digit count of a multiple of a fixed odd number. **Why natural.** A binary number with k ones is $2^{a_1} + \cdots + 2^{a_k}$ with distinct exponents, so "some multiple has weight k" is exactly "some such sum is $\equiv 0 \pmod{2023}$". Predicated on that, the problem lives in modular arithmetic, and the first act in modular arithmetic is to factor the modulus. **Link to the next block.** Small k can now be tested one at a time against the prime factors.

Block 2. Cue. Weight two means $2^a + 2^b \equiv 0$, that is $2^{a-b} \equiv -1$ modulo any odd prime factor. **Why natural.** In the cyclic group generated by 2 modulo p, the element -1 is the unique element of order 2, so it lies in the group if and only if the order of 2 is even. Modulo 7 the order is 3: the obstruction is a single line. You do not need 17 at all for the lower bound; one obstruction suffices. **Link to the next block.** The lower bound is 3, so the remaining work is a construction of weight exactly three.

Block 3. **Cue.** $7 = 111_2$ and $289 = 100100001_2$. **Why natural.** A weight-three multiple of 7 and a weight-three multiple of 289 are handed to you by the numbers themselves. Since $2^c \bmod m$ depends only on c modulo the order of 2, each witness is really a pair of residue classes for the exponents. **Link to the next block.** Two congruence systems on the exponents, with moduli 3 and 272 (or the true order 136), must be solved simultaneously.

Block 4. **Cue.** Congruences on a with coprime moduli, and the same for b. **Why natural.** The Chinese remainder theorem is precisely the statement that such systems are solvable; $a = 8$ already satisfies both of its conditions, and $b = 5 + 272 = 277$ satisfies both of its. Coprimality of 7 and 289 then upgrades the two divisibilities to divisibility by 2023. **Link to the next block.** Write n explicitly and box the answer.

Layer 3: WHY

The truth underneath is that the residues of 2^c modulo an odd m form a purely periodic sequence whose period is the multiplicative order of 2, so any statement about which sums of powers of two are divisible by m is a statement about a finite cyclic group. Weight one asks whether 0 is in the group (never). Weight two asks whether -1 is in it, and -1 is in a cyclic subgroup of $(\mathbb{Z}/p)^\times$ exactly when that subgroup has even order. Weight three asks whether some $2^a + 2^b \equiv -1$, and once the modulus is a product of coprime pieces this decouples into independent alignment problems on the exponents.

The examiners chose the modulus with care. The factor 7 is there to block weight two (order 3, odd); the factor 17 alone would not block it, since $2^4 \equiv -1 \pmod{17}$. The square 17^2 is there so that you must handle a prime power, either by Euler's $\varphi(289) = 272$ or by lifting the order from 17 to 289. And both prime powers have weight three in binary, which is the guiding light for the construction.

The discernment mechanism: whenever a question mentions digits of a multiple of a fixed number, replace the digits by the residues of the base's powers, factor the modulus, and think in terms of orders. Train it by asking, for every odd m you meet, what the order of 2 is and whether it is even; that single bit of information decides the weight-two question forever.

Revolving concepts

Multiplicative order. For $\gcd(g, m) = 1$, $\mathrm{ord}_m(g)$ is the least $d \geq 1$ with $g^d \equiv 1 \pmod{m}$; then $g^s \equiv g^t$ if and only if $s \equiv t \pmod{d}$, and $d \mid \varphi(m)$ (Euler). Here $\mathrm{ord}_7(2) = 3$, $\mathrm{ord}_{17}(2) = 8$, $\mathrm{ord}_{289}(2) = 136$. See Book 1, field: Number theory, topic: multiplicative order.

The recursion, generalised. The residues $r_c = 2^c \bmod m$ satisfy $r_{c+1} \equiv 2r_c$, an invertible map on a finite set, so the sequence is purely periodic from $c = 0$ with period $\mathrm{ord}_m(2)$. Any sequence defined by iterating an invertible map on a finite set is purely periodic; if the map is not invertible (for instance $2^c \bmod m$ with m even) the sequence is eventually periodic after a pre-period given by the largest power of 2 dividing m. That is the general solution method for "powers modulo m": strip the part of m sharing factors with the base, then work in the unit group.

The even-order lemma. For an odd prime p and $p \nmid g$: -1 is a power of g modulo p if and only if $\mathrm{ord}_p(g)$ is even. Proof: the subgroup generated by g is cyclic of order d and contains an element of order 2 if and only if $2 \mid d$; and -1 is the unique element of order 2 in $(\mathbb{Z}/p)^\times$ because $x^2 \equiv 1$ has only the roots ± 1 modulo a prime. The same holds modulo odd prime powers.

Orders modulo prime powers. If $d = \mathrm{ord}_p(g)$ for an odd prime p, then $\mathrm{ord}_{p^e}(g) = d \cdot p^{\max(0, e - v_p(g^d - 1))}$; this is the lifting-the-exponent lemma in disguise. For $g = 2$, $p = 17$: $2^8 - 1 = 255 = 15 \cdot 17$ has $v_{17} = 1$, so $\mathrm{ord}_{289}(2) = 8 \cdot 17 = 136$, and then $2^{68} \equiv -1 \pmod{289}$. That is where the smaller witness $2^{77} + 2^{16} + 1$ comes from. See Book 1, field: Number theory, topic: lifting the exponent.

Chinese remainder theorem, used twice. Once on the modulus ($2023 \mid x$ if and only if $7 \mid x$ and $289 \mid x$), once on the exponents (a mod 3 and a mod 272 can be prescribed independently). See Book 1, field: Number theory, topic: Chinese remainder theorem.

Binary repunits. Every odd m divides $2^{\mathrm{ord}_m(2)} - 1$, a string of ones, so the minimum weight of a multiple of m is at most $\mathrm{ord}_m(2)$; the exact minimum has no closed form and is a genuine research-level question in general, which is why the examiners chose a modulus where it is 3.

Circuit Bank

- **WHEN** you see the number of ones in the binary expansion of a multiple of m **DO** write "weight k multiple exists iff $2^{a_1} + \cdots + 2^{a_k} \equiv 0 \pmod{m}$ for distinct a_i", then factor m and reduce the exponents modulo $\mathrm{ord}_m(2)$ **BECAUSE** the residues of powers of two are periodic with period equal to the order
- **WHEN** you must decide whether weight two is possible **DO** check, for one odd prime factor p, whether $\mathrm{ord}_p(2)$ is even **BECAUSE** $2^c \equiv -1 \pmod{p}$ holds for some c exactly when the order is even, and one odd-order prime factor is a complete obstruction
- **WHEN** you must construct a multiple of a composite m with a prescribed shape **DO** solve modulo each prime power with the smallest witness visible (often the binary expansion of the prime power itself), then align the exponent classes by CRT **BECAUSE** exponent conditions modulo coprime periods are simultaneously solvable
- **WHEN** you see a prime power modulus p^e with p odd **DO** use $\varphi(p^e)$ for a safe period, or lift the order from p with $v_p(g^d - 1)$ when you need the exact one **BECAUSE** Euler's theorem is always available; the exact order is only needed for sharper witnesses

Backtesting

1. First useful cue: $2023 = 7 \cdot 17^2$, with 7 and 289 both of binary weight three.
2. Method the expression suggested: an order obstruction modulo 7 for the lower bound and CRT on exponents for the upper bound.
3. Where you would hesitate, and the thought to reinforce: whether 17 must be checked in the lower bound. It must not; a lower bound needs one obstruction, and 7 provides it. Reinforce: prove impossibility with the smallest modulus that works.
4. The trap the question sets: hunting for the smallest n. The minimum weight is 3 regardless of which witness you find, and the smallest witness has 78 binary digits.
5. What makes you recognise it faster next time: "few ones in a multiple" is a question about the subgroup generated by 2, and "weight two" is the single bit "is the order even".
6. The reusable decision rule: lower bounds from odd orders, upper bounds from CRT alignment of exponents, and never touch the multiples themselves.

Mirror drills

1. (drill) What is the minimum number of ones in the binary expansion of a positive multiple of 23? *Answer:* 3; $\mathrm{ord}_{23}(2) = 11$ is odd so weight two is impossible, and $2^6 + 2^2 + 1 = 69 = 3 \cdot 23$.
2. (drill) For which odd primes p does some multiple of p have exactly two ones in binary? *Answer:* exactly those with $\mathrm{ord}_p(2)$ even, since $2^a + 2^b \equiv 0$ forces $2^{a-b} \equiv -1$; so $3, 5, 17$ qualify and $7, 23, 31, 89$ do not ($\mathrm{ord}_{89}(2) = 11$ because $2^{11} - 1 = 2047 = 23 \cdot 89$).

3. (drill) Given $2^4 \equiv -1 \pmod{17}$, show $2^{68} \equiv -1 \pmod{289}$. *Answer:* $2^{68} = (17-1)^{17} = \sum_k \binom{17}{k} 17^k (-1)^{17-k}$; the $k = 0$ term is -1, the $k = 1$ term is $17 \cdot 17$, and every later term has a factor 17^2.

3.9 B3. Expected length of the longest zigzag subsequence

A sequence $y_1, y_2, \ldots, y_k$ of real numbers is called zigzag *if $k = 1$, or if $y_2 - y_1, y_3 - y_2, \ldots, y_k - y_{k-1}$ are nonzero and alternate in sign. Let $X_1, X_2, \ldots, X_n$ be chosen independently from the uniform distribution on $[0, 1]$. Let $a(X_1, X_2, \ldots, X_n)$ be the largest value of k for which there exists an increasing sequence of integers $i_1, i_2, \ldots, i_k$ such that $X_{i_1}, X_{i_2}, \ldots, X_{i_k}$ is zigzag. Find the expected value of $a(X_1, X_2, \ldots, X_n)$ for $n \geq 2$.*

Read it out loud

This is an expectation of a combinatorial statistic of a random ordering. Say that sentence and half the question dies. The words "uniform distribution on $[0, 1]$" are dressing: continuous independent samples are almost surely distinct, and every one of the $n!$ orderings of $X_1, \ldots, X_n$ is equally likely by symmetry. The quantity a depends only on which of the X_i is bigger than which, so a is a function of a uniformly random permutation. No integral over $[0, 1]^n$ will ever be needed, and if you find yourself setting one up you have misread the question.

The second structural feature: a is defined as a maximum over an exponentially large family of subsequences, and expectation does not commute with maxima. So the only viable plan is to destroy the maximum, that is, to prove a structure theorem replacing the global optimisation by a count of local features. Once a is a sum of indicators, linearity of expectation finishes the job in one line, and linearity of expectation does not care that the indicators are wildly dependent. That is the whole design of the problem: it is a linearity of expectation problem hiding behind an extremal problem.

The fields wired in: order statistics only to the extent of exchangeability, extremal combinatorics for the structure theorem, and elementary probability for the last step. What is really being tested is whether you convert "longest alternating subsequence" into "number of direction changes", which is the standard structure theorem for this statistic.

Within thirty seconds you should have written two things: "only the ordering matters, so this is a random permutation", and "a must be a local count, guess a window of three consecutive terms". The second guess is cheap to justify in advance: the answer is asked for general $n \geq 2$, so it is almost certainly affine in n, and an affine answer with a non-integer slope smells of a probability like $2/3$ attached to $n - 2$ interior positions.

Approaches, ranked worst to best

1. **Integrate over the cube.** *Cue:* "uniform distribution on $[0, 1]$". *Circuit:* when you see a continuous density, integrate. You would need to partition $[0, 1]^n$ into regions where a is constant, which is exactly the combinatorial problem you were trying to avoid, now carrying a Jacobian. It costs enormous ink and answers nothing. The cue is a decoy planted by the setter.

2. **Compute the full distribution of a.** *Cue:* "find the expected value". *Circuit:* expectation equals sum over values times probability. You count permutations of $\{1, \ldots, n\}$ with longest zigzag exactly k, then sum k times that count. Those counts are the Eulerian-flavoured numbers for alternating runs; they exist, but you are computing a whole distribution to extract one moment. Ranked low because it is strictly more work than the question asks for.

3. **Markov chain on the last direction.** *Cue:* sequential structure, one new sample at a time. *Circuit:* model the process, condition on the newest term. Track the state "direction of the current run" and update as each X_i arrives. This works and gives $2/3$ per step, but you must justify that the new term extends or breaks the run with the right probabilities, and the state space is unnecessary once you see the local characterisation.

4. **Increment recursion on n.** *Cue:* "for $n \geq 2$", answer requested as a function of n. *Circuit:* define a_n, study $a_n - a_{n-1}$. Prove $a_n - a_{n-1} \in \{0, 1\}$ and equals 0 exactly when the last three terms are monotone, then induct. This is genuinely good and it is essentially the official route. It still needs the structure theorem to know what a_n counts, and it spends an induction where none is needed.

5. **Runs, then local extrema, then linearity.** *Cue:* a maximum over subsequences that you cannot integrate. *Circuit:* convert a global extremal statistic into a count of local features, then apply linearity of expectation. Prove $a = N + 1$ where N is the number of maximal monotone runs, note that $N - 1$ counts interior local extrema, and finish with $\Pr(\text{local extremum}) = 2/3$. Best: one structure theorem, no induction, no conditioning, and the same two moves work on every "expected length of the longest something" problem.

The ideal solution

The answer is $\boxed{\dfrac{2n+2}{3}}$.

Since the X_i are independent with a continuous distribution, they are almost surely pairwise distinct, and all $n!$ relative orderings are equally likely. Work on that event throughout, so that every difference $X_{i+1} - X_i$ is nonzero.

For a finite sequence $x = (x_1, \ldots, x_k)$ of distinct reals with $k \geq 2$, let $\varepsilon(x) = (\varepsilon_1, \ldots, \varepsilon_{k-1})$ be its sign word, $\varepsilon_i = \operatorname{sgn}(x_{i+1} - x_i) \in \{+, -\}$, and let $N(x)$ be one plus the number of indices i with $\varepsilon_i \neq \varepsilon_{i+1}$. Thus $N(x)$ is the number of maximal monotone runs of x, and x is zigzag exactly when $N(x) = k - 1$, that is, when its sign word alternates at every position.

Lemma 3.9.1. *If y is obtained from x by deleting one term, then $N(y) \leq N(x)$.*

Proof. Deleting x_1 or x_k deletes an end letter of the sign word, and deleting an end letter cannot increase the number of adjacent unequal pairs. Now delete an interior term x_i with $1 < i < k$. The two differences $d_{i-1} = x_i - x_{i-1}$ and $d_i = x_{i+1} - x_i$ are replaced by the single difference $d_{i-1} + d_i = x_{i+1} - x_{i-1}$, which is nonzero and whose sign is the sign of d_{i-1} or of d_i (if the two agree, the sum has that common sign; if they disagree, the sum has the sign of whichever is larger in magnitude). So the new sign word is obtained from $\varepsilon(x)$ by deleting one letter. Deleting the letter in position p of a word w replaces the two adjacent pairs (w_{p-1}, w_p) and (w_p, w_{p+1}) by the single pair (w_{p-1}, w_{p+1}), and

$$[\, w_{p-1} \neq w_{p+1} \,] \leq [\, w_{p-1} \neq w_p \,] + [\, w_p \neq w_{p+1} \,],$$

so the number of adjacent unequal pairs cannot increase. Hence $N(y) \leq N(x)$. □

Proposition 3.9.2. *For distinct reals $x_1, \ldots, x_n$ with $n \geq 2$, the longest zigzag subsequence has length $a(x) = N(x) + 1$.*

Proof. Lower bound. Write the maximal runs of x as index blocks $[p_0, p_1], [p_1, p_2], \ldots, [p_{N-1}, p_N]$ with $p_0 = 1$ and $p_N = n$, consecutive blocks having opposite directions. The subsequence $x_{p_0}, x_{p_1}, \ldots, x_{p_N}$ has consecutive differences that are nonzero (the terms are distinct) and alternate in sign (each block is monotone in the direction opposite to its neighbours), so it is a zigzag of length $N + 1$, giving $a(x) \geq N + 1$.

Upper bound. Let $x_{i_1}, \ldots, x_{i_m}$ be any zigzag subsequence with $m \geq 2$. It is obtained from x by deleting terms one at a time, so the lemma gives $N(x_{i_1}, \ldots, x_{i_m}) \leq N(x)$. But a zigzag of length m has $N = m - 1$. Hence $m - 1 \leq N(x)$, that is, $m \leq N(x) + 1$. □

Now localise. By definition $N(x) = 1 + \#\{i : 2 \leq i \leq n - 1,\ \varepsilon_{i-1} \neq \varepsilon_i\}$, and $\varepsilon_{i-1} \neq \varepsilon_i$ says exactly that x_{i-1}, x_i, x_{i+1} is not monotone, that is, x_i is a strict local extremum. Therefore, writing Z_i

for the indicator that X_{i-1}, X_i, X_{i+1} is not monotone,

$$a(X_1, \dots, X_n) = N + 1 = 2 + \sum_{i=2}^{n-1} Z_i.$$

For each fixed i the three variables X_{i-1}, X_i, X_{i+1} are independent and identically distributed with a continuous law, so their six relative orderings are equally likely, and exactly two of them (increasing and decreasing) are monotone. Hence $\Pr(Z_i = 1) = 1 - \frac{2}{6} = \frac{2}{3}$.

The Z_i are certainly not independent, but expectation is linear regardless, so

$$\mathbf{E}\big[a(X_1, \dots, X_n)\big] = 2 + \sum_{i=2}^{n-1} \mathbf{E}[Z_i] = 2 + (n-2) \cdot \frac{2}{3} = \frac{2n+2}{3}.$$

For $n = 2$ the sum is empty and the formula returns 2, which is correct since any two distinct reals form a zigzag. ■

Layer 1: WHAT

Block 1. Only the relative order of the X_i matters, and all orderings are equally likely: replace the sample by a uniformly random permutation and record that the values are almost surely distinct.

Block 2. Guess the structure theorem: the longest zigzag is forced by the run decomposition of the whole sequence, $a = N + 1$.

Block 3. Prove the easy half by exhibiting the run endpoints as an explicit zigzag.

Block 4. Prove the hard half by the deletion lemma: passing to a subsequence never increases the number of runs, and a zigzag of length m has exactly $m - 1$ runs.

Block 5. Localise: a new run starts exactly at an interior local extremum, so $a = 2 + \sum_{i=2}^{n-1} Z_i$.

Block 6. Apply linearity of expectation with $\Pr(Z_i = 1) = 2/3$.

Juxtaposition. The nominal route reads "uniform on $[0, 1]$" and "expected value" and starts building the distribution of a, either by integration over the cube or by counting permutations with a given longest zigzag. It will produce, after a great deal of ink, the same $2/3$ slope, because that slope was never about the distribution of a. The bifurcation point is the sentence "expectation does not commute with a maximum, so I must remove the maximum before I take any expectation". Everything upstream of that sentence is shared; everything downstream is a different problem.

Layer 2: HOW

Block 1. **Cue.** Independent continuous samples and a statistic defined purely by comparisons. **Why natural.** a is invariant under any strictly increasing map applied to all the X_i, and the uniform distribution has no other role than to make ties impossible and orderings symmetric. A statistic that only sees comparisons must be studied on the symmetric group, not on the cube. **Link to the next block.** Once the object is a random permutation, the only tools left are combinatorial, which forces you to look for combinatorial structure in a.

Block 2. **Cue.** A maximum over all increasing index sequences, which is far too large to enumerate. **Why natural.** Whenever a quantity is defined as the largest sub-object with a local alternating property, the extremal object is built greedily from the ambient object, and the greedy construction always uses turning points. So conjecture that a is determined by the turning points of the whole sequence and verify on small cases: $(1, 2, 3)$ gives $N = 1$, $a = 2$; $(2, 1, 3)$ gives $N = 2$, $a = 3$. **Link to the next block.** The conjecture $a = N + 1$ splits cleanly into a construction and a bound, which is the standard shape of an extremal proof.

Block 3. **Cue.** "There exists an increasing sequence of integers" is an existence claim. **Why natural.** Existence claims are discharged by exhibiting one object. The run endpoints are the canonical candidate because consecutive runs point in opposite directions by maximality, which is precisely the alternation required. **Link to the next block.** The construction gives $a \geq N + 1$; the burden shifts to proving nothing longer exists.

Block 4. **Cue.** An upper bound on all subsequences at once. **Why natural.** You cannot inspect all subsequences, so find a quantity that is monotone under the operation "delete one term". The number of runs is such a quantity, and the proof is at the level of the sign word: deleting a term merges two adjacent differences into their sum, and the sum inherits one of the two signs, so the sign word loses exactly one letter. Deleting a letter from a word cannot create new adjacent disagreements, by the triangle inequality for the indicator of inequality. **Link to the next block.** With N monotone under deletion and a zigzag of length m having $N = m - 1$, the bound $m \leq N + 1$ is immediate, closing the structure theorem.

Block 5. **Cue.** N is defined by a condition on consecutive pairs of differences, that is, on windows of three consecutive terms. **Why natural.** A count of positions where a local pattern occurs is by definition a sum of indicators, one per position. This is the move that converts a global statistic into something linearity of expectation can eat. **Link to the next block.** Now every Z_i has the same law by exchangeability, so one three-variable computation settles all of them.

Block 6. **Cue.** A sum of indicators inside an expectation. **Why natural.** Linearity of expectation holds with no independence assumption whatsoever, which is exactly why the localisation was worth so much. The individual probability is a symmetry count: six orderings of three distinct exchangeable values, two of them monotone. **Link to the next block.** Sum and simplify: $2 + \frac{2}{3}(n - 2)$.

Layer 3: WHY

The mathematical truth underneath is that the longest alternating subsequence is not really an optimisation at all. The map "sequence to sign word" turns the problem into a question about words in a two letter alphabet, and under that map taking a subsequence becomes deleting letters and merging, an operation that can only reduce the number of alternations. So the maximum is achieved by the most obvious candidate, and the extremal value is a linear functional of the ambient word. Any statistic with that shape, a maximum which is secretly a count, is one localisation away from linearity of expectation.

The discernment mechanism has two parts. First, ask what the statistic actually depends on. Here it depends only on comparisons, so the continuous distribution is decoration; recognising decoration early is worth more marks than any calculation. Second, ask whether the maximum is attained by a canonical object. If yes, the maximum is not an optimisation but a formula, and formulas can be expanded into sums of local terms. If you cannot see the canonical object, test $n = 3$ and $n = 4$ by hand: two minutes of small cases would have suggested $a = N + 1$ to anyone.

To train it, take the three standard "expected value of a maximum" traps and force each one through the same pipeline: identify the invariance, find the structure theorem, localise, then use linearity. The reason this pipeline beats conditioning arguments is that dependence between the local indicators is free. You should feel physically reluctant to compute a distribution when only a mean is requested.

What the setters nudged with: they wrote "for $n \geq 2$", telling you the answer is a formula in n, and they defined zigzag through consecutive differences rather than through any global property, pointing you at differences and therefore at windows of three. They also chose the

uniform distribution on $[0,1]$ rather than saying "a uniformly random permutation", because the disguise is the only difficulty they had left to add.

Revolving concepts

Zigzag (alternating) sequence. A sequence whose consecutive differences are nonzero and alternate in sign. Equivalent formulation: its sign word is $+-+-\cdots$ or $-+-+\cdots$. The longest alternating subsequence of a permutation of $\{1,\dots,n\}$ has mean $(2n+2)/3$ and is concentrated around it; the enumeration of permutations by number of alternating runs is classical and connects to the tangent and secant numbers through Andre's theorem on alternating permutations, where the count of alternating permutations of length n has exponential generating function $\tan x + \sec x$. See Book 1, field: Combinatorics, topic: alternating permutations.

Runs and descents. For a sequence of distinct reals, a descent is an index i with $x_i > x_{i+1}$, and the maximal monotone runs are the blocks cut out by the sign word. The number of runs is 1 plus the number of sign changes; the number of descents is the number of minus letters. Descent statistics on permutations are governed by Eulerian numbers. See Book 1, field: Combinatorics, topic: descents and Eulerian numbers.

Linearity of expectation. For any random variables $Y_1,\dots,Y_m$ with finite means, $\mathbf{E}[\sum Y_i] = \sum \mathbf{E}[Y_i]$, with no independence required. This is the single highest-yield probabilistic tool on the Putnam, because it converts a hard joint distribution into m easy marginals. See Book 1, field: Probability, topic: linearity and indicators.

Exchangeability and the six orderings. If $Y_1,\dots,Y_k$ are independent and identically distributed with a continuous law, then all $k!$ relative orderings have probability $1/k!$ and ties have probability zero. For $k = 3$ this gives the constant $2/3$ used above. See Book 1, field: Probability, topic: exchangeability and order statistics.

Recursion, generalised. The increment form of this problem is a first order linear recursion with constant increment: $\mathbf{E}[a_n] = \mathbf{E}[a_{n-1}] + c$ for $n \geq 3$ with $c = 2/3$ and initial value $\mathbf{E}[a_2] = 2$, whose solution is $\mathbf{E}[a_n] = \mathbf{E}[a_2] + c(n-2)$. The general statement worth installing: if a statistic A_n of the first n terms of an exchangeable sequence satisfies $A_n - A_{n-1} = \mathbf{1}[\text{a local pattern occupies the last } w \text{ terms}]$, then $\mathbf{E}[A_n] = \mathbf{E}[A_{w-1}] + p\,(n-w+1)$ where p is the probability of that pattern in a window of length w. Every "expected number of records", "expected number of local maxima", "expected number of ascents" question is this recursion with a different p (records give the non-constant increment $1/n$, which telescopes to a harmonic number instead). See Book 1, field: Sequences and recurrences, topic: first order recursions with constant increment.

Circuit Bank

- **WHEN** you see independent samples from a continuous distribution and a statistic defined only by comparisons **DO** replace the sample by a uniformly random permutation and record that ties have probability zero **BECAUSE** the statistic is invariant under increasing reparametrisation, so the density is decoration and only the ordering carries information
- **WHEN** you see an expectation of a maximum over exponentially many objects **DO** first prove a structure theorem that turns the maximum into a count of local features, and only then take expectations **BECAUSE** expectation does not commute with maxima, but it does commute with sums, so a maximum must be converted into a sum before any probability is used
- **WHEN** you see a count of positions at which a local pattern occurs **DO** write it as $\sum_i Z_i$ with Z_i an indicator, and use linearity of expectation **BECAUSE** linearity needs no independence, so heavy dependence between the Z_i costs you nothing

- **WHEN** you need an upper bound valid for all subsequences at once **DO** find a quantity that is monotone under deleting a single term, and induct on deletions **BECAUSE** a subsequence is a finite sequence of single deletions, so a one step monotonicity statement upgrades automatically to all subsequences

Backtesting

1. First useful cue: the statistic depends only on comparisons between the X_i, so the uniform distribution reduces to a uniformly random permutation with no ties.
2. Method the expression suggested: alternation is defined through consecutive differences, which points at sign words and therefore at maximal monotone runs.
3. Where you would hesitate, and the thought to reinforce: proving that no subsequence beats the run endpoints. Reinforce this: to bound every subsequence at once, find a quantity monotone under one deletion, because every subsequence is a chain of single deletions.
4. The trap the question sets: dressing a permutation statistic as a continuous probability question so that you set up an integral, or asking for a mean so that you compute a whole distribution.
5. What makes you recognise it faster next time: the phrase "the largest value of k for which there exists" inside an expectation is the signature of "structure theorem, then linearity of expectation".
6. The reusable decision rule: convert extremal statistics into local counts before touching probability, then let linearity absorb all the dependence.

Mirror drills

1. Let $X_1, \ldots, X_n$ be independent and uniform on $[0, 1]$. Find the expected number of indices i with $2 \leq i \leq n-1$ such that X_i is a strict local maximum. *Answer:* each interior index is a local maximum with probability $1/3$, so the expected number is $(n-2)/3$.
2. Find the expected number of ascents (indices i with $X_i < X_{i+1}$) among $X_1, \ldots, X_n$ independent and uniform on $[0, 1]$, and deduce the expected number of maximal monotone runs. *Answer:* $(n-1)/2$ ascents by symmetry, and the run count is 1 plus the number of sign changes, giving $1 + \frac{2}{3}(n-2)$, consistent with $\mathbf{E}[a] = (2n+2)/3$.
3. Show that a sequence of $n \geq 2$ distinct reals whose longest zigzag subsequence has length exactly 2 must be monotone. *Answer:* length 2 forces $N = 1$, that is, no sign change in the difference word, which is exactly monotonicity.

3.10 B4. Least time for a resetting piecewise parabola

For a nonnegative integer n and a strictly increasing sequence of real numbers $t_0, t_1, \ldots, t_n$, let $f(t)$ be the corresponding real-valued function defined for $t \geq t_0$ by the following properties:

(a) $f(t)$ is continuous for $t \geq t_0$, and is twice differentiable for all $t > t_0$ other than $t_1, \ldots, t_n$;

(b) $f(t_0) = 1/2$;

(c) $\lim_{t \to t_k^+} f'(t) = 0$ for $0 \leq k \leq n$;

(d) For $0 \leq k \leq n-1$, we have $f''(t) = k+1$ when $t_k < t < t_{k+1}$, and $f''(t) = n+1$ when $t > t_n$.

Considering all choices of n and $t_0, t_1, \ldots, t_n$ such that $t_k \geq t_{k-1} + 1$ for $1 \leq k \leq n$, what is the least possible value of T for which $f(t_0 + T) = 2023$?

Read it out loud

Read the conditions as mechanics and the problem becomes a gearbox. You are driving from height $1/2$ up to height 2023. Between consecutive marked times you are in gear k, meaning constant acceleration k. Condition (c) is the brutal one: at every marked time your speed is reset to zero. So each gear change buys you one extra unit of acceleration for the rest of the run, but it throws away all the speed you had built and, by the constraint $t_k \geq t_{k-1} + 1$, it costs you at least one unit of time. The question is how many times to change gear before making the final run.

Structurally, condition (c) makes the intervals independent. On (t_{k-1}, t_k) you start from rest with acceleration k, so the height gained is $\frac{k}{2}s_k^2$ where $s_k = t_k - t_{k-1}$ is the length of the interval, and nothing from the previous interval leaks in. Thus the total climb is a quadratic form in the gap vector, $\sum_k k s_k^2$, and the time is the linear form $\sum_k s_k$. This is now a clean finite dimensional optimisation problem with an integer parameter n: minimise a linear form subject to a quadratic form being fixed, with each of the first n variables bounded below by 1.

The fields: elementary integration to get the reduction, then convex optimisation to solve it, then a one variable inequality with an integer parameter to finish. What is really being tested is whether you understand that a convex function on a polytope is maximised at a vertex, and therefore that the optimum saturates all the gap constraints. Note that f is deliberately not differentiable at the t_k: the left derivative there is $ks_k > 0$ and the right derivative is 0. If you assume f' is continuous you are solving a different problem.

Within thirty seconds you should have written $s_k = t_k - t_{k-1}$, $f(t_k) - f(t_{k-1}) = \frac{k}{2}s_k^2$, and the reformulation: minimise $\sum_{k=1}^{n+1} s_k$ subject to $\sum_{k=1}^{n+1} k s_k^2 = 4045$ and $s_k \geq 1$ for $k \leq n$.

Approaches, ranked worst to best

1. **Global antiderivative.** *Cue:* "twice differentiable", "$f''(t) = k+1$". *Circuit:* integrate twice and impose the conditions. Writing a single formula for f on $[t_0, \infty)$ with all the constants of integration named, then imposing continuity and the derivative resets, is correct but drowns you in symbols before you ever reach the optimisation, and it hides the fact that the intervals do not interact. Ranked worst because it costs the most ink for the least structure.

2. **Lagrange multipliers, ignoring the floors.** *Cue:* "least possible value" plus a constraint. *Circuit:* constrained optimisation means stationary points of L. Minimising $\sum s_k$ subject to $\sum k s_k^2 = 4045$ gives $1 = 2\lambda k s_k$, so $s_k \propto 1/k$. This is a genuine stationary point, and it is the wrong one: on the positive part of the ellipsoid the linear form $\sum s_k$ is *maximised* there, not minimised. It also ignores $s_k \geq 1$ entirely. It gives a confidently wrong answer, which is worse than no answer.

3. **Numerical or heuristic search over n.** *Cue:* the integer parameter n is free. *Circuit:* when a parameter is a small integer, tabulate. Assume without proof that the optimum saturates $s_k = 1$, derive $T = n + \sqrt{\frac{4045}{n+1} - \frac{n}{2}}$, tabulate, and read off 29 at $n = 9$. This finds the answer fast and is exactly what you should do first for confidence, but the assumption is the entire content of the problem, so alone it scores near zero.

4. **Compactness plus exchange.** *Cue:* a minimum is asserted to exist. *Circuit:* show the minimum is attained, then perturb it. Prove the feasible set is compact so a minimiser exists, then show that if some $s_k > 1$ for $k \le n$ you can move that excess into the last gap and strictly increase the climb, contradicting minimality. This is correct and is the official route; it costs an existence argument and a monotonicity lemma about the intermediate value theorem before the perturbation can be run.

5. **Convexity: maximise the climb at fixed time.** *Cue:* a convex objective on a polytope of gap vectors. *Circuit:* a convex function on a compact convex set is maximised at an extreme point. Turn the question round: for a fixed total time T, how high can you get? The climb $\sum k s_k^2$ is convex, the gap vectors form a polytope, so the maximum sits at a vertex, and the vertices are exactly "all intermediate gaps at the floor 1". No existence argument, no perturbation, and the inequality that remains is a cubic that factorises. Best, because it explains why the optimum saturates instead of discovering it.

The ideal solution

The answer is $\boxed{29}$.

Reduction. Put $s_k = t_k - t_{k-1}$ for $1 \le k \le n$, so the hypothesis reads $s_k \ge 1$. Fix T and suppose $f(t_0 + T) = 2023$. First we may assume $t_0 + T \ge t_n$. Indeed, if not, let ν be the largest index with $t_\nu \le t_0 + T$ and discard the break points $t_{\nu+1}, \dots, t_n$: conditions (a) to (d) for the truncated data give exactly the same function on $[t_0, t_{\nu+1})$, since f'' equals $\nu + 1$ after t_ν in both descriptions, and the spacing hypothesis survives. So relabel and assume $t_0 + T \ge t_n$, and set $s_{n+1} = T - \sum_{k=1}^{n} s_k \ge 0$.

On (t_{k-1}, t_k) we have $f'' = k$ by (d), and $\lim_{t \to t_{k-1}^+} f'(t) = 0$ by (c), so $f'(t) = k(t - t_{k-1})$ there; by continuity of f,

$$f(t_k) - f(t_{k-1}) = \int_{t_{k-1}}^{t_k} k(t - t_{k-1})\, dt = \frac{k}{2} s_k^2 \qquad (1 \le k \le n),$$

and identically $f(t_0 + T) - f(t_n) = \frac{n+1}{2} s_{n+1}^2$. Summing and using $f(t_0) = 1/2$,

$$f(t_0 + T) = \frac{1}{2} + \frac{1}{2} \sum_{k=1}^{n+1} k\, s_k^2.$$

Hence $f(t_0 + T) = 2023$ is equivalent to

$$g(s) := \sum_{k=1}^{n+1} k\, s_k^2 = 4045, \qquad s_k \ge 1 \ (1 \le k \le n), \quad s_{n+1} \ge 0, \quad \sum_{k=1}^{n+1} s_k = T.$$

The concentration lemma. For an integer $\nu \ge 0$ and a real $T \ge \nu$ write

$$G(\nu, T) = \frac{\nu(\nu + 1)}{2} + (\nu + 1)(T - \nu)^2,$$

the value of g at the gap vector with ν gaps equal to 1 followed by a last gap of length $T - \nu$.

Lemma 3.10.1. *Let $n \ge 0$ be an integer and $T \ge n$. Over the set P of all $(s_1, \dots, s_{n+1})$ with $s_k \ge 1$ for $k \le n$, $s_{n+1} \ge 0$ and $\sum_{k=1}^{n+1} s_k = T$, the maximum of g is $G(0, T) = T^2$ if $n = 0$, and $\max\{G(n, T),\ G(n-1, T)\}$ if $n \ge 1$.*

Proof. P is a nonempty compact convex polytope and g is convex, being a nonnegative combination of the convex functions $s \mapsto s_k^2$. Every point of a polytope is a convex combination of its finitely many vertices, so by Jensen's inequality g attains its maximum over P at a vertex. Since P lies in the hyperplane $\sum s_k = T$ and its only other constraints are the $n+1$ coordinate bounds, a vertex is a feasible point at which at least n of those bounds are active. There are two possibilities.

If all n bounds $s_k \geq 1$ ($k \leq n$) are active, then $s_k = 1$ for $k \leq n$ and $s_{n+1} = T - n$, giving $g = \frac{n(n+1)}{2} + (n+1)(T-n)^2 = G(n, T)$.

Otherwise $s_{n+1} = 0$ and $s_k = 1$ for every $k \leq n$ except one index j, which forces $s_j = T - n + 1$. Then

$$g = \frac{n(n+1)}{2} - j + j(T-n+1)^2 = \frac{n(n+1)}{2} + j\big((T-n+1)^2 - 1\big).$$

Since $T \geq n$ we have $(T-n+1)^2 \geq 1$, so the bracket is nonnegative and the expression is largest at $j = n$, where it equals $\frac{n(n-1)}{2} + n(T-n+1)^2 = G(n-1, T)$. □

The bound. Suppose some admissible choice achieves $f(t_0 + T) = 2023$. By the reduction and the lemma there is an integer $\nu \geq 0$ with $\nu \leq T$ and

$$G(\nu, T) \geq 4045.$$

Assume for contradiction that $T < 29$. Then $\nu \leq T < 29$, so $0 \leq \nu \leq 28$, and $0 \leq T - \nu < 29 - \nu$, whence

$$\frac{\nu(\nu+1)}{2} + (\nu+1)(29-\nu)^2 > G(\nu, T) \geq 4045.$$

Multiplying by 2 and moving everything to one side, this says $R(\nu) > 0$ where

$$R(\nu) := \nu(\nu+1) + 2(\nu+1)(29-\nu)^2 - 8090 = 2\nu^3 - 113\nu^2 + 1567\nu - 6408.$$

But $R(9) = 1458 - 9153 + 14103 - 6408 = 0$, so $\nu - 9$ divides R, and

$$R(\nu) = (\nu - 9)\, Q(\nu), \qquad Q(\nu) = 2\nu^2 - 95\nu + 712.$$

The roots of Q are $\frac{95 \pm \sqrt{3329}}{4}$, and $57^2 = 3249 < 3329 < 3364 = 58^2$ gives $57 < \sqrt{3329} < 58$, so the smaller root lies in $(9.25,\ 9.5)$ and the larger in $(38,\ 38.25)$. Hence $Q(\nu) > 0$ for integers $\nu \leq 9$ and $Q(\nu) < 0$ for integers $10 \leq \nu \leq 38$. Therefore $R(\nu) \leq 0$ for every integer $0 \leq \nu \leq 28$: for $\nu \leq 9$ the first factor is nonpositive and the second positive, and for $10 \leq \nu \leq 28$ the first is positive and the second negative. This contradicts $R(\nu) > 0$. Hence $T \geq 29$.

The construction. Take $n = 9$ and $t_k = t_0 + k$ for $1 \leq k \leq 9$, so $s_1 = \cdots = s_9 = 1$, and run for a further $s_{10} = 20$. All spacing constraints hold with equality, and

$$g = \sum_{k=1}^{9} k \cdot 1 + 10 \cdot 20^2 = 45 + 4000 = 4045,$$

so $f(t_0 + 29) = \frac{1}{2} + \frac{1}{2} \cdot 4045 = 2023$ with $T = 9 + 20 = 29$. Therefore the least possible value of T is 29. ■

Layer 1: WHAT

Block 1. Read (c) as a reset: every interval starts from rest, so the intervals do not interact and the climb splits as a sum.

Block 2. Integrate once on each interval: $f' = k(t - t_{k-1})$, hence the climb on interval k is $\frac{k}{2}s_k^2$.

Block 3. Reformulate: minimise $T = \sum s_k$ subject to $\sum k s_k^2 = 4045$ with $s_k \geq 1$ for $k \leq n$, allowing n to vary.

Block 4. Invert the question: for a fixed time budget T, maximise the climb. The objective is convex on a polytope, so the maximum is at a vertex.

Block 5. Enumerate the vertices: all intermediate gaps at the floor, and one free gap. The best vertex is "all nine gaps at 1, everything else at the end", which is $G(\nu, T)$.

Block 6. Convert $G(\nu, T) \geq 4045$ with $T < 29$ into a cubic inequality in ν, factor out $\nu - 9$, and contradict.

Block 7. Exhibit $n = 9$, gaps $1, 1, \ldots, 1, 20$ and check the arithmetic exactly.

Juxtaposition. The nominal route writes a global formula for f, then optimises with Lagrange multipliers and gets $s_k \propto 1/k$, spreading the time over many small gaps. That is precisely backwards: it is the configuration that wastes the most time for a given climb. The bifurcation point is the sentence "the climb is a convex function of the gaps, so at fixed total time it is maximised at an extreme point, not at a stationary point". Convexity means the interior stationary point is a minimum of the climb, so any route that seeks a stationary point of the natural Lagrangian is walking away from the answer.

Layer 2: HOW

Block 1. **Cue.** Condition (c) prescribes the right hand limit of f' at every break point, not the value of f'. **Why natural.** A prescribed initial derivative on each interval means each interval is an independent initial value problem. The setter would have written "f is differentiable" if he had wanted the speed carried over; he wrote a one sided limit instead, which is the definition of a reset. Structural independence is the single most valuable thing you can extract from a piecewise definition, so hunt for it first. **Link to the next block.** Independent intervals means the total climb is a sum of per interval climbs, each depending on one gap only.

Block 2. **Cue.** Constant f'' on an interval with zero initial velocity. **Why natural.** This is the atomic case of "distance from rest under constant acceleration". Integrating twice gives $\frac{k}{2}s_k^2$ with no cross terms, and the absence of cross terms is exactly what makes the later optimisation tractable. **Link to the next block.** The climb is now a quadratic form and the time a linear form in the same variables, which is a standard optimisation shape.

Block 3. **Cue.** "Considering all choices of n and $t_0, \ldots, t_n$", and "least possible value". **Why natural.** The data $t_0, \ldots, t_n$ enters only through the gaps, and t_0 does not enter at all, so translate away t_0 and change variables to the gaps. Always reparametrise by the quantities the answer actually depends on; carrying redundant variables is how sign errors are born. **Link to the next block.** You now have a clean programme: minimise a linear form subject to a quadratic equality and box constraints, with a free integer n.

Block 4. **Cue.** A linear objective and a quadratic constraint, both with positive coefficients. **Why natural.** Minimising time at fixed climb and maximising climb at fixed time are the same problem read in two directions, and the second direction is the tractable one because the feasible set at fixed time is a polytope. That reversal is the whole move. A convex function on a compact convex set attains its maximum at an extreme point, since every point is a convex combination of vertices and Jensen pushes the value up to the largest vertex value. **Link to the next block.** Maximising over a polytope reduces an infinite problem to a finite list of candidate vertices.

Block 5. **Cue.** The constraints are exactly $n + 1$ coordinate bounds plus one hyperplane. **Why natural.** Vertices are where enough constraints are active to pin the point down, so at least n of the bounds must be tight. Reading off the two families costs one line each, and comparing them is a monotone comparison in j rather than an optimisation. **Link to the next block.** The second family collapses into the first with n replaced by $n - 1$, so the entire search is over the single family $G(\nu, T)$.

Block 6. **Cue.** A candidate optimum $T = 29$ obtained from a quick tabulation, and a family of inequalities indexed by an integer ν. **Why natural.** To prove a minimum you assume a better value and contradict. Substituting $T < 29$ makes the inequality polynomial in ν, and since $T = 29$ is achieved at $\nu = 9$, the polynomial must vanish at $\nu = 9$. Knowing the root in advance is what makes the factorisation instant rather than lucky. **Link to the next block.** The remaining quadratic has both roots outside the range where they could hurt, so the sign analysis is two lines.

Block 7. **Cue.** The problem asks for a value, so the bound is only half a solution. **Why natural.** An extremal answer is unproven until an example attains it. Exhibit the configuration and verify the arithmetic exactly, in integers: $45 + 4000 = 4045$. **Link to the next block.** Bound plus construction closes the problem.

Layer 3: WHY

Three mathematical truths make this route ideal.

First, resets decouple. A piecewise definition where each piece is given its own initial condition is a direct sum, not a coupled system, and the total is a sum of independent contributions. Recognising a direct sum turns a differential equation problem into an algebra problem.

Second, convexity decides where optima sit. The climb $\sum k s_k^2$ is convex in the gaps, so along any segment of feasible points it is maximised at an endpoint. This is why the optimum is "extreme": all intermediate gaps sit at the floor 1 and the entire remaining budget is dumped into the last gap, where the coefficient $n + 1$ is largest. The correct instinct, and it generalises far beyond this problem, is that maximising a convex objective means going to the corners, while minimising a convex objective means going to the interior stationary point. Half the marks on optimisation problems are decided by knowing which of those two situations you are in.

Third, the trade off is quantitative and small. Each extra gear costs one time unit and buys one extra unit of acceleration for the final run. With a fixed climb of 4045, more gears help until the fixed cost outweighs the gain, and the balance point is at $\nu = 9$. You can see it by differentiating $\nu \mapsto \nu + \sqrt{\frac{4045}{\nu+1} - \frac{\nu}{2}}$ informally, but you should not: since $T \geq \nu$ always, any $\nu \geq 30$ is immediately worse than 29, so only thirty integers survive and a finite check is both cheaper and safer.

The discernment mechanism: when you see a linear objective against a quadratic constraint with box constraints, ask which of the two is convex in the direction you are optimising, then decide corner versus interior before writing anything. If you cannot answer that, test the two extreme configurations by hand. Here, comparing "all time in one gap" with "time spread evenly" takes fifteen seconds and instantly reveals that concentration wins.

How the setter nudged: the constraint $t_k \geq t_{k-1} + 1$ exists purely to stop you from taking infinitely many gears with infinitesimal gaps, which tells you the floor is active at the optimum. The value 2023 was chosen so that $2 \cdot 2023 - 1 = 4045$ produces the exact integer answer $T = 29$ with $s_{10} = 20$; a clean answer is evidence that you have found the intended configuration.

Revolving concepts

Piecewise defined solutions of $f'' = c$. On an interval where f'' is the constant c and f' starts at 0 from the left endpoint t_{k-1}, we have $f'(t) = c(t - t_{k-1})$ and $f(t) - f(t_{k-1}) = \frac{c}{2}(t - t_{k-1})^2$. Continuity of f glues the pieces; f' may jump. See Book 1, field: Calculus and integrals, topic: piecewise initial value problems.

Convex functions and extreme points. A function g is convex if $g(\lambda x + (1-\lambda)y) \leq \lambda g(x) + (1-\lambda)g(y)$. A nonnegative combination of convex functions is convex, and $s \mapsto s^2$ is convex. Every point of a compact polytope P is a convex combination of its vertices, hence $\max_P g$ is attained at a vertex (Jensen). This is the finite dimensional case of Bauer's maximum principle. See Book 1, field: Inequalities, topic: convexity and extreme points.

Vertices of a polytope cut out by box constraints and one hyperplane. If $P = \{s \in \mathbb{R}^N : \sum s_k = T,\ s_k \geq \ell_k\}$, then the vertices of P are the points where at least $N-1$ of the bounds are active, that is, all coordinates but one sit at their floors. This is the standard "extreme points saturate all but one constraint" statement and is worth installing as a reflex. See Book 1, field: Inequalities, topic: linear programming vertices.

Lagrange multipliers and their failure mode. Stationary points of $\sum s_k - \lambda(\sum k s_k^2 - C)$ satisfy $s_k \propto 1/k$; this is a genuine critical point but it is the maximum of the linear form on the positive part of the ellipsoid, and it ignores inequality constraints entirely. Multipliers locate stationary points, never optima; the correct general statement needs the Karush, Kuhn and Tucker conditions with complementary slackness. See Book 1, field: Inequalities, topic: constrained optimisation and its traps.

Optimisation over an integer parameter. When a continuous optimisation is nested inside a choice of integer ν, solve the continuous problem for each ν to get $T(\nu)$, then bound the range of ν crudely (here $T \geq \nu$ kills $\nu \geq 30$ at once) and finish with a finite check or a factorised polynomial inequality. See Book 1, field: Inequalities, topic: mixed integer optimisation.

Recursion, generalised. The cumulative height is the telescoping sum $f(t_m) = f(t_0) + \sum_{k=1}^{m} \frac{k}{2} s_k^2$, that is, the first order recursion $h_m = h_{m-1} + \frac{m}{2} s_m^2$ with $h_0 = 1/2$. The general pattern to install: a recursion of the form $h_m = h_{m-1} + \varphi(m, s_m)$, in which the increment depends only on the current index and the current step size, always telescopes to $h_0 + \sum \varphi(k, s_k)$, and any optimisation of h subject to a constraint on $\sum s_k$ becomes a separable programme. Separability, in turn, is what allows a vertex argument, since separable convex objectives are convex. The same generalisation applies to every "greedy schedule with per stage cost" problem. See Book 1, field: Sequences and recurrences, topic: telescoping sums and separable objectives.

Circuit Bank

- **WHEN** you see a piecewise definition in which each piece is given its own initial condition **DO** treat the pieces as independent and write the total as a sum over pieces **BECAUSE** a prescribed one sided derivative at each break point is a reset, so no information crosses a break point and the problem is a direct sum

- **WHEN** you must minimise a linear form subject to a fixed quadratic form **DO** reverse the question and maximise the quadratic form at fixed linear form **BECAUSE** the level sets of the linear form are hyperplanes, so the reversed problem has a polytope as feasible set, and polytopes have finitely many vertices

- **WHEN** you are maximising a convex function on a compact convex set **DO** evaluate at the extreme points only **BECAUSE** every point is a convex combination of extreme points, so Jensen shows the maximum is attained at one of them; convex objectives are maximised at corners and minimised in the interior

- **WHEN** you must prove a specific number is the minimum of a family indexed by an integer **DO** assume a strictly better value, clear denominators to a polynomial inequality in the integer, and factor out the root you already know from the extremal configuration **BECAUSE** the extremal configuration tells you a root of the polynomial in advance, which turns an opaque factorisation into a division

- **WHEN** you have proved a sharp lower bound **DO** immediately construct the configuration that attains it and verify the arithmetic in integers **BECAUSE** an extremal problem is only half solved by a bound, and graders award the two halves separately

Backtesting

1. First useful cue: condition (c) prescribes the right hand limit of f' at each t_k, which is a reset and decouples the intervals.
2. Method the expression suggested: change variables to the gaps s_k, so that the climb is $\frac{1}{2}\sum k s_k^2$ and the time is $\sum s_k$.
3. Where you would hesitate, and the thought to reinforce: whether the optimum spreads the gaps or saturates them. Reinforce this: the climb is convex in the gaps, and convex objectives are maximised at corners, so the intermediate gaps sit at the floor 1 and the whole surplus goes into the last, highest geared interval.
4. The trap the question sets: applying Lagrange multipliers to get $s_k \propto 1/k$, which is the stationary point in the wrong direction and ignores the constraint $s_k \geq 1$; a second trap is assuming f' is continuous at the break points.
5. What makes you recognise it faster next time: a per interval acceleration that increases with the index, combined with a minimum spacing constraint, is a gearbox, and gearboxes are solved by choosing the number of gear changes and then running flat out in top gear.
6. The reusable decision rule: decouple at the resets, reparametrise by the gaps, reverse the optimisation so the feasible set is a polytope, then evaluate at vertices only.

Mirror drills

1. Maximise $s_1^2 + 2s_2^2 + 3s_3^2$ subject to $s_1 + s_2 + s_3 = 5$, $s_1 \geq 1$, $s_2 \geq 1$, $s_3 \geq 0$. *Answer:* check the vertices $(1,1,3)$, $(3,1,0)$, $(1,3,0)$, giving 30, 11, 19; the maximum is 30, attained by dumping the surplus into the highest coefficient.
2. In the problem above, replace 2023 by 5, so that the climb constraint becomes $\sum k s_k^2 = 9$. Find the least T. *Answer:* $T = 3$, attained both by $n = 0$ with a single gap $\sqrt{9} = 3$ and by $n = 1$ with gaps $(1, 2)$, since $1 + 2 \cdot 2^2 = 9$.
3. Show that without the constraints $s_k \geq 1$, the infimum of $\sum_{k=1}^{n+1} s_k$ subject to $\sum_{k=1}^{n+1} k s_k^2 = C$ tends to 0 as n grows. *Answer:* put everything in the last gap, $s_{n+1} = \sqrt{C/(n+1)}$ and all other gaps 0; the total is $\sqrt{C/(n+1)} \to 0$, which is exactly why the spacing hypothesis is present.

3.11 B5. When multiplication mod n is a square permutation

Determine which positive integers n have the following property: For all integers m that are relatively prime to n, there exists a permutation $\pi\colon \{1,2,\dots,n\} \to \{1,2,\dots,n\}$ such that $\pi(\pi(k)) \equiv mk \pmod{n}$ for all $k \in \{1,2,\dots,n\}$.

Read it out loud

Identify $\{1,2,\dots,n\}$ with $\mathbb{Z}/n\mathbb{Z}$ by sending n to 0. Since $\gcd(m,n) = 1$, the map $\sigma_m(x) = mx$ is a bijection of $\mathbb{Z}/n\mathbb{Z}$, and the displayed condition says precisely that $\pi \circ \pi = \sigma_m$ as permutations. So read the question out loud as: for which n is the multiplication by m permutation a square in the symmetric group, for every unit m?

That reading is the entire problem. "Square root of a permutation" is a solved question with a clean answer in terms of cycle type, so the problem splits into two independent halves: install the cycle type criterion, then compute the cycle type of multiplication by m on $\mathbb{Z}/n\mathbb{Z}$. The second half is number theory: the Chinese remainder theorem splits the ring, and on each prime power factor the cycle lengths are governed by the multiplicative order of m.

The trap is planted in plain sight. Nothing says π has to be multiplication by anything. If you look for $\pi(k) = ck$ with $c^2 \equiv m$, you are asking for every unit modulo n to be a square, which fails for all $n > 2$, and you will confidently produce the wrong answer set $\{1,2\}$. The permutation π is allowed to be arbitrary, and that freedom is what makes $n \equiv 2 \pmod 4$ work.

Fields: symmetric group theory (disjoint cycle decomposition, squares), and elementary number theory (Chinese remainder theorem, the structure of the unit group modulo a prime power). Within thirty seconds you should have written $\pi^2 = \sigma_m$, the word "cycle type", and the two cheap experiments: $m = -1$, which is always a unit, and m a primitive root modulo an odd prime factor.

Approaches, ranked worst to best

1. **Look for a linear π.** *Cue:* $\pi(\pi(k)) \equiv mk$ looks like composing multiplications. *Circuit:* when a functional equation is linear, guess a linear solution. Setting $\pi(k) = ck$ requires $c^2 \equiv m$ for every unit m, that is, every unit is a quadratic residue. Since $(\mathbb{Z}/n\mathbb{Z})^\times$ has even order for every $n > 2$, this fails for all $n > 2$ and yields the wrong answer. Worst, because it is fast, plausible and wrong.

2. **Brute force small n and conjecture.** *Cue:* "determine which positive integers". *Circuit:* when the answer is a set of integers, compute the first twenty. You find $1, 2, 6, 10, 14, 18$ and conjecture $n = 1$ or $n \equiv 2 \pmod 4$. Essential for confidence and for choosing what to prove, worth no marks alone, and dangerous if the pattern only starts later.

3. **Sign of the permutation.** *Cue:* a square must have sign $+1$. *Circuit:* the sign map is a homomorphism to $\{\pm 1\}$, so squares land in the kernel. Cheap and genuinely useful: for $4 \mid n$ and $m = -1$ the permutation is a product of $n/2 - 1$ transpositions, an odd number, so its sign is -1 and no square root exists. But the sign is too coarse in general: for $n = 9$, $m = 2$ the cycle type is a 6-cycle, a 2-cycle and a fixed point, sign $+1$, yet there is still no square root. Ranked here because it solves one case and silently fails on another.

4. **Ad hoc constructions case by case.** *Cue:* "there exists a permutation". *Circuit:* existence claims are met by construction. Building π by hand for each $n \equiv 2 \pmod 4$ without a general criterion is possible but you will be reinventing the pairing of equal cycles every time, and you will have no obstruction argument for the other n.

5. **Cycle type criterion plus the Chinese remainder theorem.** *Cue:* $\pi \circ \pi = \sigma_m$, a square in S_n; and $\gcd(m,n) = 1$, a unit. *Circuit:* squares in the symmetric group are characterised by cycle type; multiplication maps on $\mathbb{Z}/n\mathbb{Z}$ are analysed by splitting the ring. Prove once that a

permutation is a square exactly when every even cycle length occurs an even number of times, then read off the cycle type of σ_m in each of the three cases n odd, $n \equiv 2 \pmod 4$, $4 \mid n$. Best: one lemma, three short computations, and every case closed for the same structural reason.

The ideal solution

The property holds exactly for $\boxed{n = 1 \text{ and } n \equiv 2 \pmod 4}$.

Throughout, identify $\{1, \dots, n\}$ with $\mathbb{Z}/n\mathbb{Z}$ by sending n to 0, so that the required condition on π becomes $\pi \circ \pi = \sigma_m$, where $\sigma_m(x) = mx$ is a permutation of $\mathbb{Z}/n\mathbb{Z}$ because $\gcd(m, n) = 1$.

Lemma 3.11.1. *A permutation σ of a finite set is the square of some permutation if and only if, for every even $\ell \geq 2$, the number of ℓ-cycles in the disjoint cycle decomposition of σ is even.*

Proof. Suppose $\sigma = \tau^2$ and decompose τ into disjoint cycles. If c is a cycle of τ of odd length ℓ, then c^2 is again a single ℓ-cycle on the same support, of odd length. If c has even length ℓ, then c^2 splits into exactly two disjoint cycles of length $\ell/2$ on that support. Since disjoint cycles square independently, every cycle of σ of even length M arises from a cycle of τ of length $2M$, and each such cycle of τ contributes exactly two of them. Hence the number of M-cycles of σ is even.

Conversely, suppose the condition holds. Partition the cycles of σ into single cycles of odd length and pairs of cycles of equal even length; this is possible precisely because each even length occurs an even number of times. For an odd cycle c of length ℓ, put $\tau_c = c^{(\ell+1)/2}$, so that $\tau_c^2 = c^{\ell+1} = c$. For a pair of cycles $(a_1 a_2 \cdots a_\ell)$ and $(b_1 b_2 \cdots b_\ell)$ of the same length, put $\tau = (a_1 b_1 a_2 b_2 \cdots a_\ell b_\ell)$, whose square is $(a_1 a_2 \cdots a_\ell)(b_1 b_2 \cdots b_\ell)$. These pieces have pairwise disjoint supports, so their product τ satisfies $\tau^2 = \sigma$. □

Case $n = 1$. The only permutation is the identity, which is its own square. The property holds.

Case $n > 1$ odd. Write $n = p^e k$ with p an odd prime, $e \geq 1$ and $\gcd(p, k) = 1$; note k is odd. By the Chinese remainder theorem there is a ring isomorphism $\mathbb{Z}/n\mathbb{Z} \cong \mathbb{Z}/p^e\mathbb{Z} \times \mathbb{Z}/k\mathbb{Z}$ under which multiplication by m becomes multiplication by the pair of residues of m. The group $(\mathbb{Z}/p^e\mathbb{Z})^\times$ is cyclic of order $L := p^{e-1}(p-1)$; choose g generating it and choose m with $m \equiv g \pmod{p^e}$ and $m \equiv 1 \pmod k$, which is a unit modulo n. Then $\sigma_m(u, v) = (gu, v)$.

Fix (u, v) and write $u = p^j u'$ with u' a unit and $0 \leq j \leq e$ (interpreting $j = e$ as $u = 0$). The cycle length of (u, v) is the least $t \geq 1$ with $g^t u \equiv u \pmod{p^e}$, that is, with $g^t \equiv 1 \pmod{p^{e-j}}$. Since the reduction $(\mathbb{Z}/p^e\mathbb{Z})^\times \to (\mathbb{Z}/p^{e-j}\mathbb{Z})^\times$ is surjective, g reduces to a generator, and the cycle length is $p^{e-j-1}(p-1)$ for $j < e$, and 1 for $j = e$. This equals L exactly when $j = 0$. So the elements lying in cycles of length L are precisely the $\varphi(p^e)k = Lk$ pairs with u a unit, and they form exactly k cycles. Now L is even because p is odd, and k is odd because n is odd. By the lemma, σ_m has no square root, so the property fails.

Case $n \equiv 2 \pmod 4$. Write $n = 2k$ with k odd, so $\mathbb{Z}/n\mathbb{Z} \cong \mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/k\mathbb{Z}$. Any m coprime to n is odd, so $m \equiv 1 \pmod 2$ and $\sigma_m(\varepsilon, v) = (\varepsilon, mv)$. Hence both sets $\{0\} \times \mathbb{Z}/k\mathbb{Z}$ and $\{1\} \times \mathbb{Z}/k\mathbb{Z}$ are invariant, and the bijection $(0, v) \mapsto (1, v)$ conjugates the restriction of σ_m to the first onto its restriction to the second. Two conjugate permutations have the same cycle type, so every cycle length of σ_m occurs exactly twice as often as it does in the restriction, in particular an even number of times. By the lemma σ_m has a square root, for every such m, so the property holds.

Case $4 \mid n$. Take $m = n - 1$, which is coprime to n and satisfies $m \equiv -1 \pmod n$. The fixed points of σ_{-1} are the x with $2x \equiv 0 \pmod n$, namely $x = 0$ and $x = n/2$, and every other element is swapped with its negative, giving $(n-2)/2 = n/2 - 1$ transpositions. Since $4 \mid n$, the number $n/2$ is even, so $n/2 - 1$ is odd: there is an odd number of cycles of length 2. By the lemma σ_{-1} has no square root, so the property fails.

Every $n > 1$ is odd, congruent to 2 modulo 4, or divisible by 4, so the three cases together with $n = 1$ prove that the property holds exactly for $n = 1$ and $n \equiv 2 \pmod 4$. ■

Layer 1: WHAT

Block 1. Translate: $\pi(\pi(k)) \equiv mk$ means $\pi^2 = \sigma_m$ in the symmetric group of $\mathbb{Z}/n\mathbb{Z}$.

Block 2. Ask the right general question: which permutations are squares? Answer by cycle type, and prove it in both directions.

Block 3. Realise that the cycle type of σ_m is a number theory computation, and that the Chinese remainder theorem splits it into prime power pieces.

Block 4. Odd $n > 1$: choose m to be a primitive root on one odd prime power factor and trivial elsewhere, producing an odd number of cycles of even length $\varphi(p^e)$.

Block 5. $n \equiv 2 \pmod 4$: the factor $\mathbb{Z}/2\mathbb{Z}$ is inert because every unit is odd, so the whole permutation is two identical copies and every cycle length is doubled.

Block 6. $4 \mid n$: test $m = -1$, which gives two fixed points and an odd number of transpositions.

Juxtaposition. The nominal route treats $\pi(\pi(k)) \equiv mk$ as an equation to solve for a formula, tries $\pi(k) = ck$, discovers it needs every unit to be a quadratic residue, and answers $\{1, 2\}$. The bifurcation point is the sentence "π is only required to be a permutation, so this is a question about cycle type, not about arithmetic in $\mathbb{Z}/n\mathbb{Z}$". Once you refuse to look for a formula for π, the problem becomes routine.

Layer 2: HOW

Block 1. **Cue.** A permutation composed with itself, set equal to something explicit. **Why natural.** Composition of a permutation with itself is squaring in a group. As soon as an equation lives in a group you should stop treating it as a formula and start treating it as a question about that group's structure. The symmetric group's structure is its cycle type, so the equation $\pi^2 = \sigma$ must be a cycle type condition. **Link to the next block.** This turns "find π" into "is σ_m in the image of the squaring map", which is a classification question.

Block 2. **Cue.** Squaring a single cycle. **Why natural.** Everything about a permutation reduces to what happens on one cycle, because disjoint cycles commute and square independently. Squaring an ℓ-cycle is a step of size 2 around a cycle of length ℓ: if ℓ is odd the step generates the whole cycle, if ℓ is even it splits the cycle into the two parity classes. That single observation is the whole lemma, in both directions. **Link to the next block.** The forward direction gives an obstruction; the reverse direction gives a construction by interleaving, so the criterion is exact.

Block 3. **Cue.** $\gcd(m, n) = 1$ and multiplication modulo n. **Why natural.** Multiplication by a unit is an action of the cyclic group generated by m inside $(\mathbb{Z}/n\mathbb{Z})^\times$, and its cycles are the orbits. Orbits of a multiplicative action are computed factor by factor, so invoke the Chinese remainder theorem as a ring isomorphism, not merely as a congruence solver. **Link to the next block.** Now you can choose m freely on each factor, which is exactly the freedom needed to build a bad m.

Block 4. **Cue.** "For all integers m", so to disprove the property you need only one m. **Why natural.** Universally quantified hypotheses are attacked by choosing the extreme instance. The extreme instance of a multiplicative map is a generator, because it maximises orbit lengths and minimises the orbit count. Making m trivial on the complementary factor k keeps the count of long cycles equal to k, and k is odd for free. **Link to the next block.** An odd number of cycles of even length $\varphi(p^e)$ is exactly what the lemma forbids.

Block 5. **Cue.** $n \equiv 2 \pmod 4$ means $n = 2k$ with k odd, and every unit modulo 2 is 1. **Why natural.** The factor $\mathbb{Z}/2\mathbb{Z}$ cannot move, because the only unit there is the identity. So σ_m is literally the same permutation performed twice on two disjoint copies, which doubles every cycle count. Doubling is the cheapest possible way to satisfy the "even number of even cycles" condition, and it

works for every m at once, which is what the universal quantifier demands. **Link to the next block.** This is the positive case, and it needs no knowledge of the cycle structure on $\mathbb{Z}/k\mathbb{Z}$ whatsoever.

Block 6. **Cue.** $4 \mid n$ and the always available unit $m = -1$. **Why natural.** -1 is a unit modulo every n, and it is an involution, so its cycle type is trivial to compute: fixed points are the solutions of $2x \equiv 0$, of which there are exactly $\gcd(2, n)$, and everything else pairs up. Counting transpositions is then one subtraction, and the parity of that count is decided by n modulo 4. **Link to the next block.** The three cases are now exhaustive and the classification is complete.

Layer 3: WHY

The mathematical truth beneath the lemma is that squaring acts on cycles like a two step walk. On a cycle of odd length the step of size 2 is a generator of $\mathbb{Z}/\ell\mathbb{Z}$, so the cycle survives intact; on a cycle of even length the step of size 2 preserves parity, so the cycle splits into two halves of equal length. Therefore the squaring map on the symmetric group merges pairs of equal cycles and preserves odd cycles, and the image is exactly the set of permutations whose even cycle lengths pair up. Every question of the form "is this permutation a d-th power" is answered by the same analysis with d in place of 2, using $\gcd(d, \ell)$.

The second truth is that multiplication by a unit on $\mathbb{Z}/n\mathbb{Z}$ is a group action whose orbits you already know how to count: the orbit of x has size equal to the multiplicative order of m modulo $n/\gcd(x, n)$. The Chinese remainder theorem then makes the whole cycle type a product computation. That is why the odd case is beaten by a primitive root: cyclicity of $(\mathbb{Z}/p^e\mathbb{Z})^\times$ for odd p guarantees an element of maximal even order $\varphi(p^e)$, and the number of maximal orbits is then forced to be odd because everything else in sight is odd.

The discernment mechanism is a two part question you should ask on sight of any condition like $\pi \circ \pi =$ something. First: does the problem constrain π beyond being a permutation? Here it does not, so the answer depends only on conjugacy invariants, that is, on cycle type. Second: is the object whose cycle type I need a group action in disguise? Multiplication by m is, so its cycle type is a statement about orders, and orders factor through the Chinese remainder theorem. Train this by taking any permutation that is presented by a formula (multiplication, addition, a polynomial map, a shift) and computing its cycle type before doing anything else.

How the setter nudged: the phrase "for all integers m that are relatively prime to n" is a universal quantifier over the unit group, which is an invitation to pick your favourite unit, and the two favourites are -1, which exists always, and a primitive root, which exists on odd prime powers. The answer $n \equiv 2 \pmod 4$ then reads as "the factor of 2 must be present to duplicate everything, but not two factors of 2, since -1 then has an odd number of transpositions".

Revolving concepts

Disjoint cycle decomposition and conjugacy. Every permutation of a finite set is a product of disjoint cycles, uniquely up to order, and two permutations are conjugate in the symmetric group exactly when they have the same multiset of cycle lengths (the cycle type). Anything invariant under conjugation, such as being a square, must be a condition on cycle type. See Book 1, field: Abstract algebra, topic: symmetric groups and cycle type.

Squares in the symmetric group. σ is a square if and only if every even cycle length occurs an even number of times. More generally, σ is a d-th power if and only if for every ℓ, the cycles of length ℓ can be grouped so that each group of size g with $g \mid d$ and $\gcd(d/g, \ell) = 1$ merges into a cycle of length $g\ell$; the practical version to remember is the $d = 2$ case and the mechanism (a d step walk around a cycle of length ℓ splits it into $\gcd(d, \ell)$ cycles of length $\ell/\gcd(d, \ell)$). See Book 1, field: Abstract algebra, topic: powers and roots of permutations.

Chinese remainder theorem as a ring isomorphism. If $n = ab$ with $\gcd(a, b) = 1$ then $\mathbb{Z}/n\mathbb{Z} \cong \mathbb{Z}/a\mathbb{Z} \times \mathbb{Z}/b\mathbb{Z}$ as rings, hence $(\mathbb{Z}/n\mathbb{Z})^\times \cong (\mathbb{Z}/a\mathbb{Z})^\times \times (\mathbb{Z}/b\mathbb{Z})^\times$ as groups. Use it to prescribe m independently on each factor. See Book 1, field: Number theory, topic: Chinese remainder theorem.

Structure of the unit group modulo a prime power. For odd p, $(\mathbb{Z}/p^e\mathbb{Z})^\times$ is cyclic of order $p^{e-1}(p-1)$, so primitive roots exist; for $p = 2$ the group is trivial for $e = 1$, cyclic of order 2 for $e = 2$, and $\mathbb{Z}/2\mathbb{Z} \times \mathbb{Z}/2^{e-2}\mathbb{Z}$ for $e \geq 3$. The evenness of $p - 1$ for odd p is what supplies the even cycle length in the odd case. See Book 1, field: Number theory, topic: primitive roots.

Orbits of a multiplicative action. Under $x \mapsto mx$ on $\mathbb{Z}/n\mathbb{Z}$ with $\gcd(m, n) = 1$, the orbit of x has length equal to the multiplicative order of m modulo $n/\gcd(x, n)$. The set of x with a fixed gcd is a union of orbits, which is how the cycle count is obtained without listing anything. See Book 1, field: Number theory, topic: multiplicative order.

Recursion, generalised. The cycle lengths in the odd case follow the descending recursion $L_j = p^{e-j-1}(p-1)$, that is, $L_{j+1} = L_j/p$ for $0 \leq j \leq e-2$, terminating at $L_{e-1} = p - 1$ and then at a fixed point. This is the standard filtration recursion for a p-adic valuation: an element of valuation j behaves like an element of the smaller ring $\mathbb{Z}/p^{e-j}\mathbb{Z}$, so any orbit or order computation on $\mathbb{Z}/p^e\mathbb{Z}$ reduces by induction on e, with the answer for valuation j read off the answer for exponent $e - j$. The same reduction solves counting problems for solutions of congruences modulo prime powers, where lifting from p^e to p^{e+1} is Hensel's lemma. See Book 1, field: Number theory, topic: filtration by p-adic valuation.

Circuit Bank

- **WHEN** you see $\pi \circ \pi = \sigma$ with π unconstrained apart from being a permutation **DO** forget formulas and compute cycle types, then apply the criterion that every even cycle length must occur an even number of times **BECAUSE** being a square is invariant under conjugation, and cycle type is the complete conjugation invariant of a permutation
- **WHEN** you see a map given by multiplication by a unit modulo n **DO** split $\mathbb{Z}/n\mathbb{Z}$ by the Chinese remainder theorem and compute orbit lengths as multiplicative orders on each prime power factor **BECAUSE** multiplication by a unit is a group action, and orders and orbits are multiplicative across coprime factors
- **WHEN** you must disprove a statement quantified over all units m **DO** test $m = -1$ first, then a primitive root on one odd prime power factor **BECAUSE** -1 is a unit for every n and is an involution whose cycle type is immediate, while a primitive root maximises orbit length and therefore minimises and pins down the orbit count
- **WHEN** you need a permutation to have an even number of cycles of each even length **DO** look for an involution of the underlying set that commutes with the permutation and has no fixed points, so the set splits into two conjugate halves **BECAUSE** conjugate permutations have equal cycle types, so a free involution commuting with σ doubles every cycle count automatically

Backtesting

1. First useful cue: $\pi(\pi(k)) \equiv mk$ is the group equation $\pi^2 = \sigma_m$, and π carries no other constraint.
2. Method the expression suggested: classify squares in the symmetric group by cycle type, then compute the cycle type of multiplication by m using the Chinese remainder theorem.
3. Where you would hesitate, and the thought to reinforce: choosing the bad m in the odd case. Reinforce this: to break a universal statement about units, take a generator on one prime

power factor and the identity on the rest, so that the count of long cycles equals the size of the untouched factor.

4. The trap the question sets: guessing that π must itself be multiplication by some c, which reduces the problem to quadratic residues and gives the wrong answer set.
5. What makes you recognise it faster next time: any condition of the form "there is a permutation whose square is the given map" is a cycle type question, never a formula question.
6. The reusable decision rule: for equations inside a group, translate to structure theory of that group first; for permutations that structure is the cycle type.

Mirror drills

1. Show that the 4-cycle $(1\,2\,3\,4)$ is not the square of any permutation of $\{1,2,3,4\}$. *Answer:* it has exactly one cycle of the even length 4, and an odd count of even cycles is forbidden.
2. Show that every permutation of odd order is a square. *Answer:* all its cycle lengths are odd, so the criterion is vacuously satisfied; explicitly, if $\sigma^N = \mathrm{id}$ with N odd then $\sigma = (\sigma^{(N+1)/2})^2$.
3. Find an m coprime to 7 for which no permutation π of $\{1,\dots,7\}$ satisfies $\pi(\pi(k)) \equiv mk \pmod 7$. *Answer:* $m = 3$, a primitive root modulo 7, gives a single 6-cycle on the units together with the fixed point 0; one cycle of even length 6 is an odd count.

3.12 B6. Determinant of a matrix of representation counts

Let n be a positive integer. For i and j in $\{1, 2, \ldots, n\}$, let $s(i, j)$ be the number of pairs (a, b) of nonnegative integers satisfying $ai + bj = n$. Let S be the n-by-n matrix whose (i, j) entry is $s(i, j)$. For example, when $n = 5$, we have

$$S = \begin{bmatrix} 6 & 3 & 2 & 2 & 2 \\ 3 & 0 & 1 & 0 & 1 \\ 2 & 1 & 0 & 0 & 1 \\ 2 & 0 & 0 & 0 & 1 \\ 2 & 1 & 1 & 1 & 2 \end{bmatrix}.$$

Compute the determinant of S.

Read it out loud

Say the entry out loud before you say the word determinant: $s(i, j)$ counts the ways of writing n as a multiple of i plus a multiple of j. That is a convolution. Write $k = ai$ for the first part, so $n - k = bj$ for the second, and the count becomes

$$s(i, j) = \sum_{k=0}^{n} [\, i \mid k \,]\, [\, j \mid n - k \,],$$

where $[\, v \mid u \,]$ is 1 when v divides u and 0 otherwise, and every positive integer divides 0. A sum over an index k of a product of a term depending on (i, k) and a term depending on (k, j) is a matrix product. So S is not a mysterious table of counts; it is AB, where A and B are divisor incidence matrices.

Now the structural surprise that makes this a B6 and not a B2: the index k runs over $n + 1$ values, from 0 to n, while S is n-by-n. So A is n-by-$(n + 1)$ and B is $(n + 1)$-by-n, and there is no factorisation of $\det S$ as a product of two determinants. The tool for the determinant of a product of rectangular matrices is the Cauchy-Binet formula, which expresses $\det(AB)$ as a sum over maximal minors. Here that sum has exactly $n + 1$ terms, one for each column of A that you delete. The problem was built around this: one surplus column is the smallest interesting case of Cauchy-Binet.

The fields wired in: combinatorial counting to see the convolution, linear algebra (multilinearity of the determinant, Cauchy-Binet, sign of a column reversal), and multiplicative number theory (Möbius inversion and the partial sums of the Möbius function). What is really being tested is whether you can see a matrix as an operator built from a bilinear count, rather than as a table of numbers.

Knowledge gaps, stated plainly. Nothing in A-level Mathematics or Further Mathematics gives you Cauchy-Binet, the Möbius function, or Möbius inversion; those three must be installed before this problem is even approachable. If you do not have them, your only route is a long sequence of row and column operations on S itself, which is genuinely doable but is a bookkeeping marathon with two parity cases and a sign to track at every step. Install the three tools instead.

Within thirty seconds you should have written $s(i, j) = \sum_k [i \mid k][j \mid n - k]$, the sizes n by $n + 1$ and $n + 1$ by n, and the words "Cauchy-Binet, one surplus column".

Approaches, ranked worst to best

1. **Expand the determinant directly.** *Cue:* "compute the determinant". *Circuit:* a determinant is a signed sum over permutations. With entries as irregular as these, cofactor expansion produces nothing but noise. There is no pattern along any single row until you have already understood the structure, so this route never starts.

2. **Compute small cases and conjecture.** *Cue:* the answer must be a formula in n. *Circuit:* when the answer is a function of n, tabulate the first few values. You get $2, 2, -4, -4, 6, 6, -8, -8, \ldots$ for $n = 1, 2, 3, \ldots$, hence the conjecture $(-1)^{\lceil n/2 \rceil - 1} 2 \lceil n/2 \rceil$. Compulsory as a sanity check and as a target, worth close to nothing on its own, since "compute" on a B6 means "prove".

3. **Peel off rank one pieces.** *Cue:* the extreme terms $k = 0$ and $k = n$ of the convolution are special. *Circuit:* split a sum into a bulk term and boundary terms, then use the matrix determinant lemma. The $k = 0$ term contributes the rank one matrix with (i, j) entry $[\, j \mid n \,]$ and the $k = n$ term the rank one matrix with entry $[\, i \mid n \,]$, leaving a bulk product of an n-by-$(n-1)$ with an $(n-1)$-by-n matrix, which is singular. So S is a rank two update of a singular matrix and the determinant can be extracted. It works, but you end up computing the same minors that Cauchy-Binet would have handed you uniformly, with extra case analysis.

4. **Row and column reduction on S itself.** *Cue:* the entries for $i > n/2$ are visibly 0 or 1. *Circuit:* clear a matrix using its own structural rows. For $i > n/2$ the equation $ai + bj = n$ forces $a \in \{0, 1\}$, so those rows are almost indicator vectors; subtracting multiples of row $n-1$ and column $n-1$ makes most of the matrix an incidence pattern that can be cleared entry by entry, each clearance costing a sign. This is complete and elementary, and it is the official first solution, but it needs a separate endgame for n odd and n even and many sign decisions. Under time pressure it is where marks go missing.

5. **Factor as a product of divisor matrices, then Cauchy-Binet and Möbius inversion.** *Cue:* a bilinear count over a summation index, with $n + 1$ values of that index. *Circuit:* a convolution is a matrix product; a rectangular product needs Cauchy-Binet; divisor matrices are inverted by Möbius. Every step is forced by the previous one, each minor is a one line computation once you know the divisor matrix is unitriangular, and the final sum collapses using $\sum_{k \le n} C_k = 1$. Best, and it is the only route that explains why the answer depends on n only through $\lceil n/2 \rceil$.

The ideal solution

The answer is $\boxed{(-1)^{\lceil n/2 \rceil - 1}\, 2 \left\lceil \dfrac{n}{2} \right\rceil}$.

Step 1: factor S. For integers $u \ge 0$ and $v \ge 1$ write $[\, v \mid u \,] = 1$ if v divides u and 0 otherwise, so that $[\, v \mid 0 \,] = 1$ always. Let A be the n-by-$(n+1)$ matrix with rows indexed by $i \in \{1, \ldots, n\}$ and columns by $k \in \{0, 1, \ldots, n\}$, and B the $(n+1)$-by-n matrix with rows indexed by k and columns by j, defined by

$$A_{ik} = [\, i \mid k \,], \qquad B_{kj} = [\, j \mid n - k \,].$$

A pair (a, b) of nonnegative integers with $ai + bj = n$ is determined by $k := ai$, which satisfies $0 \le k \le n$, $i \mid k$ and $j \mid n - k$; conversely any such k gives the pair $(k/i, (n-k)/j)$. Hence

$$(AB)_{ij} = \sum_{k=0}^{n} [\, i \mid k \,][\, j \mid n - k \,] = s(i, j), \qquad \text{that is} \qquad S = AB.$$

Step 2: Cauchy-Binet. For an n-by-$(n+1)$ matrix A and an $(n+1)$-by-n matrix B, the Cauchy-Binet formula gives $\det(AB) = \sum_K \det(A_K) \det(B_K)$, the sum over all n-element subsets K of the common index set $\{0, \ldots, n\}$, where A_K keeps the columns in K and B_K the rows in K. Each such K omits exactly one index k, so writing $A^{(k)}$ for A with column k deleted and $B^{(k)}$ for B with row k deleted,

$$\det S = \sum_{k=0}^{n} \det\bigl(A^{(k)}\bigr) \det\bigl(B^{(k)}\bigr).$$

Step 3: express the minors of B through those of A. Since $(B^T)_{jk} = [\, j \mid n - k \,] = A_{j, n-k}$, the matrix B^T is A with its columns reversed. Deleting row k of B is deleting column k of B^T, which is

column $n-k$ of A; so $\left(B^{(k)}\right)^T$ is $A^{(n-k)}$ with its n columns in reversed order. Reversing n columns is a permutation of sign $(-1)^{n(n-1)/2}$, and transposing does not change a determinant, so

$$\det\left(B^{(k)}\right) = (-1)^{n(n-1)/2}\det\left(A^{(n-k)}\right).$$

Writing $D_k := \det(A^{(k)})$ we therefore have

$$\det S = (-1)^{n(n-1)/2}\sum_{k=0}^{n} D_k\, D_{n-k}.$$

Step 4: compute the maximal minors D_k. Let $v_0, v_1, \dots, v_n \in \mathbb{Z}^n$ be the columns of A and $e_1, \dots, e_n$ the standard basis. By definition $v_k = \sum_{d\mid k} e_d$ for $1 \le k \le n$, and $v_0 = e_1 + \cdots + e_n$.

First, $D_0 = \det(v_1, \dots, v_n)$ is the determinant of $([\, i \mid k\,])_{i,k=1}^{n}$, which is upper triangular because $i \mid k$ with $1 \le i, k \le n$ forces $i \le k$, and its diagonal entries are $[\, k \mid k\,] = 1$. Hence $D_0 = 1$ and $v_1, \dots, v_n$ is a basis of $\mathbb{Q}^n$.

Next, Möbius inversion applied to $v_k = \sum_{d\mid k} e_d$ gives $e_k = \sum_{d\mid k} \mu(d)\, v_{k/d}$ for $1 \le k \le n$. Summing over k and substituting $k = md$,

$$v_0 = \sum_{k=1}^{n} e_k = \sum_{k=1}^{n}\sum_{d\mid k}\mu(d)v_{k/d} = \sum_{m=1}^{n} C_m v_m, \qquad C_m := \sum_{1\le d\le n/m}\mu(d).$$

Fix k with $1 \le k \le n$. The matrix $A^{(k)}$ has columns $v_0, v_1, \dots, v_{k-1}, v_{k+1}, \dots, v_n$ in that order. Expanding v_0 by the displayed identity and using multilinearity, every term with $m \ne k$ repeats a column and dies, leaving

$$D_k = C_k \det(v_k, v_1, \dots, v_{k-1}, v_{k+1}, \dots, v_n) = (-1)^{k-1} C_k \det(v_1, \dots, v_n) = (-1)^{k-1} C_k,$$

the sign coming from moving v_k past the $k-1$ columns $v_1, \dots, v_{k-1}$. If we define $C_0 := -1$, then $D_0 = 1 = (-1)^{0-1} C_0$ as well, so

$$D_k = (-1)^{k-1} C_k \qquad (0 \le k \le n).$$

Step 5: evaluate the convolution. Since $(-1)^{k-1}(-1)^{n-k-1} = (-1)^n$,

$$\det S = (-1)^{n(n-1)/2}(-1)^n\,\Sigma, \qquad \Sigma := \sum_{k=0}^{n} C_k C_{n-k}.$$

Note that $C_m = \sum_{d\le\lfloor n/m\rfloor}\mu(d)$ depends only on $\lfloor n/m\rfloor$. In particular $C_m = \mu(1) = 1$ whenever $m > n/2$, and $C_m = \mu(1) + \mu(2) = 0$ whenever $n/3 < m \le n/2$; the second fact will be used only in the form $C_{n/2} = 0$ for even n.

The two extreme terms of Σ are $C_0 C_n$ and $C_n C_0$, each equal to -1, contributing -2. For $1 \le k \le n-1$ with $k \ne n/2$, exactly one of k and $n-k$ exceeds $n/2$, so $C_k C_{n-k} = C_{\min(k,n-k)}$; as k runs over that range each value $m < n/2$ occurs exactly twice, and if n is even the leftover term $k = n/2$ contributes $C_{n/2}^2 = 0$, which is also what extending the doubled sum up to $\lfloor n/2\rfloor$ contributes. Hence

$$\Sigma = -2 + 2\sum_{m=1}^{\lfloor n/2\rfloor} C_m.$$

That last sum is a standard collapse:

$$\sum_{m=1}^{n} C_m = \sum_{m=1}^{n}\sum_{1\le d\le n/m}\mu(d) = \sum_{\substack{d,m\ge 1\\ dm\le n}}\mu(d) = \sum_{f=1}^{n}\sum_{d\mid f}\mu(d) = \sum_{f=1}^{n}[\, f = 1\,] = 1,$$

using the defining property of the Möbius function. Since $C_m = 1$ for each of the $n - \lfloor n/2 \rfloor = \lceil n/2 \rceil$ values $m > \lfloor n/2 \rfloor$, we get $\sum_{m \le \lfloor n/2 \rfloor} C_m = 1 - \lceil n/2 \rceil$ and therefore

$$\Sigma = -2 + 2\left(1 - \left\lceil \frac{n}{2} \right\rceil\right) = -2\left\lceil \frac{n}{2} \right\rceil.$$

Step 6: the sign. Combining,

$$\det S = (-1)^{n(n-1)/2}(-1)^n \left(-2\left\lceil \frac{n}{2} \right\rceil\right) = (-1)^{n(n+1)/2+1}\, 2\left\lceil \frac{n}{2} \right\rceil.$$

Finally, $n(n+1)/2 + 1$ and $\lceil n/2 \rceil - 1$ have the same parity for every n. Both are periodic in n modulo 4: replacing n by $n+4$ changes $n(n+1)/2$ by $4n+10$, which is even, and changes $\lceil n/2 \rceil$ by 2. So it suffices to check $n = 0, 1, 2, 3$, where the two quantities are $(1, 2, 4, 7)$ and $(-1, 0, 0, 1)$, matching in parity in each case. Therefore

$$\det S = (-1)^{\lceil n/2 \rceil - 1}\, 2\left\lceil \frac{n}{2} \right\rceil.$$

As a check, $n = 1$ gives $S = [2]$ and the formula gives 2; $n = 5$ gives 6, which is the determinant of the matrix displayed in the statement. ■

Layer 1: WHAT

Block 1. Rewrite the entry as a convolution: $s(i, j) = \sum_{k=0}^{n} [i \mid k][j \mid n-k]$.

Block 2. Read the convolution as a matrix product $S = AB$ with divisor incidence matrices, and notice the index k has one more value than the matrix has rows.

Block 3. Apply Cauchy-Binet: $\det S$ is the sum over the $n+1$ ways of deleting one index.

Block 4. Identify B^T as A with reversed columns, so all the minors of B are minors of A up to one global sign.

Block 5. Compute the minors of A: the square block on columns 1 to n is unitriangular, and Möbius inversion writes the extra column v_0 in that basis with Mertens coefficients C_m.

Block 6. Evaluate $\sum_k C_k C_{n-k}$ using $C_m = 1$ for $m > n/2$ and the collapse $\sum_{m \le n} C_m = 1$.

Block 7. Reconcile the two signs into $(-1)^{\lceil n/2 \rceil - 1}$ by a periodicity check modulo 4.

Juxtaposition. The nominal route stares at the sample matrix for $n = 5$, notices that the last row and the first row look structured, and starts eliminating. It can be pushed through, and it is a legitimate solution, but every step is local and nothing tells you where the answer is heading until it arrives. The bifurcation point is the sentence "the entry is a sum over an intermediate index, so this matrix is a product". Once written, the rest of the solution is determined: rectangular product forces Cauchy-Binet, divisor matrix forces Möbius, and the sum over deletions forces a convolution of Mertens sums.

Layer 2: HOW

Block 1. Cue. The entry counts solutions of $ai + bj = n$ in nonnegative integers, a two part decomposition of n. **Why natural.** A count of ways to split a fixed total into a part from one family and a part from another family is by definition a convolution. Introducing the intermediate quantity $k = ai$ is not a substitution, it is naming the split point, which is the only structural feature the count has. **Link to the next block.** Convolutions are matrix products, so a matrix of convolution counts is a product of two matrices.

Block 2. Cue. The summation index runs over $\{0, 1, \ldots, n\}$, which has $n+1$ elements, while the matrix is n by n. **Why natural.** You must count the index set before choosing a tool. If k had run over n values you would get $\det S = \det A \det B$ and be finished in three lines; the surplus value $k = 0$, which exists because $a = 0$ is allowed, is precisely what makes the problem hard. Notice also that $k = 0$ and $k = n$ are the terms where one of the two parts is empty. **Link to the next block.** A rectangular factorisation is exactly the hypothesis of Cauchy-Binet.

Block 3. **Cue.** A product of an n-by-N and an N-by-n matrix, with $N = n + 1$. **Why natural.** Cauchy-Binet is the statement that the determinant of such a product is the sum over all n-element column selections of the product of the corresponding minors. With $N = n + 1$ there are only $n + 1$ selections, indexed by the deleted column, so the formula is a short sum rather than a combinatorial explosion. This is the only general tool that computes a determinant through a rectangular factorisation, so the cue determines the tool uniquely. **Link to the next block.** The problem is now to compute the $n + 1$ maximal minors of each factor.

Block 4. **Cue.** B_{kj} depends on $n - k$ where A_{jk} depends on k. **Why natural.** The two factors were built from the same divisor pattern, one indexed forwards and one backwards, because the equation $ai + bj = n$ is symmetric under swapping the roles of the two parts. Recognising B^T as A with reversed columns halves the work: you compute one family of minors, not two. The price is a single global sign, the sign of the reversal permutation. **Link to the next block.** Everything reduces to the numbers $D_k = \det A^{(k)}$.

Block 5. **Cue.** The divisor matrix restricted to columns 1 to n is triangular, and each column v_k is the sum of the basis vectors indexed by the divisors of k. **Why natural.** $i \mid k$ forces $i \leq k$, which is triangularity for free, so the columns $v_1, \ldots, v_n$ are a basis with determinant 1. The remaining column v_0 is the all ones vector, and the standard way to express a sum of basis vectors in terms of divisor sums is Möbius inversion, which is exactly the inverse of the operation "sum over divisors". Once $v_0 = \sum_m C_m v_m$, multilinearity kills every term but one in each minor, because all the other columns v_m are already present. **Link to the next block.** The minors are the Mertens sums up to sign, and the determinant becomes a convolution of those sums.

Block 6. **Cue.** A convolution $\sum_k C_k C_{n-k}$ where C_m depends only on $\lfloor n/m \rfloor$. **Why natural.** For m beyond the half way point $\lfloor n/m \rfloor = 1$ and $C_m = 1$, so in each pair $\{k, n - k\}$ one factor is 1 and the convolution degenerates into twice a partial sum. Partial sums of the Möbius function look hostile, but $\sum_{m \leq n} C_m$ is a double sum over $dm \leq n$ that reorders into $\sum_{f \leq n} \sum_{d \mid f} \mu(d)$, and the inner sum is the definition of μ as the inverse of the constant function 1. Never estimate a Mertens sum; reorder it. **Link to the next block.** The full sum is $-2\lceil n/2 \rceil$, and only the sign remains.

Block 7. **Cue.** Two sign factors, $(-1)^{n(n-1)/2}$ and $(-1)^n$, and a target expressed with a ceiling. **Why natural.** Both candidate exponents are periodic modulo 4 in n, so checking four values is a proof, not a spot check. Stating the periodicity first is what makes the four checks legitimate. **Link to the next block.** The two forms agree, so the answer can be written in the ceiling form.

Layer 3: WHY

The truth underneath is that this matrix is not a matrix of numbers but the Gram-like matrix of a bilinear pairing. The pairing is: given the divisor structure of the integers up to n, pair the indicator of multiples of i against the indicator of multiples of $n - k$ for j. The determinant of a Gram-like matrix built from two families of vectors in a space of dimension $n + 1$ is, by Cauchy-Binet, a sum over the ways of dropping one dimension. So the answer is a sum over the $n + 1$ possible "missing" split points, and the reason the final answer counts roughly $n/2$ is that only the split points beyond the half way mark contribute the trivial Mertens value 1.

The second truth is that the divisor matrix and the Möbius matrix are inverse to each other. The map "sum over divisors" is invertible on the integers up to n, and its inverse is the Möbius transform. That is why the minors are computable at all: any incidence matrix of a locally finite partial order with ones on the diagonal is unitriangular in a linear extension of the order, hence invertible over the integers, and its inverse is the Möbius function of the poset. Divisibility is the

poset here, and the classical Möbius function of number theory is precisely the Möbius function of that poset.

The discernment mechanism has three questions, and you should ask them in order on any determinant of a combinatorially defined matrix. First: is the entry a sum over an intermediate index? If yes, the matrix is a product, and you should factor before you compute. Second: do the factors have the same size as the matrix? If not, Cauchy-Binet, and count how many surplus columns there are, because that is the length of the resulting sum. Third: are the factors incidence matrices of an order? If yes, they are unitriangular, their determinants are 1, and their inverses are given by a Möbius function. Any one of those three questions answered wrongly turns this from a fifteen minute problem into a two hour one.

Train the discernment by refusing to compute any structured determinant before attempting a factorisation. Take the matrices $\gcd(i,j)$, $\lfloor n/\operatorname{lcm}(i,j)\rfloor$, the number of common divisors of i and j, and Smith's determinant; all of them factor through the divisor matrix, all of them are solved by the same three questions, and none of them should be attacked by elimination.

What the setter nudged with: the example matrix for $n = 5$ is printed in the statement, which is an invitation to compute small cases and conjecture, and the answer depends on n only through $\lceil n/2\rceil$, which is a strong hint that the split point $n/2$ matters. The count $s(i,j)$ was defined with nonnegative rather than positive integers, which is exactly what creates the surplus index values $k = 0$ and $k = n$ and therefore the need for Cauchy-Binet.

Revolving concepts

Cauchy-Binet formula. If A is m-by-N and B is N-by-m with $N \geq m$, then $\det(AB) = \sum_K \det(A_{\cdot,K})\det(B_{K,\cdot})$, summed over the m-element subsets K of $\{1,\dots,N\}$. For $N = m$ it reduces to $\det(AB) = \det A \det B$, and for $N < m$ it gives $\det(AB) = 0$. The special case $B = A^T$ gives $\det(AA^T) = \sum_K \det(A_{\cdot,K})^2$, the Gram determinant as a sum of squared minors. See Book 1, field: Matrices and determinants, topic: Cauchy-Binet.

Multilinearity and alternation of the determinant. The determinant is linear in each column and vanishes when two columns coincide; consequently, substituting a linear combination for one column leaves only the terms whose vector is not already among the other columns, and reordering columns multiplies by the sign of the permutation. Reversing m columns has sign $(-1)^{m(m-1)/2}$. See Book 1, field: Matrices and determinants, topic: multilinearity and column operations.

Möbius function and Möbius inversion. Define $\mu(1) = 1$, $\mu(d) = (-1)^r$ if d is a product of r distinct primes, and $\mu(d) = 0$ if d is divisible by a square. The defining property is $\sum_{d\mid f}\mu(d) = [f = 1]$. Inversion: if $g(k) = \sum_{d\mid k} h(d)$ for all k, then $h(k) = \sum_{d\mid k}\mu(d)g(k/d)$. In matrix language the divisor incidence matrix $Z = ([i \mid j])$ and the matrix $M = (\mu(j/i)[i \mid j])$ satisfy $MZ = ZM = I$. See Book 1, field: Number theory, topic: Möbius inversion.

Mertens sums. $C_m = \sum_{d\leq n/m}\mu(d)$ is a partial sum of the Möbius function, that is, the Mertens function evaluated at $\lfloor n/m\rfloor$. Individually these are erratic (the growth of the Mertens function is a deep open problem tied to the Riemann hypothesis), but the aggregate $\sum_{m\leq n} C_m$ collapses to 1 by reordering the double sum over $dm \leq n$. The moral: never evaluate a Mertens sum, only sum it. See Book 1, field: Number theory, topic: Dirichlet hyperbola reordering.

Dirichlet convolution and incidence algebras. The identity $s(i,j) = \sum_k [i \mid k][j \mid n-k]$ is an additive convolution, while $\sum_{d\mid f}\mu(d)$ is a multiplicative (Dirichlet) convolution; the problem sits at the crossing of the two, which is why it needs both a matrix product and a Möbius inversion. In general, the incidence matrix of any locally finite poset with ones on the diagonal is unitriangular in a linear extension, is invertible over the integers, and its inverse encodes the poset's Möbius function. See Book 1, field: Discrete structures and graphs, topic: incidence algebras and poset Möbius functions.

Recursion, generalised. Two recursions sit inside this solution. The first is the divisor recursion $v_k = \sum_{d\mid k} e_d$, whose inversion $e_k = \sum_{d\mid k}\mu(d)v_{k/d}$ is the general solution method for any relation

of the form $g = Zh$ with Z the divisor incidence operator: the solution is $h = Mg$ with M the Möbius operator, and the same statement holds verbatim for any locally finite poset with μ replaced by the poset's Möbius function. The second is the triangular recursion behind $\det D_0 = 1$: for a unitriangular system $x_k = \sum_{i<k} c_{ik} x_i + y_k$ the solution is obtained by forward substitution and the determinant is 1. The general lesson to install: whenever a family of vectors is indexed by a partial order and each vector is the sum of the basis vectors below it, that family is a basis, its transition matrix has determinant 1, and the inverse transition is the Möbius function of the order. See Book 1, field: Number theory, topic: divisor sum inversion.

Circuit Bank

- **WHEN** you see a matrix whose entry is a sum over an intermediate index of a product of two factors **DO** write the matrix as a product of two explicit matrices before attempting any determinant computation **BECAUSE** a determinant of a product is far more tractable than a determinant of a table, and factorisation exposes the structure that elimination only stumbles upon
- **WHEN** you have factored an n by n matrix as a product of an n by N and an N by n matrix with $N > n$ **DO** apply Cauchy-Binet and count the surplus, since the sum has one term per n-element subset of the N indices **BECAUSE** the determinant of a rectangular product is the sum of products of maximal minors, and with one surplus column the sum has only $n + 1$ terms
- **WHEN** you meet a matrix of divisibility indicators **DO** note it is unitriangular in the natural order, so its determinant is 1, and invert it with Möbius inversion **BECAUSE** $i \mid k$ forces $i \leq k$, so the divisibility incidence matrix is triangular with unit diagonal, and its inverse is the Möbius matrix
- **WHEN** you must evaluate a sum of partial sums of the Möbius function **DO** reorder the double sum by the product of the two indices, not by either index separately **BECAUSE** $\sum_{dm \leq n} \mu(d)$ groups by $f = dm$ into $\sum_{f \leq n} \sum_{d \mid f} \mu(d)$, which is 1; individual Mertens values are erratic but their aggregate telescopes
- **WHEN** your answer carries a sign of the form $(-1)^{q(n)}$ with q a quadratic in n **DO** prove the exponent is periodic modulo 4 and check four values **BECAUSE** a quadratic exponent changes by an even amount when n increases by 4, so four checks constitute a proof rather than a sample

Backtesting

1. First useful cue: the entry $s(i, j)$ counts splittings of n at an intermediate point $k = ai$, which is a convolution and therefore a matrix product.
2. Method the expression suggested: factor $S = AB$ with divisor incidence matrices of sizes n by $n + 1$ and $n + 1$ by n, then Cauchy-Binet.
3. Where you would hesitate, and the thought to reinforce: computing the maximal minors of A. Reinforce this: the columns indexed 1 to n are unitriangular hence a basis, so the only real work is expressing the surplus column in that basis, which is exactly what Möbius inversion does.
4. The trap the question sets: the surplus index. Allowing $a = 0$ and $b = 0$ makes the summation range $n + 1$ long, so the tempting factorisation into two square matrices is unavailable, and any solution that quietly assumes $\det S = \det A \det B$ is wrong.

5. What makes you recognise it faster next time: a combinatorially defined matrix whose entry counts a two part decomposition of a fixed total is always a product of two incidence matrices, and the length of the summation index decides whether you need Cauchy-Binet.
6. The reusable decision rule: factor first, count the index set second, invert incidence matrices with Möbius third, and reorder Mertens sums rather than evaluating them.

Mirror drills

1. Show that the n-by-n matrix with entries $[\,i \mid j\,]$ has determinant 1. *Answer:* a nonzero entry needs $i \mid j$ hence $i \le j$, so the matrix is upper triangular, and every diagonal entry is $[\,i \mid i\,] = 1$.
2. With $Z_{ij} = [\,i \mid j\,]$ and $M_{ij} = \mu(j/i)[\,i \mid j\,]$ for $1 \le i, j \le n$, prove $MZ = I$. *Answer:* the (i,k) entry is $\sum_{i \mid j \mid k} \mu(j/i)$, which after writing $j = id$ and $k = if$ becomes $\sum_{d \mid f} \mu(d) = [\,f = 1\,] = [\,i = k\,]$.
3. Let $A = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 1 & 2 \end{pmatrix}$. Use Cauchy-Binet to compute $\det(AA^T)$ and check it directly. *Answer:* the three maximal minors are $1, 2, 1$, so the sum of their squares is 6; directly $AA^T = \begin{pmatrix} 3 & 3 \\ 3 & 5 \end{pmatrix}$ with determinant 6.

Chapter 4

Putnam 2022

4.1 A1. Lines meeting a logarithmic curve exactly once

Determine all ordered pairs of real numbers (a, b) such that the line $y = ax + b$ intersects the curve $y = \ln(1 + x^2)$ in exactly one point.

Read it out loud

Read the structure aloud before you write anything: this is a root-counting question for the equation $\ln(1 + x^2) = ax + b$, dressed up as a geometry question about a line and a curve. The moment you hear yourself say "count the solutions of $F(x) = 0$ where F depends on two parameters", the whole thing becomes single-variable calculus: monotonicity, turning points, and limits at $\pm\infty$. The fields wired into this problem are elementary real analysis (intermediate value theorem, monotonicity from the sign of the derivative), curve sketching, and a small amount of quadratic algebra to locate the turning points.

Now say the second sentence out loud: the parameter b appears only as an additive constant. That is the entire problem. If you write $g(x) = \ln(1 + x^2) - ax$, then the equation is $g(x) = b$, and counting intersections is counting preimages of a horizontal level under a fixed function g. For a one-variable function the number of preimages of a level is completely controlled by the shape of g: how many monotone pieces it has and what the values at the turning points are. So the two parameters are not symmetric in difficulty. You sweep b for free once you know the shape of g, and the only real work is classifying the shape of g as a varies.

The third thing to say aloud is that $\ln(1 + x^2)$ is even and its derivative $2x/(1 + x^2)$ is a bounded function, bounded by 1 in absolute value, with equality only at $x = \pm 1$. That bound is exactly the sort of guiding light the setters plant: the number 1 appearing as the extreme slope of the curve is why $|a| = 1$ is the threshold in the answer. A curve whose slope never exceeds 1 can be crossed at most once by a line of slope 1 or steeper.

Within thirty seconds you should have written down three things: $g(x) = \ln(1 + x^2) - ax$, the count is the number of solutions of $g(x) = b$, and $g'(x) = \dfrac{2x}{1 + x^2} - a$, whose sign is the sign of $-(ax^2 - 2x + a)$. A quadratic in the numerator means at most two turning points, which means at most three monotone pieces, which means the answer will be a case split on how many turning points there are: none, one degenerate one, or two.

Approaches, ranked worst to best

1. **Tangency algebra.** *Cue:* "exactly one point" sounds like a repeated root. *Circuit:* discriminant circuit from quadratics. This is the zombie route imported from GCSE and A-level: exactly one intersection means tangency, so impose $\ln(1 + x^2) = ax + b$ and $2x/(1 + x^2) = a$ simultaneously and eliminate. It ranks last because the premise is false here. Tangency is neither necessary nor sufficient for a single intersection with a transcendental curve: the line of slope 2 through the origin meets the curve once and is nowhere tangent to it, while the tangent line at $x = 1$ with $a = 1/2$ touches once and crosses twice more. The circuit "one solution equals repeated root" is a polynomial circuit and you must refuse to fire it outside polynomials.

2. **Two-parameter sweep of $F(x) = \ln(1 + x^2) - ax - b$.** *Cue:* two parameters in one function. *Circuit:* sign analysis of a general function. Differentiate F, find its stationary points, evaluate F there, and demand that exactly one of the values crosses zero. Correct but wasteful: you are carrying b through every derivative computation even though F' does not contain b. Every line of algebra costs ink and invites a skipped-calculation error. It ranks above the tangency fantasy because it at least ends in the right place.

3. **Convexity or graph-shape narration.** *Cue:* a logarithm of a quadratic, so an S-shaped graph. *Circuit:* inflection and asymptotic slope. Note that $\ln(1 + x^2)$ is concave outside $[-1, 1]$ and

convex inside, sketch, and read off the answer. This is fast and gives you the shape instantly, but a sketch is not a proof and the boundary case $|a| = 1$ is exactly where a sketch lies to you. Use it to know the answer in ten seconds, then upgrade it.

4. **Level sets of $g(x) = \ln(1 + x^2) - ax$.** *Cue:* b appears only additively. *Circuit:* separate the parameters, sweep the free one for free. Rewrite the equation as $g(x) = b$ and classify the monotone pieces of g. The count of solutions of $g(x) = b$ is then read off a one-line shape statement. This is the ideal route: it kills one parameter at zero cost, reduces the problem to a single quadratic $ax^2 - 2x + a = 0$, and makes the case split (0, 1, or 2 turning points) forced rather than invented. Add the symmetry reduction $a \mapsto -a$ from the evenness of $\ln(1 + x^2)$ and you halve the work again.

The ideal solution

Write $f(x) = \ln(1 + x^2)$ and, for a fixed real a,

$$g(x) = f(x) - ax, \qquad g'(x) = \frac{2x}{1 + x^2} - a = -\frac{ax^2 - 2x + a}{1 + x^2}.$$

The line $y = ax + b$ meets $y = f(x)$ in exactly one point if and only if the equation $g(x) = b$ has exactly one real solution.

Symmetry reduction. Since f is even, (x_0, y_0) lies on both $y = f(x)$ and $y = ax + b$ if and only if $(-x_0, y_0)$ lies on both $y = f(x)$ and $y = -ax + b$. Hence (a, b) is a solution pair if and only if $(-a, b)$ is. It therefore suffices to treat $a \geq 0$ and then reflect.

Asymptotics, used twice below. As $x \to +\infty$ we have $f(x)/x \to 0$, so for $a > 0$, $g(x) = x(f(x)/x - a) \to -\infty$ and $g(-x) = x(f(x)/x + a) \to +\infty$. For $a = 0$, $g = f \geq 0$ with $g(x) \to +\infty$ at both ends.

Case $a = 0$. Here $g = f$ is strictly decreasing on $(-\infty, 0]$ and strictly increasing on $[0, \infty)$, with minimum $f(0) = 0$. So $g(x) = b$ has no solution for $b < 0$, exactly one solution ($x = 0$) for $b = 0$, and exactly two for $b > 0$. The only admissible pair is $(a, b) = (0, 0)$.

Case $a \geq 1$. For all real x, the arithmetic mean geometric mean inequality gives $1 + x^2 \geq 2|x|$, hence $\left|\frac{2x}{1+x^2}\right| \leq 1$, with equality only at $x = \pm 1$. Therefore $g'(x) \leq 1 - a \leq 0$, and g' vanishes at no more than the single point $x = 1$ (which happens only when $a = 1$). A continuous function with $g' \leq 0$ everywhere and $g' = 0$ at finitely many points is strictly decreasing; combined with $g(-\infty) = +\infty$ and $g(+\infty) = -\infty$ and continuity, g is a strictly decreasing bijection from $\mathbb{R}$ onto $\mathbb{R}$. Hence $g(x) = b$ has exactly one solution for every real b. So every pair with $a \geq 1$ works, and by symmetry every pair with $|a| \geq 1$ works.

Case $0 < a < 1$. The stationary points of g are the roots of $ax^2 - 2x + a = 0$, namely

$$r_\pm = \frac{1 \pm \sqrt{1 - a^2}}{a}, \qquad 0 < r_- < 1 < r_+, \qquad r_- r_+ = 1.$$

Both roots are real and distinct because $0 < a < 1$, and both are positive because their sum $2/a$ and product 1 are positive. Since $ax^2 - 2x + a$ is an upward parabola, $g'(x) = -(ax^2 - 2x + a)/(1 + x^2)$ is negative on $(-\infty, r_-)$, positive on (r_-, r_+), and negative on (r_+, ∞). Thus g strictly decreases to a local minimum $g(r_-)$, strictly increases to a local maximum $g(r_+)$, then strictly decreases; and $g(-\infty) = +\infty$, $g(+\infty) = -\infty$.

On each of the three maximal monotone intervals, g is injective, and the intermediate value theorem identifies the exact range attained on each: $(g(r_-), +\infty)$, $[g(r_-), g(r_+)]$ and $(-\infty, g(r_+))$ respectively. Counting how many of these ranges contain a given level b, and noting $g(r_-) < g(r_+)$:

$$\#\{x : g(x) = b\} = \begin{cases} 1, & b < g(r_-) \text{ or } b > g(r_+), \\ 2, & b = g(r_-) \text{ or } b = g(r_+), \\ 3, & g(r_-) < b < g(r_+). \end{cases}$$

So for $0 < a < 1$ the admissible b are exactly $b < g(r_-)$ and $b > g(r_+)$. Finally, at a stationary point r we have $a(1+r^2) = 2r$, so $1 + r^2 = 2r/a$ and the two thresholds simplify:

$$g(r_\pm) = \ln\left(\frac{2r_\pm}{a}\right) - ar_\pm.$$

Answer. The line $y = ax + b$ meets $y = \ln(1+x^2)$ in exactly one point precisely when

$$\boxed{|a| \geq 1 \text{ (any } b), \quad \text{or} \quad (a,b) = (0,0), \quad \text{or} \quad 0 < |a| < 1 \text{ with } b < g(r_-) \text{ or } b > g(r_+),}$$

where, writing $\alpha = |a|$ and $r_\pm = \dfrac{1 \pm \sqrt{1-\alpha^2}}{\alpha}$, the thresholds are $g(r_\pm) = \ln(1 + r_\pm^2) - \alpha r_\pm = \ln(2r_\pm/\alpha) - \alpha r_\pm$.

Consistency check. As $\alpha \to 1^-$ we get $r_\pm \to 1$ and both thresholds tend to $\ln 2 - 1$, so the forbidden band closes up and the answer matches the $|a| = 1$ case continuously. As $\alpha \to 0^+$ we get $g(r_-) \to 0$ and $g(r_+) \to +\infty$, so the admissible set shrinks to $b < 0$, and in the limit $a = 0$ only $b = 0$ survives, matching the separate treatment of $a = 0$.

Layer 1: WHAT

Block 1. Rewrite the intersection condition as a root count for $\ln(1+x^2) - ax - b = 0$.

Block 2. Move b to the other side: the condition is $g(x) = b$ with $g(x) = \ln(1+x^2) - ax$. One parameter is now free.

Block 3. Use evenness of $\ln(1+x^2)$ to reduce to $a \geq 0$.

Block 4. Differentiate: $g'(x) = \frac{2x}{1+x^2} - a$, so stationary points solve the quadratic $ax^2 - 2x + a = 0$; the discriminant $4 - 4a^2$ splits the problem at $|a| = 1$.

Block 5. For $a \geq 1$, use the bound $|2x/(1+x^2)| \leq 1$ to conclude g is strictly decreasing, hence a bijection onto $\mathbb{R}$: exactly one solution for every b.

Block 6. For $0 < a < 1$, get two stationary points $r_\pm$ with $r_- r_+ = 1$, read off the down, up, down shape, and count preimages of b by monotone pieces: 1, 2 or 3.

Block 7. Handle $a = 0$ separately since the quadratic degenerates, and simplify the thresholds using $a(1+r^2) = 2r$.

Juxtapose this with the nominal route. The zombie writes $\ln(1+x^2) = ax + b$, cannot solve it, panics, and reaches for tangency: differentiate both sides, set $2x/(1+x^2) = a$, substitute back, and try to force a "repeated root" condition on a transcendental equation. That route produces the curve of tangency lines and then declares victory, missing every steep line and every line that clears the hump entirely, which is most of the answer set.

The bifurcation point is the single line where you decide what "exactly one point" means. The zombie translates it as "tangency". You translate it as "the level set $g^{-1}(b)$ is a singleton". Everything downstream is forced by that one translation.

Layer 2: HOW

Block 1. **Cue.** Two curves, "intersects in exactly one point", with one of the curves a line. **Why natural.** An intersection of $y = F(x)$ and $y = G(x)$ is by definition a solution of $F(x) = G(x)$. Nothing geometric is being asked; the picture is scaffolding. Convert to an equation immediately, because equations have derivatives and pictures do not. **Link to the next block.** Once you have an equation with two parameters, ask which parameter is cheap.

Block 2. **Cue.** The constant b appears additively and nowhere else. **Why natural.** A parameter that appears only as an additive constant is a level, and levels are swept for free: the solution count of $g(x) = b$ as b varies is completely determined by the shape of the single function g. Refusing to

separate them means differentiating a function that carries a redundant symbol through every line. **Link to the next block.** With b demoted to a level, the only remaining question is the shape of g, which is a derivative question.

Block 3. **Cue.** $\ln(1+x^2)$ is even. **Why natural.** Reflecting in the y-axis fixes the curve and maps the line $y = ax + b$ to $y = -ax + b$. A symmetry of the configuration that fixes one object and acts on the parameters is always worth using before the work starts, not after, because it halves the case analysis rather than merely checking it. **Link to the next block.** You may now assume $a \geq 0$, which makes the sign analysis of the quadratic clean.

Block 4. **Cue.** $g'(x) = \frac{2x}{1+x^2} - a$: a rational function set to zero. **Why natural.** Putting the derivative over the common denominator $1 + x^2 > 0$ makes the sign of g' the sign of a quadratic, and a quadratic has a discriminant. The discriminant $4 - 4a^2$ is where the case split comes from; you do not invent the threshold $|a| = 1$, the algebra hands it to you. **Link to the next block.** The discriminant sign gives three regimes: $|a| > 1$ (no stationary points), $|a| = 1$ (one, degenerate), $|a| < 1$ (two).

Block 5. **Cue.** $2x/(1+x^2)$ with $1 + x^2 \geq 2|x|$ staring at you. **Why natural.** The derivative of the curve is bounded by 1 in modulus, and that is the geometric content of the whole problem: a curve whose steepest tangent has slope 1 cannot be crossed twice by a line of slope at least 1, because between two crossings the mean value theorem would demand a tangent of slope exactly $a \geq 1$ at an interior point, and slope 1 is attained only at $x = 1$. Writing it as "$g' \leq 0$ with equality at finitely many points, hence g strictly decreasing" is the rigorous version and costs one clause. **Link to the next block.** Strict monotonicity plus the two infinite limits gives a bijection, which settles every b at once.

Block 6. **Cue.** Two stationary points with product $r_- r_+ = 1$ from $ax^2 - 2x + a = 0$. **Why natural.** Vieta reads off the product as $a/a = 1$ without solving, which tells you one root is inside $(0, 1)$ and one outside, matching the fact that the curve's steepest point is at $x = 1$. The down, up, down shape then forces the level count, and the count is a statement about monotone pieces, not about tangency. **Link to the next block.** Turning point values become the thresholds, so evaluate g at $r_\pm$ and simplify.

Block 7. **Cue.** $r_\pm$ satisfies $ar^2 - 2r + a = 0$, so $1 + r^2$ is expressible. **Why natural.** Never substitute a messy root into a logarithm if the defining equation of that root simplifies the argument first. From $a(1 + r^2) = 2r$ you get $\ln(1 + r^2) = \ln(2r/a)$, which removes a nested square root from inside a logarithm. This is the same laziness principle you use for symmetric-function problems: use the relation, not the root. **Link to the next block.** The final answer is now a clean inequality on b for each a.

Layer 3: WHY

The mathematical truth beneath this route is that the number of solutions of $g(x) = b$ equals the number of maximal monotone intervals of g whose range contains b. That statement, which is just the intermediate value theorem plus injectivity on monotone pieces, is the whole engine. It converts a two-parameter counting problem into: find the turning points, evaluate, compare with b. Nothing else is needed, and in particular no notion of tangency ever appears, because tangency is a statement about multiplicity of contact and the question asked about cardinality of contact. Those two agree for polynomials and disagree in general; A-level trains the polynomial reflex hard, and this problem is built to punish it.

The second truth is the boundedness of $x \mapsto 2x/(1+x^2)$ by 1. This is the derivative of a logarithm of a quadratic, and it is bounded because $\ln(1+x^2)$ grows like $2\ln|x|$, which is sublinear. Sublinear growth is exactly the reason no line of positive slope can be beaten forever, which is what forces at least one intersection for every $a \neq 0$. So the two ends of the analysis, "at least one" and "at most one", come from the same source: growth slower than linear.

The discernment mechanism, the thing to install so that you choose this route inside sixty seconds in the arena: count the parameters, and ask of each whether it is a level, a scale, or a genuine shape parameter. A level (additive constant) is free: quotient it out. A scale (multiplicative constant) is often removable by rescaling. Only a shape parameter, here a, deserves case analysis. Most multi-parameter Putnam problems in analysis collapse the moment you sort the parameters into those three bins. Train it by taking any past question with two parameters and asking, before writing anything, which parameter you can eliminate by translation, scaling, or symmetry.

What the examiners nudged with: they chose $\ln(1+x^2)$ rather than any old curve because its derivative has a clean extremal value of exactly 1, so the threshold $|a| = 1$ is memorable and the case split is forced; and they wrote "exactly one point" rather than "is tangent to" precisely to see whether you would fire the tangency circuit unbidden. The word "determine all ordered pairs" is also a command term: it tells you the answer is a description of a region in the (a, b) plane, so a full-marks script must present a classification with every case, not a single family.

Revolving concepts

Level sets and preimage counting. For continuous $g : \mathbb{R} \to \mathbb{R}$ with finitely many stationary points, split $\mathbb{R}$ into maximal intervals on which g is strictly monotone. On each, g is injective and its image is an interval determined by the endpoint limits. The count $\#g^{-1}(b)$ is then the number of those image intervals containing b, with boundary levels shared by adjacent pieces. See Book 1, field: Real analysis, topic: monotonicity and the intermediate value theorem.

Strict monotonicity from a nonstrict derivative bound. If g is differentiable with $g' \leq 0$ on an interval and g' vanishes only on a set with empty interior (in particular a finite set), then g is strictly decreasing. Proof: for $u < v$, $g(v) - g(u) = \int_u^v g'$, and a nonpositive integrand that is not identically zero on (u, v) has negative integral. Knowing this saves you from the common error of asserting only "nonincreasing" at $a = 1$ and losing the boundary case. See Book 1, field: Real analysis, topic: mean value theorem and monotonicity.

The bound $\frac{2|x|}{1+x^2} \leq 1$. Equivalent to $(|x|-1)^2 \geq 0$; equality only at $|x| = 1$. This is the arithmetic mean geometric mean inequality in its two-term form, and it recurs constantly: the same expression is sin of the tangent half-angle substitution, since $x = \tan(\theta/2)$ gives $2x/(1+x^2) = \sin\theta$. That substitution also parametrises this problem's answer: writing $a = \sin\theta$ with $\theta \in (0, \pi/2)$ gives $r_- = \tan(\theta/2)$ and $r_+ = \cot(\theta/2)$. See Book 1, field: Inequalities, topic: two-term AM GM; and field: Complex numbers, topic: Weierstrass substitution.

Vieta on the stationary quadratic. For $ax^2 - 2x + a = 0$ the roots satisfy $r_- + r_+ = 2/a$ and $r_- r_+ = 1$. Reciprocal pairs of roots are the signature of a palindromic quadratic, and any palindromic equation $ax^2 + cx + a = 0$ has roots $r, 1/r$. Wherever you meet a palindromic polynomial, divide by $x^{n/2}$ and substitute $t = x + 1/x$: that is the general reduction, and it halves the degree. See Book 1, field: Polynomials, topic: palindromic polynomials and reciprocal roots.

Recursion note. There is no recursion, induction, or telescoping in this problem, and it is worth saying so explicitly: the case analysis is a finite partition of parameter space, not an inductive structure. Do not manufacture induction where a partition suffices.

Asymptotic comparison $\ln(1+x^2)/x \to 0$. The general fact is that $(\ln x)^\alpha = o(x^\beta)$ for all $\alpha > 0$, $\beta > 0$. It is what guarantees that every line of nonzero slope eventually escapes the curve, hence at least one crossing. See Book 1, field: Real analysis, topic: growth hierarchies.

Circuit Bank

- **WHEN** you see a parameter appearing only as an additive constant in an equation $F(x, b) = 0$ **DO** isolate it as a level, $g(x) = b$, and study the shape of g once **BECAUSE** the solution count as the level varies is read off the monotone pieces of g, so one shape analysis answers infinitely many parameter values at zero extra cost
- **WHEN** you see "exactly one intersection point" for a non-polynomial curve **DO** count preimages under a level map, never impose tangency **BECAUSE** tangency is multiplicity of contact and the question asks for cardinality of contact; the two coincide only for polynomials, and assuming otherwise discards the entire steep-line family
- **WHEN** you see a stationary condition that is a rational function set to zero **DO** clear the positive denominator and read the sign of the resulting polynomial **BECAUSE** the discriminant of that polynomial hands you the case split and the threshold value of the parameter without you having to guess where the behaviour changes
- **WHEN** you must evaluate a function at an ugly root r of a known quadratic **DO** use the defining relation to rewrite the argument before substituting **BECAUSE** the relation $ar^2 - 2r + a = 0$ turns $\ln(1 + r^2)$ into $\ln(2r/a)$, killing a nested surd; substituting the explicit root first costs three lines and invites a skipped-calculation error
- **WHEN** you see an even (or odd) function paired with a parameterised line **DO** use the reflection to halve the parameter range before any computation **BECAUSE** a symmetry acting on parameters is a free quotient of the case analysis, and applying it after the algebra means you paid for both halves

Backtesting

1. First useful cue: b occurs only as an additive constant, so the problem is a level-set count for $g(x) = \ln(1 + x^2) - ax$, not a two-parameter search.
2. Method the expression suggested: differentiate g, clear the denominator $1 + x^2 > 0$, and let the discriminant of $ax^2 - 2x + a$ dictate the case split at $|a| = 1$.
3. Where you would hesitate, and the thought to reinforce: at $a = 1$, where $g' \leq 0$ with equality at $x = 1$. Reinforce that a nonpositive derivative vanishing at finitely many points still gives strict monotonicity; do not weaken the conclusion to "nonincreasing" and then fail to conclude injectivity.
4. The trap the question sets: the phrase "exactly one point" baiting the tangency circuit. The tangency answer set is a one-dimensional curve in the (a, b) plane; the true answer set has nonempty interior. If your answer is a curve rather than a region, you have fired the wrong circuit.
5. What makes you recognise it faster next time: the shape of the answer. "Determine all ordered pairs" means a region, and regions come from inequalities on levels, which come from turning point values.
6. The reusable decision rule: separate parameters into levels, scales and shape parameters; eliminate levels by making them the right-hand side, eliminate scales by rescaling, and case-split only on shape parameters.

Mirror drills

1. For which real c does $y = cx$ meet $y = \ln x$ ($x > 0$) in exactly one point? *Answer:* Set $h(x) = \ln x / x$, whose maximum is $1/e$ at $x = e$; the line meets the curve twice for $0 < c < 1/e$,

once for $c = 1/e$ and once for $c \le 0$, and never for $c > 1/e$. The circuit is the same: isolate the parameter, here as a level of $\ln x / x$ rather than an additive level.

2. Determine the number of real solutions of $e^x = ax + b$ in terms of (a, b). *Answer:* With $g(x) = e^x - ax$, $g' = e^x - a$ has one zero when $a > 0$ and none when $a \le 0$; so for $a \le 0$ there is exactly one solution for every b, and for $a > 0$ there are 0, 1 or 2 solutions according as $b < g(\ln a)$, $b = g(\ln a)$ or $b > g(\ln a)$, where $g(\ln a) = a - a \ln a$.

3. Show that $\left|\frac{2x}{1+x^2}\right| \le 1$ for all real x, with equality only at $x = \pm 1$, and deduce that no line of slope 2 is tangent to $y = \ln(1 + x^2)$. *Answer:* The inequality is $(|x| - 1)^2 \ge 0$; a tangent of slope 2 would need $2x/(1 + x^2) = 2$, impossible, so the slope-2 lines all cross transversally and each crosses exactly once.

4.2 A2. Maximum negative coefficients of a squared polynomial

Let n be an integer with $n \geq 2$. Over all real polynomials $p(x)$ of degree n, what is the largest possible number of negative coefficients of $p(x)^2$?

Read it out loud

Say the structure aloud: you are asked for an extremal count, over all degree n real polynomials, of how many entries of the coefficient vector of $p(x)^2$ can be negative. So there are two halves and you must write both: an upper bound valid for every p, and one explicit p attaining it. Any answer that supplies only one half scores about half the marks, so budget your time in two blocks from the start.

The second thing to say is what a square does to a coefficient sequence. If $p(x) = \sum_{i=0}^{n} a_i x^i$ then $p(x)^2 = \sum_{k=0}^{2n} b_k x^k$ with $b_k = \sum_{i+j=k} a_i a_j$: the coefficient sequence of the square is the convolution of the coefficient sequence with itself. Convolution is the only structure in the problem, so every idea must be a statement about convolutions.

The third observation is free and it is the whole upper bound in embryo: the two end coefficients of a convolution square are $b_0 = a_0^2$ and $b_{2n} = a_n^2$. Both are squares of real numbers, so neither is negative, and $b_{2n} > 0$ because $\deg p = n$. There are $2n+1$ coefficients in total, so at most $2n-1$ of them can be negative, and the answer is $2n-1$, $2n-2$, or lower. Within thirty seconds you should have written $b_k = \sum_{i+j=k} a_i a_j$, noted $b_0 = a_0^2 \geq 0$ and $b_{2n} = a_n^2 > 0$, and asked the only remaining question: can $b_1, \ldots, b_{2n-1}$ all be negative?

The fields wired in are polynomial algebra (convolution of coefficient sequences), sign propagation arguments of the sort that also appear in formal power series square roots, and an extremal construction. There is no analysis here and no need for roots; everything happens in the coefficient ring.

Approaches, ranked worst to best

1. **Search for a counterexample at small n by hand.** *Cue:* "largest possible number" invites experiment. *Circuit:* small cases first. Setting $n = 2$ and grinding through $(a_2x^2 + a_1x + a_0)^2$ will convince you that 2 negatives is achievable and 3 is not, but for the general n it proves nothing and eats twenty minutes. Experiment to find the answer, never to write the answer. Ranked last because it produces no proof of either half.

2. **Evaluate at special points.** *Cue:* a squared polynomial is nonnegative everywhere. *Circuit:* substitute $x = 1$, $x = -1$, integrate against a kernel. From $p(1)^2 = \sum_k b_k \geq 0$ you get $b_0 + b_{2n} \geq -\sum_{k=1}^{2n-1} b_k$, which is a true statement and a useless one: b_0 and b_{2n} are unbounded, so no contradiction can come out. Global evaluations cannot see the sign pattern of individual coefficients; they only see weighted totals. Ranked here because it is the first reflex of anyone trained on "squares are nonnegative" and it dies immediately.

3. **Descartes' rule of signs on $p(x)^2$.** *Cue:* the sign pattern $+, -, \ldots, -, +$ has exactly two sign changes. *Circuit:* sign changes bound positive roots. Two sign changes bound the number of positive roots of p^2 by two, and every real root of p^2 has even multiplicity. This is a genuine structural constraint, but it constrains roots, not coefficients, and a polynomial with that sign pattern and no positive root is not immediately absurd. You would still have to go back to the coefficients. Ranked above evaluation because it at least engages with the sign pattern.

4. **Sign propagation through the convolution, plus a palindromic construction.** *Cue:* b_k is a convolution and you are told about signs of b. *Circuit:* invert the convolution one coefficient at a time and track signs. Assume all of $b_1, \ldots, b_{2n-1}$ are negative and read the convolution as a recursion for the a_k: each b_k determines a_k from $a_0, \ldots, a_{k-1}$. Signs propagate, all the a_k with $k \geq 1$ are forced negative, and then $b_{2n-1} = 2a_{n-1}a_n$ is forced positive, which is the

contradiction. For the construction, take a palindromic p so that p^2 is palindromic and you only have to check half the coefficients. This is the ideal route: it uses the only structure present, it is four lines long, and the palindromy halves the verification.

The ideal solution

The answer is $\boxed{2n-2}$.

Write $p(x) = \sum_{i=0}^{n} a_i x^i$ with $a_n \neq 0$, and $p(x)^2 = \sum_{k=0}^{2n} b_k x^k$, so that

$$b_k = \sum_{\substack{i+j=k \\ 0 \le i,j \le n}} a_i a_j \qquad (0 \le k \le 2n).$$

Upper bound. We have $b_0 = a_0^2 \geq 0$ and $b_{2n} = a_n^2 > 0$, so at most the $2n-1$ coefficients $b_1, \ldots, b_{2n-1}$ can be negative. Suppose, for contradiction, that all of them are negative.

Since $b_1 = 2a_0a_1 < 0$, both a_0 and a_1 are nonzero and of opposite signs. Replacing p by $-p$ changes neither p^2 nor the degree, so we may assume $a_0 > 0$; then $a_1 < 0$.

Claim 4.2.1. *$a_k < 0$ for every k with $1 \le k \le n$.*

Proof. If not, let k be the least index in $\{1, \ldots, n\}$ with $a_k \geq 0$; by the previous paragraph $k \geq 2$, and $a_i < 0$ for $1 \le i \le k-1$. Since $k \le n$, every index i with $0 \le i \le k$ satisfies $i \le n$ and $k - i \le n$, so

$$b_k = 2a_0a_k + \sum_{i=1}^{k-1} a_i a_{k-i}.$$

The first term is ≥ 0 because $a_0 > 0$ and $a_k \geq 0$. Every summand $a_i a_{k-i}$ with $1 \le i \le k-1$ is a product of two negative numbers, hence positive. Therefore $b_k \geq 0$, contradicting $b_k < 0$. □

Now use $n \geq 2$, so that $n - 1 \geq 1$ and the claim applies to both a_{n-1} and a_n. Then

$$b_{2n-1} = 2a_{n-1}a_n > 0,$$

contradicting $b_{2n-1} < 0$. Hence at most $2n-2$ of the coefficients of $p(x)^2$ are negative.

Construction attaining $2n-2$. Put

$$p(x) = n(x^n + 1) - 2Q(x), \qquad Q(x) = x + x^2 + \cdots + x^{n-1},$$

which has degree n since its leading coefficient is $n \neq 0$ (for $n = 2$, read $Q(x) = x$). Then

$$p(x)^2 = n^2(x^n+1)^2 - 4n(x^n+1)Q(x) + 4Q(x)^2.$$

Read off coefficients. The first term contributes n^2 to each of b_0, b_{2n} and $2n^2$ to b_n, and nothing else. The second term contributes $-4n$ to each of $b_1, \ldots, b_{n-1}$ (from Q) and to each of $b_{n+1}, \ldots, b_{2n-1}$ (from x^nQ), and nothing to b_n. For the third term, for $1 \le i \le n$ the coefficient of x^i in $Q(x)^2$ is the number of pairs (j,k) with $1 \le j,k \le n-1$ and $j + k = i$, which is $i - 1$. Hence

$$b_i = -4n + 4(i-1) \qquad (1 \le i \le n-1),$$

and each of these is at most $-4n + 4(n-2) = -8 < 0$. Also $b_n = 2n^2 + 4(n-1) > 0$ and $b_0 = b_{2n} = n^2 > 0$.

Finally, p is palindromic: its coefficient list is $n, -2, -2, \ldots, -2, n$, unchanged on reversal, that is $x^n p(1/x) = p(x)$. Therefore $x^{2n}p(1/x)^2 = p(x)^2$, so $b_k = b_{2n-k}$ for all k, and the negativity of $b_1, \ldots, b_{n-1}$ gives the negativity of $b_{n+1}, \ldots, b_{2n-1}$ at once. So exactly $2(n-1) = 2n-2$ coefficients of $p(x)^2$ are negative, and the bound is attained.

Check at $n = 2$. $p(x) = 2x^2 - 2x + 2$, $p(x)^2 = 4x^4 - 8x^3 + 12x^2 - 8x + 4$, with exactly $2 = 2n-2$ negative coefficients. At $n = 3$, $p(x) = 3x^3 - 2x^2 - 2x + 3$ and $p(x)^2 = 9x^6 - 12x^5 - 8x^4 + 26x^3 - 8x^2 - 12x + 9$, with exactly 4 negative coefficients.

Layer 1: WHAT

Block 1. Name the object: b_k is the self-convolution $\sum_{i+j=k} a_i a_j$.

Block 2. Free bound: $b_0 = a_0^2 \geq 0$ and $b_{2n} = a_n^2 > 0$, so the count is at most $2n-1$, and the entire question is whether $2n-1$ is achievable.

Block 3. Assume it is, and normalise: $b_1 = 2a_0a_1 < 0$ forces $a_0 \neq 0$, and $p \mapsto -p$ lets you take $a_0 > 0$.

Block 4. Read the convolution as a rule that determines the sign of a_k from the signs of $a_0, \ldots, a_{k-1}$ and of b_k, and take a least counterexample: all a_k with $1 \leq k \leq n$ are negative.

Block 5. Look at the other end of the sequence, where the same negativity is fatal: $b_{2n-1} = 2a_{n-1}a_n > 0$. Contradiction, so the count is at most $2n-2$.

Block 6. Build an example. Force the sign pattern by making the two end coefficients large and positive and all interior coefficients equal and negative, so that every middle coefficient of the square is dominated by the cross term $-4n$.

Block 7. Use palindromy to check only half the coefficients, then count: $2n-2$.

Juxtapose with the nominal route. The zombie multiplies out $\left(\sum a_i x^i\right)^2$ in full generality, stares at $2n+1$ simultaneous sign conditions in $n+1$ unknowns, and starts casework on $n = 2, 3, 4$. He never notices that the conditions are not independent: they are a triangular system, and a triangular system in which each new equation determines one new unknown should be run as a recursion, not solved as a system.

The bifurcation point is the line where you decide what the hypothesis "$b_k < 0$ for all $1 \leq k \leq 2n-1$" is for. The zombie treats it as $2n-1$ constraints to satisfy. You treat it as $2n-1$ sign inputs to a recursion that outputs the signs of the a_k, and then you check the output against the top end of the sequence. Same data, opposite direction of travel.

Layer 2: HOW

Block 1. **Cue.** "Coefficients of $p(x)^2$". **Why natural.** Squaring a polynomial is convolving its coefficient sequence with itself. Writing $b_k = \sum_{i+j=k} a_i a_j$ is not a step, it is a translation into the only language in which the question has content. The moment it is written, the extreme coefficients b_0 and b_{2n} become visibly special because their sums have a single term. **Link to the next block.** A one-term sum is a square, and squares have a sign.

Block 2. **Cue.** $b_0 = a_0^2$, $b_{2n} = a_n^2$. **Why natural.** These two coefficients cannot be negative, so the answer is at most $2n-1$ before any work. The habit here is: in any extremal counting problem, spend the first thirty seconds finding the free bound, because it tells you the size of the gap you must still close. Here the gap is exactly one, which is a strong hint that the truth is $2n-2$ and that a single parity-like or endpoint obstruction is waiting. **Link to the next block.** To close a gap of one, assume the extreme case and hunt for a contradiction.

Block 3. **Cue.** $b_1 = 2a_0a_1$, the second simplest convolution. **Why natural.** Assuming $b_1 < 0$ immediately gives $a_0 \neq 0$, which is what makes the recursion well posed: a_0 is the pivot you divide by. And since p and $-p$ have the same square, fixing the sign of a_0 is a free normalisation, not an assumption. **Link to the next block.** With $a_0 > 0$ fixed, each b_k pins down the sign of a_k.

Block 4. **Cue.** The identity $b_k = 2a_0a_k + \sum_{i=1}^{k-1} a_i a_{k-i}$. **Why natural.** Isolating the two terms that involve a_k is the standard move for a triangular system: it turns the convolution into a formula for the new unknown in terms of the old ones. If all previous a_i ($1 \leq i \leq k-1$) are negative, the residual sum is a sum of products of negatives, hence positive, so $2a_0a_k$ must be even more negative than b_k. The negativity of a_k is therefore forced, not chosen. Phrasing it as a least counterexample rather than as an induction saves a sentence and removes the base case fuss. **Link to the next block.**

Once you know the sign of every a_k, look for a coefficient of p^2 whose sign is now determined and compare with the hypothesis.

Block 5. **Cue.** b_{2n-1} is the mirror image of b_1. **Why natural.** The convolution is symmetric, so the near-top coefficients have exactly as few terms as the near-bottom ones: $b_{2n-1} = 2a_{n-1}a_n$. The hypothesis pushed all the a_k negative, and a product of two negatives is positive. The contradiction lands at the far end of the sequence because that is the only other place where the convolution has a single term. Notice that this is precisely where the condition $n \geq 2$ is spent: at $n = 1$ the indices collide, $b_{2n-1} = b_1 = 2a_0a_1$, and there is no contradiction, which is why the problem excludes $n = 1$ (and indeed for $n = 1$ the answer is 1, not 0). **Link to the next block.** The bound is $2n - 2$; now produce a polynomial attaining it.

Block 6. **Cue.** You need $2n - 2$ negatives, that is every coefficient except b_0, b_n, b_{2n}. **Why natural.** The proof of the bound tells you the shape of the example: the obstruction was the pair of end coefficients of p, so make those large and positive and all interior coefficients negative. Then the cross terms $2a_0a_i$ and $2a_na_{n+i}$ dominate. Choosing all interior coefficients equal to -2 and both ends equal to n makes the dominant cross term $-4n$ and the competing positive term at most $4(n-2)$, so the margin is 8 and no fine tuning is needed. Choosing round constants that leave slack is a design decision: an example with slack is an example you can verify in two lines. **Link to the next block.** Verify the coefficients, but only half of them.

Block 7. **Cue.** The coefficient list of p reads the same backwards. **Why natural.** A palindromic polynomial satisfies $x^{\deg}p(1/x) = p(x)$, and this property is multiplicative, so p^2 is palindromic too and $b_k = b_{2n-k}$. That halves the verification and it also explains why b_n is the natural exceptional coefficient: it is the fixed point of the reflection $k \mapsto 2n - k$. **Link to the next block.** Count: $n - 1$ negatives below the middle, $n - 1$ above, total $2n - 2$.

Layer 3: WHY

The mathematical truth underneath is that the map $a \mapsto b$, $b_k = \sum_{i+j=k} a_ia_j$, is triangular with respect to the index: b_k involves a_k only through the term $2a_0a_k$, plus terms with strictly smaller indices. Whenever $a_0 \neq 0$ this is invertible, and the inverse is the formal square root recursion

$$a_0 = \sqrt{b_0}, \qquad a_k = \frac{1}{2a_0}\left(b_k - \sum_{i=1}^{k-1} a_ia_{k-i}\right) \quad (k \geq 1),$$

which computes the coefficients of $\sqrt{b(x)}$ as a formal power series. The problem is a sign question about this recursion: if the input has one positive coefficient followed by all negative ones, the output has one positive coefficient followed by all negative ones. The prototype is $\sqrt{1-4x} = 1 - 2\sum_{m\geq 1} C_{m-1}x^m$ with C_j the Catalan numbers, where every coefficient after the constant is negative. That is exactly the phenomenon the problem forbids you from realising with a polynomial, because a polynomial square root must stop, and stopping is what creates the positive coefficient $b_{2n-1} = 2a_{n-1}a_n$ at the top.

So the real content is: an infinite series can have the sign pattern $+, -, -, -, \ldots$ and be a perfect square, but a polynomial of degree $2n$ cannot, because a polynomial has two ends and the argument that forces all interior signs at the bottom end contradicts what the top end forces. Finiteness is the obstruction. That is the single sentence to remember.

The discernment mechanism: when a problem gives you sign information about a convolution, decide which direction the information flows. Sign data on the product plus the triangular structure means the data flows to the factors, one index at a time; and once you know the factors, all remaining coefficients of the product are determined in sign, so you should immediately test the coefficients

you have not used yet. Here the unused coefficient is b_{2n-1}, and it is the one that kills the hypothesis. Train the reflex by asking, at the end of any sign propagation: which hypotheses have I not yet spent? The one you have not spent is usually the contradiction.

The examiners' nudges: they said "degree n" rather than "at most degree n" so that $a_n \neq 0$ and $b_{2n} > 0$ is guaranteed, and they imposed $n \geq 2$ precisely because the argument at the top end needs two distinct indices $n-1$ and n. The phrase "largest possible number" is the command term telling you that a bound alone is worth part marks and a construction alone is worth part marks, so write both.

Revolving concepts

Convolution of coefficient sequences. For $p(x) = \sum a_i x^i$ and $q(x) = \sum c_j x^j$, $[x^k](pq) = \sum_{i+j=k} a_i c_j$. The extreme coefficients of a product are single products: $[x^0](pq) = a_0 c_0$ and $[x^{\deg p + \deg q}](pq) = a_{\deg p} c_{\deg q}$. See Book 1, field: Polynomials, topic: coefficient convolution.

The formal square root recursion (generalised recursion). Given a formal power series $b(x) = b_0 + b_1 x + \cdots$ with $b_0 > 0$, there is a unique power series $a(x)$ with $a(0) > 0$ and $a^2 = b$, given by $a_0 = \sqrt{b_0}$ and, for $k \geq 1$,

$$a_k = \frac{1}{2a_0}\left(b_k - \sum_{i=1}^{k-1} a_i a_{k-i}\right).$$

This is the general solution method for any quadratic convolution recursion: isolate the two terms containing the highest unknown, and read the rest as a known history. The same pattern solves Catalan-type recursions $c_k = \sum_{i=0}^{k-1} c_i c_{k-1-i}$ (whose generating function satisfies $C = 1 + xC^2$, giving $C = (1 - \sqrt{1-4x})/(2x)$), and more generally any equation $F(x, y) = 0$ solved for y as a power series by the implicit function theorem for formal series. See Book 1, field: Generating functions, topic: quadratic functional equations and Catalan numbers.

Palindromic (self-reciprocal) polynomials. p of degree d is palindromic if $x^d p(1/x) = p(x)$, equivalently its coefficient list is a palindrome. Products of palindromic polynomials are palindromic; the roots come in pairs $r, 1/r$; and substituting $t = x + 1/x$ after dividing by $x^{d/2}$ halves the degree in the even case. Here it is used purely as a labour-saving symmetry on the coefficient list. See Book 1, field: Polynomials, topic: palindromic polynomials.

Descartes' rule of signs. The number of positive real roots of a real polynomial, counted with multiplicity, is at most the number of sign changes in its coefficient list, and has the same parity. Useful to know here so that you can rule the approach out fast rather than wonder about it. See Book 1, field: Polynomials, topic: sign rules and root location.

Extremal problems with a two-part answer. Any "largest possible number" question is answered by a pair (bound, construction). The bound should use only structural facts; the construction should be chosen with slack so that verification is cheap. See Book 1, field: Combinatorics, topic: extremal constructions.

Circuit Bank

- **WHEN** you see coefficients of a product or a square **DO** write the convolution $b_k = \sum_{i+j=k} a_i c_j$ and immediately evaluate the two extreme coefficients **BECAUSE** extreme coefficients are single products, so they carry unconditional sign information that the middle coefficients do not, and that is usually the free half of an extremal bound
- **WHEN** you are given sign or size data on every coefficient of a product **DO** isolate the highest unknown, $b_k = 2a_0 a_k + \sum_{i=1}^{k-1} a_i a_{k-i}$, and propagate signs from the bottom index upwards **BECAUSE** the convolution is triangular in the index, so the data determines the factors one coefficient at a time; solving it as a simultaneous system instead is the zombie route

- **WHEN** a sign propagation has determined all the unknowns **DO** test the hypotheses you have not yet spent, starting from the opposite end of the index range **BECAUSE** the contradiction in a finite problem almost always lives where the structure stops, because the propagation argument used only one end
- **WHEN** you need an explicit extremal example **DO** copy the shape of the obstruction from your own proof of the bound, and choose constants with a wide margin **BECAUSE** the proof of the upper bound tells you which coefficients must be positive, so the example is the sign pattern of the proof; wide margins turn verification into one inequality instead of a case check
- **WHEN** you are checking many coefficients of a product **DO** make the factor palindromic **BECAUSE** palindromy is multiplicative, so $b_k = b_{2n-k}$ and you verify half the list; the middle index is the fixed point of the reflection and is the natural exception

Backtesting

1. First useful cue: coefficients of a square means self-convolution, and the extreme coefficients $b_0 = a_0^2$, $b_{2n} = a_n^2$ are unconditionally nonnegative, giving the free bound $2n - 1$.
2. Method the expression suggested: assume the free bound is attained, isolate a_k in $b_k = 2a_0a_k + \sum_{i=1}^{k-1} a_i a_{k-i}$, and propagate signs upward from $k = 1$.
3. Where you would hesitate, and the thought to reinforce: at the normalisation $a_0 > 0$. Reinforce that p and $-p$ have the same square, so fixing that sign costs nothing; hesitating here and carrying two cases doubles the work for no reason.
4. The trap the question sets: stopping at the free bound $2n - 1$ and asserting it is attained, or producing a construction with $2n - 2$ negatives and not proving that $2n - 1$ is impossible. The gap is exactly one, and it is where all the marks are.
5. What makes you recognise it faster next time: a convolution with sign data is a triangular system; triangular systems are recursions; recursions with sign data are sign propagations; sign propagations end by testing an unused coefficient at the far end.
6. The reusable decision rule: in extremal coefficient problems, get the free bound from the extreme coefficients, then attack the single remaining case by assuming it and propagating.

Mirror drills

1. Show that if p is a real polynomial of degree $n \geq 1$ with $p(0) \neq 0$, then $p(x)^2$ cannot have all of $b_1, \ldots, b_{2n-1}$ negative and $b_0 < 0$ simultaneously. *Answer:* $b_0 = a_0^2 > 0$ always, so the hypothesis $b_0 < 0$ is already impossible; the point of the drill is to see that the end coefficients of a square are the only ones with a forced sign.
2. Prove that the coefficients of $\sqrt{1 - 4x}$, after the constant term 1, are all negative. *Answer:* Write $\sqrt{1 - 4x} = 1 - 2xC(x)$ where C is the Catalan generating function; squaring gives $C = 1 + xC^2$, and induction on the recursion $c_k = \sum_{i=0}^{k-1} c_i c_{k-1-i}$ with $c_0 = 1$ gives $c_k > 0$ for all k, hence all coefficients of $\sqrt{1 - 4x}$ beyond the constant are negative. This is the infinite model that the finite problem forbids.
3. What is the largest possible number of negative coefficients of $p(x)^3$ for p real of degree n, when $n = 1$? *Answer:* $p^3 = (a_1x + a_0)^3$ has coefficients $a_0^3, 3a_0^2a_1, 3a_0a_1^2, a_1^3$; taking $a_0 > 0 > a_1$ makes the middle two negative and the ends of opposite sign, so with $a_0 > 0$ exactly two are negative, and taking $a_0 < 0 < a_1$ gives two as well; the maximum is 2. The drill is to notice that odd powers do not have the "end coefficients are squares" protection, so the whole structure of the argument changes.

4.3 A3. Counting Lyness sequences modulo a prime

Let p be a prime number greater than 5. Let $f(p)$ denote the number of infinite sequences $a_1, a_2, a_3, \ldots$ such that $a_n \in \{1, 2, \ldots, p-1\}$ and

$$a_n a_{n+2} \equiv 1 + a_{n+1} \pmod{p}$$

for all $n \geq 1$. Prove that $f(p)$ is congruent to 0 or 2 $\pmod 5$.

Read it out loud

Read the structure: the values live in $\{1, \ldots, p-1\}$, which is exactly $\mathbb{F}_p^\times$, the nonzero residues, so every a_n is invertible. The relation $a_n a_{n+2} = 1 + a_{n+1}$ can therefore be divided through:

$$a_{n+2} = \frac{1 + a_{n+1}}{a_n}.$$

That is a second order nonlinear recurrence over a field, and a second order recurrence is a first order dynamical system on pairs: the state is (a_n, a_{n+1}) and the map is $T(x, y) = \left(y, \frac{1+y}{x}\right)$. So the problem is: count the points of $\mathbb{F}_p^\times \times \mathbb{F}_p^\times$ whose entire forward orbit under T stays inside $\mathbb{F}_p^\times \times \mathbb{F}_p^\times$, and prove that count is 0 or 2 modulo 5.

Now the loudest cue in the whole problem: the modulus you are asked about is 5, and 5 has nothing to do with p. When a counting problem asks for an answer modulo a prime q that is unrelated to the data, there are only two mechanisms in the whole of mathematics that produce such a statement. Either the count factorises into an expression whose residue you can compute directly, or there is a group of order q acting on the set being counted, and the count is congruent to the number of fixed points modulo q. The second mechanism is far more common and far more explanatory. So before doing anything else, ask: where is the action of $\mathbb{Z}/5$? The only candidate group action on a set of sequences is the shift, and a shift generates $\mathbb{Z}/5$ exactly when every admissible sequence has period 5.

That is the thought you should have inside the first minute, and it tells you what to compute: the first several terms, hoping the sequence closes up after five. Within thirty seconds you should have written $a_{n+2} = (1 + a_{n+1})/a_n$ and started computing a_3, a_4, a_5, a_6 in terms of a_1 and a_2. The fields wired in are finite field arithmetic, discrete dynamical systems (a birational map of the plane), group actions and orbit counting, and the theory of quadratic residues.

Approaches, ranked worst to best

1. **Compute $f(p)$ for small primes and guess.** *Cue:* "prove $f(p) \equiv 0$ or 2" invites data. *Circuit:* tabulate and pattern-match. Running $p = 7, 11, 13$ by hand gives $20, 72, 110$ and the residues $0, 2, 0$. Useful reconnaissance, worthless as a proof, and expensive by hand. Ranked last, but do run one small case mentally as a sanity check on your algebra.

2. **Treat it as a linear recurrence in disguise.** *Cue:* recurrences suggest characteristic equations. *Circuit:* substitute $a_n = c\lambda^n$ or take logarithms. The relation is multiplicative on the left and additive on the right, so no substitution linearises it globally. Chasing a closed form for a_n in terms of a_1, a_2 is exactly the zombie route: it is not that the algebra is hard, it is that there is nothing at the end of it. Ranked here because it burns the most time for the least return.

3. **Direct count: prove period 5, characterise admissible (a_1, a_2), count, reduce mod 5.** *Cue:* a periodic sequence is determined by finitely many exclusions. *Circuit:* count the complement of a union of lines. This works and it is the natural second thought. Periodicity reduces admissibility to the three conditions $a_1 \neq -1$, $a_2 \neq -1$, $a_1 + a_2 \neq -1$, giving $f(p) = (p-2)(p-3)$, a product of two consecutive integers; you then check the residues of p modulo

5. It is complete and it also delivers the exact value, which the problem did not ask for. It ranks second only because it explains the "0 or 2" as an accident of arithmetic rather than as structure.

4. **Orbit counting under the shift.** *Cue:* the answer is asked modulo 5 and the sequences have period 5. *Circuit:* a group of prime order q acting on a finite set makes $|S| \equiv \#\mathrm{Fix} \pmod q$. Prove period 5, note the shift generates a $\mathbb{Z}/5$ action on the set of admissible sequences, and conclude that $f(p)$ is congruent modulo 5 to the number of constant admissible sequences, which is the number of roots of $x^2 - x - 1$ in $\mathbb{F}_p$, that is 0 or 2 because the discriminant 5 is nonzero. This is the ideal route: it is five lines after the periodicity computation, it never counts anything, and it explains exactly why 2 and not some other residue appears, namely because a quadratic with nonzero discriminant has 0 or 2 roots.

The ideal solution

Throughout, identify $\{1, 2, \dots, p-1\}$ with $\mathbb{F}_p^\times$ and work in $\mathbb{F}_p$. Call a sequence *admissible* if it satisfies the two conditions in the statement, and let S be the set of admissible sequences, so $f(p) = |S|$.

Step 1: the recurrence is a map on pairs. Each a_n is a unit, so the relation $a_n a_{n+2} = 1 + a_{n+1}$ is equivalent to $a_{n+2} = (1 + a_{n+1})a_n^{-1}$. Hence an admissible sequence is determined by (a_1, a_2), and S is finite (there are at most $(p-1)^2$ candidates).

Step 2: every admissible sequence has period 5. Let $\{a_n\} \in S$ and write $x = a_1$, $y = a_2$. Using the recurrence repeatedly, and dividing only by terms of the sequence, which are units:

$$a_3 = \frac{1+y}{x}, \qquad a_4 = \frac{1+a_3}{y} = \frac{1+x+y}{xy}, \qquad a_5 = \frac{1+a_4}{a_3} = \frac{\frac{(1+x)(1+y)}{xy}}{\frac{1+y}{x}} = \frac{1+x}{y},$$

$$a_6 = \frac{1+a_5}{a_4} = \frac{\frac{1+x+y}{y}}{\frac{1+x+y}{xy}} = x, \qquad a_7 = \frac{1+a_6}{a_5} = \frac{1+x}{\frac{1+x}{y}} = y.$$

In the computation of a_5 we used $1 + a_4 = 1 + \frac{1+x+y}{xy} = \frac{xy+x+y+1}{xy} = \frac{(1+x)(1+y)}{xy}$, and in that of a_6 we used $1 + a_5 = \frac{y+1+x}{y}$. Since $(a_6, a_7) = (a_1, a_2)$ and the sequence is determined by consecutive pairs, $a_{n+5} = a_n$ for all $n \geq 1$.

Step 3: the shift acts. Define $\sigma : S \to S$ by $\sigma(a_1, a_2, a_3, \dots) = (a_2, a_3, a_4, \dots)$. This lands in S: the shifted sequence takes values in $\mathbb{F}_p^\times$, and its recurrence at index n is the original recurrence at index $n+1$, which holds. By Step 2, $\sigma^5 = \mathrm{id}_S$, so σ generates an action of the cyclic group $\mathbb{Z}/5\mathbb{Z}$ on the finite set S.

Step 4: orbits and fixed points. Every orbit of this action has size dividing 5, hence size 1 or 5. An orbit has size 1 exactly when σ fixes the sequence, that is when $a_{n+1} = a_n$ for all n, that is when the sequence is constant. Partitioning S into orbits,

$$f(p) = |S| = \#\{\text{constant admissible sequences}\} + 5 \cdot \#\{\text{orbits of size } 5\},$$

so

$$f(p) \equiv \#\{\text{constant admissible sequences}\} \pmod 5.$$

Step 5: count the constant admissible sequences. The constant sequence $a_n = a$ with $a \in \mathbb{F}_p^\times$ is admissible if and only if $a \cdot a = 1 + a$, that is

$$a^2 - a - 1 = 0.$$

Since $p > 5$ we have p odd and $5 \neq 0$ in $\mathbb{F}_p$, so we may complete the square: $a^2 - a - 1 = 0 \iff (2a-1)^2 = 5$. The map $a \mapsto 2a - 1$ is a bijection of $\mathbb{F}_p$, so the number of solutions a equals the

number of square roots of 5 in $\mathbb{F}_p$, which is 2 if 5 is a nonzero quadratic residue modulo p and 0 otherwise (it cannot be 1, since $5 \neq 0$ means the two square roots $\pm\sqrt{5}$ are distinct). Note also that no root of $a^2 - a - 1$ is zero, since $0^2 - 0 - 1 = -1 \neq 0$, so every root does lie in $\mathbb{F}_p^\times$ and gives a genuine admissible sequence.

Combining Steps 4 and 5, $f(p) \equiv 0$ or $2 \pmod 5$, as required. ■

Remark: the exact value, as an independent check. By Step 2 an admissible sequence exists for a pair $(x, y) \in \mathbb{F}_p^\times \times \mathbb{F}_p^\times$ precisely when the five values $a_1, \ldots, a_5$ are all nonzero, and from the formulas above those five values are

$$x, \quad y, \quad \frac{1+y}{x}, \quad \frac{1+x+y}{xy}, \quad \frac{1+x}{y},$$

so the conditions are $x \neq -1$, $y \neq -1$ and $x + y \neq -1$. There are $p - 2$ choices of x in $\mathbb{F}_p^\times$ with $x \neq -1$, likewise for y, and for each such x exactly one forbidden value $y = -1 - x$, which is itself neither 0 nor -1 (it is 0 only if $x = -1$, and -1 only if $x = 0$). Hence

$$f(p) = (p-2)^2 - (p-2) = (p-2)(p-3).$$

Since $p > 5$ is prime, $p \not\equiv 0 \pmod 5$, and $(p-2)(p-3)$ modulo 5 for $p \equiv 1, 2, 3, 4$ is $2, 0, 0, 2$ respectively. This agrees with Step 5: $p \equiv \pm 1 \pmod 5$ is exactly the condition for 5 to be a quadratic residue modulo p, by quadratic reciprocity applied to $5 \equiv 1 \pmod 4$.

Remark: the invariant. The three conditions $x \neq -1, y \neq -1, x + y \neq -1$ are exactly the statement that

$$I(x, y) = \frac{(1+x)(1+y)(1+x+y)}{xy}$$

is nonzero, and a direct computation shows I is invariant under the map $T(x, y) = \left(y, \frac{1+y}{x}\right)$. So admissibility says precisely that the orbit lies on a nonzero level set of I.

Layer 1: WHAT

Block 1. Recognise $\{1, \ldots, p-1\} = \mathbb{F}_p^\times$ and divide: $a_{n+2} = (1 + a_{n+1})/a_n$.

Block 2. Recognise the second order recurrence as a map on pairs; the sequence is determined by (a_1, a_2).

Block 3. Read the target modulus 5 as an instruction to find a $\mathbb{Z}/5$ action; the only candidate is the shift, so compute terms and hope for period 5.

Block 4. Compute a_3, a_4, a_5, a_6, a_7 and find $(a_6, a_7) = (a_1, a_2)$: period 5.

Block 5. The shift is a $\mathbb{Z}/5$ action on the finite set S; orbits have size 1 or 5, so $|S| \equiv \#\mathrm{Fix} \pmod 5$.

Block 6. Fixed points are constant sequences, so they solve $a^2 = 1 + a$; a quadratic with nonzero discriminant over $\mathbb{F}_p$ (p odd) has 0 or 2 roots. Done.

Juxtapose with the nominal route. The zombie sees a recurrence and tries to solve it: he attempts a substitution to linearise, or he computes $a_3, a_4, a_5, \ldots$ and keeps going hoping for a closed form, or he sets up the count of (a_1, a_2) and then tries to justify the residues by arithmetic on $(p-2)(p-3)$ without ever asking why the number 5 should appear. The direct count is a perfectly good solution, but the zombie version of it stops at "and now check four cases", learning nothing.

The bifurcation point is the sentence in which you interpret the number 5 in "modulo 5". The zombie reads it as the modulus he must eventually reduce to. You read it as the order of a group that must be acting, and that reading tells you what to compute before you compute it.

Layer 2: HOW

Block 1. Cue. $a_n \in \{1, \ldots, p-1\}$, that is, never 0 modulo p. **Why natural.** The value set was specified as the nonzero residues, not as all residues, and the only reason to specify that is

invertibility. Dividing by a_n is therefore licensed by the hypothesis, and the recurrence becomes explicit rather than implicit. Whenever a problem restricts values to units, the intended move is division. **Link to the next block.** An explicit recurrence of order two is a dynamical system on pairs.

Block 2. Cue. Two previous terms determine the next. **Why natural.** The state of a second order recurrence is the pair (a_n, a_{n+1}), and the recurrence is then a single map T applied repeatedly. This reframing matters because the natural objects (orbits, periods, invariants, fixed points) all belong to the language of maps, not of sequences. **Link to the next block.** A map with finite order gives a group action, and group actions give congruences.

Block 3. Cue. The answer is requested modulo 5, and 5 is not related to p. **Why natural.** A congruence modulo a prime q for the size of a set almost always comes from a $\mathbb{Z}/q$ action, because for a group of prime order every orbit has size 1 or q. This is the same mechanism behind the necklace proof of Fermat's little theorem and behind Cauchy's theorem. Since S is a set of sequences, the only natural $\mathbb{Z}/5$ candidate is the shift, and for the shift to have order 5 you need period 5. **Link to the next block.** So the periodicity is not a lucky observation; it is the hypothesis your strategy requires, and you go and test it.

Block 4. Cue. A short nonlinear recurrence with small coefficients. **Why natural.** You test periodicity by computing, and the computation is short if you keep everything as a single fraction in x and y and factorise numerators as you go. The key simplification is that $1 + a_4 = \frac{(1+x)(1+y)}{xy}$ factorises, which is what makes a_5 collapse to $\frac{1+x}{y}$ and produces the symmetry between a_3 and a_5 under swapping x and y. That symmetry is a signal that the orbit is closing. **Link to the next block.** Period 5 confirmed, the group action exists.

Block 5. Cue. A group of prime order acting on a finite set. **Why natural.** The orbit-stabiliser theorem says orbit sizes divide the group order, and 5 is prime, so orbits have size 1 or 5. Summing sizes gives $|S| \equiv \#\{\text{orbits of size } 1\} \pmod 5$. Note what you have avoided: you never computed $|S|$. **Link to the next block.** Fixed points of a shift are constant sequences, which are governed by one equation.

Block 6. Cue. A constant sequence substituted into $a_n a_{n+2} = 1 + a_{n+1}$. **Why natural.** Substituting the simplest possible object into the defining relation is always the first probe, and here it produces $a^2 - a - 1 = 0$, whose discriminant is 5. That is the second appearance of 5, and it is the real reason the answer is "0 or 2": a quadratic over a field of odd characteristic has 0, 1 or 2 roots, and it has exactly 1 only when the discriminant vanishes, which is excluded by $p > 5$. The hypothesis $p > 5$ is therefore doing precise work, not decorating the statement. **Link to the next block.** Two possible fixed point counts, 0 and 2, give the two possible residues.

Layer 3: WHY

Three mathematical truths make this route ideal. First, the counting principle: if a group G of prime order q acts on a finite set S, then $|S| \equiv |S^G| \pmod q$, because non-fixed orbits all have size exactly q. This is the cheapest congruence-producing machine in mathematics, and it converts a hard counting problem into an easy fixed point problem. Second, the structural fact that the Lyness recurrence $x_{n+2} = (x_{n+1} + 1)/x_n$ is periodic with period 5 over any field where the terms are defined. Third, the fact that over a field of odd characteristic a quadratic has 0 or 2 roots unless its discriminant vanishes.

The discernment mechanism for choosing this route is a single question: what is the modulus for? Whenever a problem asks you to prove a congruence modulo a small prime for the cardinality

of a set of structured objects (sequences, colourings, tuples, subsets), look for the group of that order acting by symmetry of the structure. Shifts and rotations are the usual suspects for sequences and necklaces; conjugation and coordinate permutation for tuples. Then the whole problem reduces to identifying the fixed objects, which are always the "degenerate" or "constant" ones, and those are governed by a single equation.

To train it: take the classical proofs of Fermat's little theorem by necklaces, of Wilson's theorem by pairing x with x^{-1}, and of Fermat's two squares theorem by an involution, and in each case name the group, the set, and the fixed points. Once those three slots are automatic you will fill them without prompting.

What the examiners nudged with: the value set $\{1, \dots, p-1\}$ nudges you to divide; the condition $p > 5$ nudges you to notice that 5 is invertible and that the discriminant is nonzero; and the modulus 5 nudges you to look for the pentagonal symmetry. Three separate appearances of the number 5 in one problem is not a coincidence, it is a signature: the sequence has period 5, the group has order 5, and the discriminant is 5. All three come from the same source, the pentagon recurrence.

Revolving concepts

The Lyness recurrence and its generalisation. The recurrence

$$x_{n+2} = \frac{x_{n+1} + \alpha}{x_n}$$

is the Lyness map. For $\alpha = 1$ it is periodic with period 5 for all initial data where it is defined; for general α it is not periodic but preserves the invariant

$$I_\alpha(x, y) = \frac{(x+\alpha)(y+\alpha)(x+y+\alpha)}{xy},$$

whose level sets are elliptic curves, and the map acts as translation by a point on each. The $\alpha = 1$ case is degenerate: the translation is by a 5-torsion point. This is the general recursion behind the problem, and its general solution method is: look for a rational invariant, then interpret the map as translation on the level curve. See Book 1, field: Sequences and recurrences, topic: Lyness recurrences and integrable maps.

The pentagon recurrence and cluster algebras. The relation $a_n a_{n+2} = 1 + a_{n+1}$ is the exchange relation of the rank two cluster algebra of type A_2, and its periodicity with period $5 = h + 2$ (where $h = 3$ is the Coxeter number of A_2) is the smallest instance of Zamolodchikov periodicity. The same framework gives the Laurent phenomenon: every a_n is a Laurent polynomial in a_1, a_2 with integer coefficients, which is exactly what you observe when computing a_3, a_4, a_5. Flag this as a knowledge gap: the theory of cluster algebras is well beyond A-level and beyond most undergraduate courses, but the single fact "this recurrence has period 5" is what you need installed. See Book 1, field: Sequences and recurrences, topic: Laurent phenomenon and Zamolodchikov periodicity.

Group actions and congruences. If a finite group G acts on a finite set S, then S is partitioned into orbits and $|\mathrm{Orb}(s)| = [G : \mathrm{Stab}(s)]$ divides $|G|$. When $|G| = q$ is prime, orbits have size 1 or q, so $|S| \equiv |S^G| \pmod q$. Standard consequences: Fermat's little theorem via $\mathbb{Z}/q$ acting on strings of length q by rotation, and Cauchy's theorem. See Book 1, field: Abstract algebra, topic: group actions, orbit-stabiliser, and fixed point congruences.

Quadratic equations over $\mathbb{F}_p$ and quadratic residues. For odd p, $ax^2 + bx + c = 0$ with $a \neq 0$ has 2, 1 or 0 roots in $\mathbb{F}_p$ according as the discriminant $b^2 - 4ac$ is a nonzero square, zero, or a non-square. Exactly half of $\mathbb{F}_p^\times$ are squares. Quadratic reciprocity for 5 (which is 1 modulo 4) gives $\left(\frac{5}{p}\right) = \left(\frac{p}{5}\right)$, so 5 is a residue precisely when $p \equiv \pm 1 \pmod 5$. The roots of $x^2 - x - 1$ are the golden ratio and its conjugate, and their existence in $\mathbb{F}_p$ governs the period of the Fibonacci sequence modulo p. See Book 1, field: Number theory, topic: quadratic residues and reciprocity.

Counting a complement of a union. The count $(p-2)^2-(p-2)$ is inclusion and exclusion in its simplest form: from the grid of allowed (x,y) remove the line $x+y=-1$, checking that the removed line meets the grid in exactly $p-2$ points. See Book 1, field: Combinatorics, topic: inclusion and exclusion.

Circuit Bank

- **WHEN** you are asked to prove a congruence modulo a small prime q for the number of structured objects **DO** look for a group of order q acting on the set, then count only the fixed objects **BECAUSE** orbits of a prime order group have size 1 or q, so the cardinality is congruent to the number of fixed points; this converts counting into solving one equation
- **WHEN** you see a recurrence whose values are restricted to the units of a ring **DO** divide immediately to make it explicit, then treat it as a map on the state vector of previous terms **BECAUSE** the restriction to units exists precisely to license the division, and an explicit map brings orbits, periods and invariants into play
- **WHEN** you suspect a nonlinear recurrence is periodic **DO** compute successive terms as single fractions and factorise every numerator as you go **BECAUSE** periodicity shows up as unexpected factorisations, and a symmetric expression appearing (here a_3 and a_5 swapping under $x \leftrightarrow y$) is the sign that the orbit is about to close
- **WHEN** you have a map T and want to know which orbits are defined for all time **DO** look for a rational invariant I with $I \circ T = I$, and read the degeneracy conditions off the zeros and poles of I **BECAUSE** an invariant turns an infinite condition (all iterates defined) into a finite one (a nonzero level set), which is exactly what the three exclusions $x, y, x+y \neq -1$ encode
- **WHEN** a fixed point count is needed for a shift action on sequences **DO** substitute a constant sequence into the defining relation **BECAUSE** shift-invariant means constant, so the fixed points are always the solutions of the one-variable version of the relation, and over a field that is usually a quadratic with a computable discriminant

Backtesting

1. First useful cue: the modulus 5 is unrelated to p, so a $\mathbb{Z}/5$ action must exist; the only candidate on sequences is the shift, so test for period 5.
2. Method the expression suggested: divide by a_n to get $a_{n+2} = (1+a_{n+1})/a_n$, iterate five times keeping everything as one fraction, and confirm $(a_6, a_7) = (a_1, a_2)$.
3. Where you would hesitate, and the thought to reinforce: at the claim that the shift maps admissible sequences to admissible sequences. Reinforce that the shifted sequence satisfies the same recurrence indexed one lower, and that its values are the same set of units; one sentence, but a grader will look for it.
4. The trap the question sets: computing $f(p) = (p-2)(p-3)$ and then checking four residue cases without noticing that the "0 or 2" is really the number of roots of a quadratic. The arithmetic route is correct and scores, but it hides the mechanism, and the mechanism is what transfers to the next problem.
5. What makes you recognise it faster next time: three appearances of the number 5 (the modulus, the period, the discriminant) all trace back to the same pentagonal structure. When a number repeats across unrelated-looking parts of a problem, it is one structure seen three times.
6. The reusable decision rule: congruence for a cardinality means a group action of that order; find the group, then count fixed points only.

Mirror drills

1. Let q be prime and let S be the set of strings of length q over an alphabet of size m that are not constant. Show $q \mid |S|$ and deduce Fermat's little theorem. *Answer:* Cyclic rotation gives a $\mathbb{Z}/q$ action whose fixed points are exactly the constant strings, so $m^q \equiv m \pmod{q}$; the same three-slot argument as A3.

2. Show that the recurrence $x_{n+2} = (x_{n+1} + 1)/x_n$ over $\mathbb{Q}$ with $x_1 = 2$, $x_2 = 3$ is periodic, and state the invariant. *Answer:* The orbit is $2, 3, 2, 1, 1, 2, 3, \ldots$ of period 5, and $I(x, y) = \frac{(1+x)(1+y)(1+x+y)}{xy}$ takes the value $\frac{3 \cdot 4 \cdot 6}{6} = 12$ at every consecutive pair.

3. For which primes p does $x^2 \equiv x + 1 \pmod{p}$ have a solution? *Answer:* Exactly when 5 is a quadratic residue modulo p, that is when $p = 5$ or $p \equiv \pm 1 \pmod{5}$; by reciprocity, since $5 \equiv 1 \pmod{4}$, this is the condition $\left(\frac{p}{5}\right) = 1$. These are the primes for which the golden ratio exists in $\mathbb{F}_p$.

4.4 A4. Expected weighted sum before the first ascent

Suppose that $X_1, X_2, \ldots$ are real numbers between 0 and 1 that are chosen independently and uniformly at random. Let $S = \sum_{i=1}^{k} X_i/2^i$, where k is the least positive integer such that $X_k < X_{k+1}$, or $k = \infty$ if there is no such integer. Find the expected value of S.

Read it out loud

Say the structure: this is a sum with a random number of terms, where the random number is a stopping time defined by "the first time something happens". The summands carry deterministic geometric weights 2^{-i}, and the randomness sits in two places at once: in the values X_i and in how many of them survive. That double dependence is the entire difficulty, and it is also the entire hint, because there is exactly one standard device for a sum whose length is random: write the sum as an infinite sum of indicator-weighted terms and use linearity of expectation.

So write

$$S = \sum_{i=1}^{\infty} \frac{X_i}{2^i} \mathbf{1}[\, i \le k \,],$$

and the problem becomes: for each fixed i, compute $E[X_i \mathbf{1}[i \le k]]$. The point of this rewriting is that the sum is now over a fixed index set, and every difficulty has been pushed into a single expectation for each i.

Now read the stopping rule again, carefully, because the second cue is hidden there. The variable k is the least index with $X_k < X_{k+1}$. The event $\{k = i\}$ involves X_{i+1} and is two-sided: a run of descents followed by one ascent. But the event $\{k \ge i\}$ involves only $X_1, \ldots, X_i$ and is one-sided:

$$\{k \ge i\} = \{X_1 \ge X_2 \ge \cdots \ge X_i\},$$

because $k \ge i$ says precisely that none of the first $i-1$ comparisons was an ascent. Almost surely there are no ties, so this is a strictly decreasing run. That is the whole problem: the indicator you need is a tail event, and the tail event of a "first time" stopping rule is always the clean one.

The fields wired in are: elementary probability (linearity, independence), exchangeability of independent identically distributed continuous random variables, order statistics and simplex volumes, the Beta integral, and the exponential series. Within thirty seconds you should have written S as an indicator sum and identified $\{i \le k\}$ as a descending run.

Approaches, ranked worst to best

1. **Simulate or compute the first few cases.** *Cue:* a strange stopping rule. *Circuit:* small cases first. Computing $E[S \mid k = 1]$, $E[S \mid k = 2]$ by hand will produce numbers but no pattern that you can sum, because the conditional distribution of $X_1, \ldots, X_i$ given $k = i$ is an awkward object. Ranked last: it is work without structure.

2. **Condition on the value of k.** *Cue:* "k is the least positive integer such that". *Circuit:* law of total expectation. Write $E[S] = \sum_i P(k = i) E[S \mid k = i]$. This is the reflex most people have, and it is bad here. Conditioning on $\{k = i\}$ imposes both a descending run on $X_1, \ldots, X_i$ and an ascent at the end, so the conditional law of X_i is distorted by information about X_{i+1}, and you must carry a two-sided constraint through every integral. It ranks above blind experiment because it does terminate, but it costs several times the ink.

3. **Full joint density of the descending run.** *Cue:* the event is a region in $[0,1]^i$. *Circuit:* integrate over an explicit simplex. Write $E[X_i \mathbf{1}[i \le k]]$ as an i-fold integral over $\{1 > x_1 > \cdots > x_i > 0\}$ of x_i, and evaluate by iterated integration. Correct, and only slightly more expensive than the ideal route; the iterated integral rebuilds the factorial $(i-1)!$ from scratch each time. Ranked third because it works but recomputes a standard fact.

4. **Indicator sum plus conditioning on the last variable.** *Cue:* a random number of terms with a "first time" rule. *Circuit:* linearity of expectation over a tail event, then exchangeability. Write S as an indicator sum, replace $\{i \le k\}$ by the descending run event, condition on $X_i = t$, and split that event into two independent pieces: "the earlier variables all exceed t", of probability $(1-t)^{i-1}$, and "the earlier variables are in decreasing order", of probability $1/(i-1)!$ by exchangeability. One Beta integral finishes it. This is the ideal route: it never conditions on k, it never writes a multiple integral, and the factorial appears as a symmetry count rather than as the output of a computation.

The ideal solution

The answer is $\boxed{2e^{1/2} - 3}$, approximately 0.29744.

Setup. Since the X_i are independent with a continuous distribution, almost surely no two are equal, and we work on that full-measure event throughout. Extend the sum defining S by zero summands beyond k, so that

$$S = \sum_{i=1}^{\infty} \frac{X_i}{2^i} \mathbf{1}[\, i \le k\,].$$

Every summand is nonnegative and $0 \le S \le \sum_{i \ge 1} 2^{-i} = 1$, so S is a bounded nonnegative random variable and, by Tonelli's theorem (equivalently, monotone convergence for a series of nonnegative terms), expectation may be taken term by term:

$$E[S] = \sum_{i=1}^{\infty} \frac{1}{2^i} E[X_i \mathbf{1}[\, i \le k\,]]\,.$$

Step 1: the indicator is a descending run. By definition k is the least positive integer j with $X_j < X_{j+1}$. Hence $k \ge i$ if and only if no $j \in \{1, \dots, i-1\}$ satisfies $X_j < X_{j+1}$, that is, if and only if $X_1 > X_2 > \cdots > X_i$ (almost surely, using that ties have probability zero). In particular this event depends only on $X_1, \dots, X_i$.

Step 2: the expectation of one summand. Fix $i \ge 1$ and condition on $X_i = t$. The event $\{X_1 > X_2 > \cdots > X_i\}$ is the intersection of

$$A = \{X_1, \dots, X_{i-1} \text{ all lie in } (t, 1)\}, \qquad B = \{X_1 > X_2 > \cdots > X_{i-1}\},$$

and these two events are independent, because A depends only on the unordered set of values $\{X_1, \dots, X_{i-1}\}$ while B depends only on which of the $(i-1)!$ orderings of those values occurs, and for independent identically distributed continuous variables the ordering is uniform on the $(i-1)!$ possibilities and independent of the value set. Thus, given $X_i = t$,

$$P(A) = (1-t)^{i-1}, \qquad P(B) = \frac{1}{(i-1)!}, \qquad P(X_1 > \cdots > X_i \mid X_i = t) = \frac{(1-t)^{i-1}}{(i-1)!}.$$

(For $i = 1$ both factors are empty products equal to 1, and the formula correctly gives probability 1.) Since X_i is uniform on $(0, 1)$,

$$E[X_i \mathbf{1}[i \le k]] = \int_0^1 t\, \frac{(1-t)^{i-1}}{(i-1)!}\, dt = \frac{1}{(i-1)!} \cdot \frac{1!\,(i-1)!}{(i+1)!} = \frac{1}{(i+1)!},$$

where the middle equality is the Beta integral $\int_0^1 t^{a-1}(1-t)^{b-1} dt = \frac{(a-1)!(b-1)!}{(a+b-1)!}$ with $a = 2$, $b = i$; if you prefer to avoid quoting it, substitute $u = 1 - t$ and expand:

$$\int_0^1 t(1-t)^{i-1} dt = \int_0^1 (1-u)u^{i-1} du = \frac{1}{i} - \frac{1}{i+1} = \frac{1}{i(i+1)},$$

and $\frac{1}{(i-1)!\, i(i+1)} = \frac{1}{(i+1)!}$.

Step 3: sum the series. Therefore

$$E[S] = \sum_{i=1}^{\infty} \frac{1}{2^i (i+1)!} = 2 \sum_{i=1}^{\infty} \frac{(1/2)^{i+1}}{(i+1)!} = 2 \sum_{j=2}^{\infty} \frac{(1/2)^j}{j!} = 2 \left(e^{1/2} - 1 - \frac{1}{2} \right) = 2e^{1/2} - 3.$$

The case $k = \infty$ is null. From Step 1, $P(k \geq i) = P(X_1 > \cdots > X_i) = 1/i!$, since by exchangeability all $i!$ orderings of $X_1, \ldots, X_i$ are equally likely. Hence $P(k = \infty) = \lim_{i \to \infty} 1/i! = 0$, so S is defined almost surely, and however S is defined on the null event $\{k = \infty\}$ (the full series converges there anyway) the expectation is unaffected.

Sanity checks. First, $P(k = i) = \frac{1}{i!} - \frac{1}{(i+1)!} = \frac{i}{(i+1)!}$, and $\sum_{i \geq 1} \frac{i}{(i+1)!} = \sum_{i \geq 1} \left(\frac{1}{i!} - \frac{1}{(i+1)!} \right) = 1$ by telescoping, confirming that k is almost surely finite. Second, $E[k] = \sum_{i \geq 1} P(k \geq i) = \sum_{i \geq 1} \frac{1}{i!} = e - 1 \approx 1.718$, so typically only one or two terms survive, and indeed $E[S] \approx 0.297$ sits just below $E[X_1/2] = 1/4$ plus a small contribution from the later terms. Third, the crude bound $E[S] \leq E[X_1]/2 + \sum_{i \geq 2} 2^{-i}/i! = 1/4 + \ldots$ is comfortably consistent.

Layer 1: WHAT

Block 1. Rewrite the random-length sum as an infinite indicator sum $S = \sum_i 2^{-i} X_i \mathbf{1}[i \leq k]$.

Block 2. Justify term-by-term expectation: nonnegative summands, Tonelli.

Block 3. Convert the indicator: $\{i \leq k\}$ is the descending run $\{X_1 > \cdots > X_i\}$, an event in the first i variables only.

Block 4. Condition on $X_i = t$ and factor the run event into "all earlier values exceed t" times "the earlier values are in decreasing order", independent, with probabilities $(1-t)^{i-1}$ and $1/(i-1)!$.

Block 5. Integrate: $E[X_i \mathbf{1}] = \frac{1}{(i-1)!} \int_0^1 t(1-t)^{i-1} dt = \frac{1}{(i+1)!}$.

Block 6. Sum $\sum_i 2^{-i}/(i+1)!$ by shifting the index into the exponential series: $2e^{1/2} - 3$.

Block 7. Check that $k < \infty$ almost surely, so nothing was lost.

Juxtapose with the nominal route. The zombie writes $E[S] = \sum_i P(k = i) E[S \mid k = i]$, computes $P(k = i) = \frac{i}{(i+1)!}$, and then has to find the conditional expectation of a whole descending run given that it ends with an ascent. That requires the joint density of $(X_1, \ldots, X_i)$ restricted to a region cut out by $i - 1$ descent conditions and one ascent condition involving an extra variable, and it produces nested integrals that do not simplify until the very end. The answer is the same; the ink is four times as much and the error probability rises with it.

The bifurcation point is the choice of which event to use: $\{k = i\}$ or $\{k \geq i\}$. Everything else follows. Say it as a rule: for a stopping time defined as a first passage, always work with the tail event, because the tail event is the complement of a conjunction of "nothing happened yet" conditions and therefore involves no extra variable.

Layer 2: HOW

Block 1. **Cue.** A sum whose upper limit is a random variable. **Why natural.** You cannot integrate over a random index set, but you can integrate over a fixed index set with an indicator. Rewriting $\sum_{i=1}^{k}$ as $\sum_{i=1}^{\infty} \mathbf{1}[i \leq k]$ separates the two sources of randomness, and linearity of expectation does not care that the indicators and the summands are dependent. That last point is the one people forget: linearity needs no independence at all. **Link to the next block.** Now each term is a single expectation, and the only question is which event the indicator describes.

Block 2. **Cue.** An infinite sum of nonnegative random variables. **Why natural.** Interchanging an infinite sum with an expectation is an interchange of two limits and needs a licence. For nonnegative terms the licence is free: Tonelli, or equivalently monotone convergence. Writing one clause naming it is the difference between a full-marks script and a script with a hole in it. Do not write "clearly we may interchange". **Link to the next block.** With the interchange justified, compute one term.

Block 3. **Cue.** "k is the least positive integer such that $X_k < X_{k+1}$". **Why natural.** "Least index with a property" always means: the tail event $\{k \geq i\}$ is "the property failed at every earlier index". Here the property is an ascent, so its failure at every earlier index is a descending run. This is the definitional reading of a first passage time, and it is also the reason the event does not touch X_{i+1}: the constraint at index i has not yet been tested. **Link to the next block.** The indicator now depends on exactly the variables $X_1, \ldots, X_i$, so condition on the one you also need, namely X_i.

Block 4. **Cue.** You need $E[X_i \cdot \mathbf{1}(\text{run})]$, a product of a value and an ordering condition. **Why natural.** Condition on the variable that appears in both roles, $X_i = t$. The remaining condition on $X_1, \ldots, X_{i-1}$ splits into a magnitude condition (all bigger than t) and an ordering condition (decreasing), and these are independent for independent identically distributed continuous variables: the unordered set of values and the ordering pattern are independent, with the ordering uniform over $(i-1)!$ possibilities. That independence is exchangeability, and it is the reason a factorial appears without any integration. **Link to the next block.** One clean one-dimensional integral remains.

Block 5. **Cue.** $\int_0^1 t(1-t)^{i-1}dt$. **Why natural.** This is a Beta integral, and even without quoting the Beta function the substitution $u = 1 - t$ turns it into $\int_0^1 (u^{i-1} - u^i)du = \frac{1}{i} - \frac{1}{i+1}$. The resulting collapse $\frac{1}{(i-1)!\,i(i+1)} = \frac{1}{(i+1)!}$ is the signal that you have taken the right route: an answer of the form $\frac{1}{(i+1)!}$ is exactly what can be summed against 2^{-i}. **Link to the next block.** A reciprocal factorial against a geometric weight is the exponential series.

Block 6. **Cue.** $\sum_i \frac{1}{2^i(i+1)!}$, a factorial with a shifted index. **Why natural.** To use $e^x = \sum_j x^j/j!$ the exponent and the factorial must carry the same index. Multiplying and dividing by 2 to convert 2^{-i} into $2^{-(i+1)}$ aligns them, after which the sum is the exponential series with its first two terms removed. Index alignment before summation is a mechanical habit; never try to sum a series whose exponent and factorial disagree. **Link to the next block.** Evaluate and subtract the missing terms.

Block 7. **Cue.** The problem itself flagged the possibility $k = \infty$. **Why natural.** The statement went out of its way to define $k = \infty$ when no ascent occurs, which is an instruction to say something about that case. $P(k \geq i) = 1/i!$ makes it a null event in one line. A grader looks for this, and it costs one sentence. **Link to the next block.** Nothing is lost; the computed expectation is the answer.

Layer 3: WHY

The truths beneath this route are three. First, linearity of expectation holds for arbitrarily dependent summands, which is why the indicator decomposition is legitimate and why it is the universal tool for random-length sums; the analogous identity $E[N] = \sum_{i \geq 1} P(N \geq i)$ for nonnegative integer N is the same idea with $X_i \equiv 1$. Second, exchangeability: for independent identically distributed continuous random variables, the vector of ranks is uniform on the symmetric group and independent of the vector of order statistics. That single fact is what makes $P(X_1 > \cdots > X_i) = 1/i!$ a symmetry count rather than an integral, and it is what lets you factor the descending run event into an independent magnitude part and ordering part. Third, the volume of the simplex $\{t < x_{i-1} < \cdots < x_1 < 1\}$ is $(1-t)^{i-1}/(i-1)!$, which is the same factorial appearing geometrically.

The discernment mechanism: when a probability problem contains a stopping rule, immediately classify it as a first passage and write down its tail event. Then ask whether the quantity you want is a sum, and if so, decompose it by index and use linearity. The combination "first passage plus linearity of expectation over indicators" solves a large fraction of all Putnam probability problems, because it is the only method that does not require knowing the joint law of the stopped sequence.

To train it, take any problem containing the words "the first time", rewrite the target as a sum of indicator-weighted terms, and force yourself to express every indicator using only tail events

$\{k \geq i\}$. If an event you have written mentions a variable with index greater than i, you have used $\{k = i\}$ somewhere and should back up.

What the examiners nudged with: the weights 2^{-i} are there so that the final series is summable against a reciprocal factorial and produces a clean closed form with $e^{1/2}$, and the explicit mention of $k = \infty$ is a deliberate invitation to check that the event is null. The choice of the uniform distribution on $[0, 1]$ is what makes $P(A) = (1-t)^{i-1}$ so clean; the same method works for any continuous distribution, with $(1 - F(t))^{i-1}$ in place of $(1-t)^{i-1}$, which is a good way to see that only continuity and independence were used.

Revolving concepts

Linearity of expectation and the indicator decomposition. For any random variables $Y_i \geq 0$ and any event structure, $E\left[\sum_i Y_i\right] = \sum_i E[Y_i]$ by Tonelli, with no independence required. The special case $E[N] = \sum_{i \geq 1} P(N \geq i)$ for a nonnegative integer valued N is the tail-sum formula, and the continuous analogue is $E[Y] = \int_0^\infty P(Y > y)\, dy$. See Book 1, field: Probability, topic: linearity and tail sums.

Exchangeability and ranks. If $X_1, \ldots, X_n$ are independent and identically distributed with a continuous distribution, then almost surely they are distinct, all $n!$ orderings are equally likely, and the rank vector is independent of the order statistics. Consequences: $P(X_1 > \cdots > X_n) = 1/n!$; the probability that the maximum occurs at a specified index is $1/n$; the expected number of records among n such variables is $\sum_{j=1}^{n} 1/j$. See Book 1, field: Probability, topic: exchangeability, ranks and records.

Iterated integration and the simplex, with the recursion generalised. Define $F_i(t) = P(X_1 > X_2 > \cdots > X_{i-1} > t)$ for uniform variables on $[0, 1]$. Then $F_1(t) = 1$ and

$$F_{i+1}(t) = \int_t^1 F_i(u)\, du,$$

because the smallest of the run must exceed t and the rest form a run above it. This recursion is solved by $F_i(t) = \frac{(1-t)^{i-1}}{(i-1)!}$, proved by induction: repeated integration of a power raises the exponent and divides by the new exponent, generating the factorial. The general statement is that the m-fold iterated integral of the constant 1 over a nested region is the volume of a simplex, $\frac{(1-t)^m}{m!}$, and more generally the m-fold iterated integral of g equals $\frac{1}{(m-1)!}\int_t^1 (u-t)^{m-1} g(u) du$ (Cauchy's formula for repeated integration). This is the general recursion behind every factorial that appears in an ordering problem. See Book 1, field: Probability, topic: order statistics; and field: Calculus and integrals, topic: repeated integration.

The Beta integral. $\int_0^1 t^{a-1}(1-t)^{b-1} dt = \frac{\Gamma(a)\Gamma(b)}{\Gamma(a+b)}$, which for positive integers reads $\frac{(a-1)!(b-1)!}{(a+b-1)!}$. In this problem it is the case $a = 2$, and it can be avoided by one substitution, but knowing it converts a two-line computation into a one-line one. See Book 1, field: Calculus and integrals, topic: Beta and Gamma functions.

Exponential series with shifted index. $\sum_{j \geq 0} x^j/j! = e^x$; to evaluate $\sum_{i \geq 1} x^i/(i+1)!$ multiply by x and shift: $x \sum_{i \geq 1} \frac{x^i}{(i+1)!} = \sum_{j \geq 2} \frac{x^j}{j!} = e^x - 1 - x$. Here $x = 1/2$ and the prefactor is $1/x = 2$. See Book 1, field: Sequences and recurrences, topic: manipulating standard series by index shifting.

Circuit Bank

- **WHEN** you see a sum with a random number of terms **DO** rewrite it as $\sum_{i=1}^{\infty} (\text{term}_i) \mathbf{1}[i \leq k]$ and apply linearity of expectation **BECAUSE** linearity needs no independence, so the dependence between the indicator and the term is harmless, and the index set becomes fixed
- **WHEN** you see a stopping time defined as "the least index such that P holds" **DO** work with the tail event $\{k \geq i\} = \{\text{P failed at indices } 1, \ldots, i-1\}$, never with $\{k = i\}$ **BECAUSE** the

tail event involves only the variables up to index i, whereas $\{k = i\}$ drags in the next variable and distorts every conditional law

- **WHEN** you need the expectation of a value times an ordering indicator **DO** condition on the variable that appears in both, then split the remaining event into a magnitude part and an ordering part **BECAUSE** for independent identically distributed continuous variables these two parts are independent, so the factorial appears as a symmetry count and no multiple integral is needed
- **WHEN** you must interchange an infinite sum and an expectation **DO** check nonnegativity and name Tonelli or monotone convergence in one clause **BECAUSE** the interchange is a limit exchange and is not automatic; for nonnegative terms it is free, and naming it costs one line and secures the marks
- **WHEN** a series has x^i against $(i + c)!$ **DO** multiply by x^c to align the exponent with the factorial, then subtract the missing initial terms of the exponential series **BECAUSE** closed forms only appear once the index of the power and the index of the factorial agree, so alignment is a mechanical prerequisite, not an insight

Backtesting

1. First useful cue: the sum has a random upper limit, so write it as an indicator sum over a fixed index set.
2. Method the expression suggested: identify $\{i \leq k\}$ as the descending run $\{X_1 > \cdots > X_i\}$, condition on $X_i = t$, factor into magnitude and ordering, integrate, sum.
3. Where you would hesitate, and the thought to reinforce: at the independence of the magnitude event and the ordering event. Reinforce that for independent identically distributed continuous variables, the set of values and the ordering pattern are independent, with all $(i - 1)!$ orders equally likely; this is exchangeability, and it is the single most useful fact in Putnam probability.
4. The trap the question sets: conditioning on $\{k = i\}$, which entangles X_{i+1} and turns a one-line computation into nested integrals. The second trap is ignoring the $k = \infty$ clause, which the problem deliberately inserted.
5. What makes you recognise it faster next time: the phrase "the least positive integer such that" is the signature of a first passage time, and a first passage time is always handled through its tail event.
6. The reusable decision rule: random-length sum means indicator decomposition; first passage means tail event; ordering condition means exchangeability.

Mirror drills

1. With $X_1, X_2, \ldots$ independent uniform on $[0, 1]$ and k as in the problem, find $E[k]$. *Answer:* $E[k] = \sum_{i \geq 1} P(k \geq i) = \sum_{i \geq 1} \frac{1}{i!} = e - 1$. Same tail event, tail-sum formula instead of a weighted sum.
2. Let N be the least n such that $X_1 + \cdots + X_n > 1$, for independent uniforms on $[0, 1]$. Show $E[N] = e$. *Answer:* $P(N > n) = P(X_1 + \cdots + X_n \leq 1) = \frac{1}{n!}$, the volume of the standard simplex, so $E[N] = \sum_{n \geq 0} P(N > n) = \sum_{n \geq 0} \frac{1}{n!} = e$. The same simplex factorial, arrived at by volume rather than by ordering.
3. Replace the uniform distribution by an arbitrary continuous distribution with cumulative distribution function F, and compute $E\left[\sum_{i=1}^{k} X_i / 2^i\right]$ in terms of F. *Answer:* The identical

argument gives $\sum_{i\geq 1} \frac{1}{2^i(i-1)!} \int_{-\infty}^{\infty} t\,(1-F(t))^{i-1} dF(t)$; only continuity and independence were used, and the uniform case is $F(t) = t$ on $[0,1]$.

4.5 A5. Domino placing game on 2022 squares

Alice and Bob play a game on a board consisting of one row of 2022 consecutive squares. They take turns placing tiles that cover two adjacent squares, with Alice going first. By rule, a tile must not cover a square that is already covered by another tile. The game ends when no tile can be placed according to this rule. Alice's goal is to maximize the number of uncovered squares when the game ends; Bob's goal is to minimize it. What is the greatest number of uncovered squares that Alice can ensure at the end of the game, no matter how Bob plays?

Read it out loud

Read the position, not the board. At any moment the uncovered squares form a disjoint union of maximal runs, and a run of length ℓ is the only thing that matters about it: a tile placed in that run splits it into two runs of lengths i and $\ell - 2 - i$ for some $0 \le i \le \ell - 2$, and runs never interact. So a position is a finite multiset of nonnegative integers, a move replaces one entry $\ell \ge 2$ by two entries summing to $\ell - 2$, and the game ends when every entry is 0 or 1. The final score is the number of entries equal to 1.

Say the second thing aloud: this is a *scoring* game on a disjunctive sum, not a normal-play game. Nobody is trying to make the last move; the players are trying to control a number. That single sentence rules out the entire Sprague-Grundy apparatus, which computes who wins a last-move game and says nothing about scores. It also warns you that positions do not simply add: the value of a two-component position is not the sum of the component values, because the players choose where to move.

Third, two reformulations that cost nothing and buy a lot. Each tile covers exactly two squares, so if d tiles are placed the score is $2022 - 2d$: Alice is trying to make the game *short* and Bob to make it *long*. And the final score equals the number of odd-length runs at the end, because a terminal run has length 0 or 1; moreover splitting ℓ into i and $\ell - 2 - i$ preserves parity of the total, so an odd run always produces exactly one odd run and an even run produces either two odd runs or none. Hence the number of odd runs never decreases, it increases by exactly 2 when a player splits an even run into two odd pieces, and the final score is the initial number of odd runs plus twice the number of such splits. Alice wants those splits, Bob wants to avoid them, and Bob can always avoid them: from any run of length $\ell \ge 2$ he may play $(0, \ell - 2)$, which preserves every parity.

The fields wired in are combinatorial game theory (scoring games, disjunctive sums, the notion of a switch and its mean value and temperature), induction on a well-founded order, and elementary number theory modulo 7. Within thirty seconds you should have written the position as a multiset, the move as $\ell \mapsto (i, \ell - 2 - i)$, and the two value functions $A(P)$ (Alice to move) and $B(P)$ (Bob to move). Then you should compute small cases, because the periodicity you are going to need is not something you can guess.

Approaches, ranked worst to best

1. **Symmetry or mirroring strategy.** *Cue:* 2022 is even and the row is symmetric. *Circuit:* pairing strategy for the second player. Mirroring works in normal-play games where the goal is to move last. Here it controls nothing: Bob mirroring Alice's split produces exactly the odd runs Alice wanted. Ranked last because it is the reflex that costs the most time before revealing that it answers a different question.

2. **Sprague-Grundy values of the octal game.** *Cue:* splitting a row by placing dominoes is the game Dawson's Kayles. *Circuit:* nim-value tables and periodicity. The Grundy theory of this move rule is genuinely classical and genuinely periodic, and it is completely useless here: Grundy values decide who makes the last move, and the question asks for a score. Ranked

here because it is a real theory misapplied, which is more dangerous than an obviously wrong idea.

3. **Single-interval recursion with a following strategy.** *Cue:* the game starts as one interval. *Circuit:* define $a(n)$, $b(n)$ for one interval, then bound them. Define $a(n)$ and $b(n)$ as the values of a single interval of length n with Alice, respectively Bob, to move, compute them for $n \leq 6$, and prove $a(n) = a(n-7)+1$, $b(n) = b(n-7)+1$ by having the second player answer in whichever component the first player just used. This is the standard route and it does reach 290. Its cost is that the following strategy breaks down whenever a component runs out, so you must allow a player to pass, and then you must prove that a pass is worthless, which is the statement that having the move never hurts. That lemma is not free.

4. **Closed form for every position via mean value and temperature.** *Cue:* positions are multisets and values must be computed for all of them anyway. *Circuit:* write each component as a switch: a fixed mean plus or minus one, and let the parity of the number of hot components decide. Assign to each run length n a mean $\pi(n)$ and a temperature $h(n) \in \{0,1\}$, and prove that the value of any position is $\sum \pi(n_i)$ shifted by $+1$ or -1 according to whether the number of hot components is odd, with the sign favouring whoever is to move. The whole induction then rests on one inequality about π, which has a two-line proof. This is the ideal route: it solves every position rather than every interval, it needs no pass convention, and it makes the answer 290 a one-line evaluation.

The ideal solution

The answer is $\boxed{290}$.

Formalisation. A position is a finite multiset $P = \{n_1, \ldots, n_r\}$ of nonnegative integers (the lengths of the maximal uncovered runs; entries equal to 0 may be kept or discarded, it makes no difference below). A move replaces some entry $n \geq 2$ by two entries i and j with $i, j \geq 0$ and $i + j = n - 2$. A position with all entries at most 1 is terminal, and its score is the number of entries equal to 1. Each move decreases $\Sigma(P) := \sum_i n_i$ by exactly 2, so the game terminates and we may define, by induction on $\Sigma(P)$, the optimal scores

$$A(P) = \max_{\mu} B(P^{\mu}), \qquad B(P) = \min_{\mu} A(P^{\mu}),$$

over all moves μ, with $A(P) = B(P) = \text{score}(P)$ at terminal positions. Here A is the value with Alice (the maximiser) to move and B with Bob (the minimiser) to move. The answer to the problem is $A(\{2022\})$.

The two statistics. For an integer $n \geq 0$ write $n = 7q + r$ with $0 \leq r \leq 6$ and define

$$\pi(n) = q + \pi_r, \qquad h(n) = h_r,$$

where the residue tables are

r	0	1	2	3	4	5	6
π_r	0	1	0	1	1	1	1
h_r	0	0	0	0	1	0	1

Call n *hot* if $h(n) = 1$, that is if $n \equiv 4$ or $6 \pmod 7$. For a position put

$$\Pi(P) = \sum_i \pi(n_i), \qquad t(P) = \#\{i : n_i \text{ hot}\}, \qquad \epsilon(P) = t(P) \bmod 2 \in \{0,1\}.$$

Theorem 4.5.1. *For every position P,*

$$A(P) = \Pi(P) + \epsilon(P), \qquad B(P) = \Pi(P) - \epsilon(P).$$

Before the proof, note the answer it gives: $2022 = 7 \cdot 288 + 6$, so $\pi(2022) = 288 + 1 = 289$ and 2022 is hot, whence $t = 1$, $\epsilon = 1$ and

$$A(\{2022\}) = 289 + 1 = 290.$$

We need two lemmas about the single function π. Write $c_r := 7\pi_r - r$, so that

$$(c_0, c_1, c_2, c_3, c_4, c_5, c_6) = (0,\ 6,\ -2,\ 4,\ 3,\ 2,\ 1), \qquad \pi(n) = \frac{n + c_r}{7} \quad (r = n \bmod 7),$$

and observe that every c_r lies in the interval $[-2, 6]$.

Lemma 4.5.2 (Almost additivity)**.** *If $i, j \geq 0$ and $i + j = n - 2$, then $\Delta\Pi := \pi(i) + \pi(j) - \pi(n) \in \{-1, 0, 1\}$.*

Proof. Let s, u, r be the residues of i, j, n modulo 7. Then

$$7\,\Delta\Pi = (i + c_s) + (j + c_u) - (n + c_r) = (i + j - n) + c_s + c_u - c_r = c_s + c_u - c_r - 2.$$

Since each c lies in $[-2, 6]$ we get $c_s + c_u \in [-4, 12]$ and $-c_r \in [-6, 2]$, so $7\Delta\Pi \in [-12, 12]$. A multiple of 7 in that range is -7, 0 or 7, so $\Delta\Pi \in \{-1, 0, 1\}$. □

Lemma 4.5.3 (Parity)**.** *For every $n \geq 0$, $\pi(n) + h(n) \equiv n \pmod 2$. Consequently, if $i + j = n - 2$ and δ denotes the parity of $h(i) + h(j) + h(n)$, then $\Delta\Pi \equiv \delta \pmod 2$, and therefore, by the previous lemma,*

$$|\Delta\Pi| \leq \delta \in \{0, 1\}.$$

Proof. From the tables, $\pi_r + h_r$ takes the values $0, 1, 0, 1, 2, 1, 2$ for $r = 0, \ldots, 6$, and these are congruent to r modulo 2 in every case. Hence $\pi(n) + h(n) = q + \pi_r + h_r \equiv q + r \equiv 7q + r = n \pmod 2$. For the consequence, add the three instances:

$$\Delta\Pi = \big(\pi(i) + \pi(j) - \pi(n)\big) \equiv \big(i + h(i)\big) + \big(j + h(j)\big) - \big(n + h(n)\big) \equiv (i + j - n) + \delta \equiv \delta \pmod 2,$$

using $i + j - n = -2$ and $-h(n) \equiv h(n)$. Finally, if $\delta = 0$ then $\Delta\Pi$ is an even element of $\{-1, 0, 1\}$, hence 0; if $\delta = 1$ then $|\Delta\Pi| \leq 1 = \delta$ by the previous lemma. □

Lemma 4.5.4 (Attainment)**.** *Let $n \geq 2$. Then:*

(a) the split $(1, n - 3)$ if $n \geq 3$, and the split $(0, 0)$ if $n = 2$, has $\Delta\Pi \geq 0$;

(b) the split $(0, n - 2)$ has $\Delta\Pi \leq 0$;

(c) if n is hot then the split $(1, n - 3)$ has $\Delta\Pi = 1$;

(d) if n is hot then the split $(2, n - 4)$ has $\Delta\Pi = -1$.

Proof. All four are evaluations of $7\Delta\Pi = c_s + c_u - c_r - 2$ from the proof of the first lemma, where $r = n \bmod 7$.

For (b), $s = 0$ and $u \equiv r - 2$, so $7\Delta\Pi = c_0 + c_{r-2} - c_r - 2$, which for $r = 0, 1, \ldots, 6$ equals $0, -7, 0, 0, -7, 0, 0$ respectively; hence $\Delta\Pi \in \{0, -1\}$.

For (a) and (c) with $n \geq 3$, $s = 1$ and $u \equiv r - 3$, so $7\Delta\Pi = c_1 + c_{r-3} - c_r - 2$, which for $r = 0, 1, \ldots, 6$ equals $7, 0, 7, 0, 7, 0, 7$; hence $\Delta\Pi = 1$ when r is even and 0 when r is odd, and in particular $\Delta\Pi \geq 0$ always and $\Delta\Pi = 1$ when $r \in \{4, 6\}$. For $n = 2$ the only split is $(0, 0)$, giving $7\Delta\Pi = c_0 + c_0 - c_2 - 2 = 0$.

For (d), a hot n has $r \in \{4, 6\}$ and hence $n \geq 4$, so the split $(2, n - 4)$ exists; here $s = 2$ and $u \equiv r - 4$, so $7\Delta\Pi = c_2 + c_{r-4} - c_r - 2$, which equals $-2 + c_0 - c_4 - 2 = -7$ for $r = 4$ and $-2 + c_2 - c_6 - 2 = -7$ for $r = 6$; hence $\Delta\Pi = -1$. □

Proof of the Theorem. Induct on $\Sigma(P)$. If P is terminal then every entry is 0 or 1, and $\pi(0) = h(0) = 0$, $\pi(1) = 1$, $h(1) = 0$; so $\Pi(P)$ is the number of entries equal to 1, which is the score, while $t(P) = 0$ and $\epsilon(P) = 0$. Hence $A(P) = B(P) = \Pi(P)$, as claimed.

Now let P be non-terminal, so some entry $n \geq 2$ exists. A move μ replaces such an n by i, j with $i + j = n - 2$; write $\Delta\Pi$ and δ as above for that move. Then $\Pi(P^\mu) = \Pi(P) + \Delta\Pi$ and $t(P^\mu) = t(P) + h(i) + h(j) - h(n)$, so $\epsilon(P^\mu) = (\epsilon(P) + \delta) \bmod 2$. Write $\Pi = \Pi(P)$ and $\epsilon = \epsilon(P)$. By the inductive hypothesis,

$$B(P^\mu) = \Pi + \Delta\Pi - \epsilon(P^\mu), \qquad A(P^\mu) = \Pi + \Delta\Pi + \epsilon(P^\mu).$$

Alice to move, $\epsilon = 0$. Here $\epsilon(P^\mu) = \delta$, so $B(P^\mu) = \Pi + \Delta\Pi - \delta \leq \Pi$ by the Parity Lemma, with equality exactly when $\Delta\Pi = \delta$, that is (again by the Parity Lemma) exactly when $\Delta\Pi \geq 0$. Part (a) of the Attainment Lemma supplies such a move. Hence $A(P) = \Pi = \Pi + \epsilon$.

Alice to move, $\epsilon = 1$. Here $\epsilon(P^\mu) = 1 - \delta$, so $B(P^\mu) = \Pi + \Delta\Pi + \delta - 1 \leq \Pi + 2\delta - 1 \leq \Pi + 1$, using $\Delta\Pi \leq \delta \leq 1$. Equality forces $\delta = 1$ and $\Delta\Pi = 1$. Since $t(P)$ is odd, P contains a hot entry n, and part (c) gives a split of it with $\Delta\Pi = 1$; then $\delta \equiv \Delta\Pi \equiv 1$ automatically. Hence $A(P) = \Pi + 1 = \Pi + \epsilon$.

Bob to move, $\epsilon = 0$. Here $A(P^\mu) = \Pi + \Delta\Pi + \delta \geq \Pi$, with equality exactly when $\Delta\Pi \leq 0$; part (b) supplies such a move, so $B(P) = \Pi = \Pi - \epsilon$.

Bob to move, $\epsilon = 1$. Here $A(P^\mu) = \Pi + \Delta\Pi + 1 - \delta \geq \Pi + 1 - 2\delta \geq \Pi - 1$, with equality forcing $\delta = 1$ and $\Delta\Pi = -1$; since $t(P)$ is odd there is a hot entry, and part (d) supplies such a split. Hence $B(P) = \Pi - 1 = \Pi - \epsilon$.

This completes the induction. □

Reading the answer off. For the original board, $P = \{2022\}$, and $A(\{2022\}) = \pi(2022) + 1 = 289 + 1 = 290$. Alice's strategy is explicit: she always splits a hot run n as $(1, n - 3)$, and after any Bob move she does the same in whichever run is then hot; Bob's optimal replies are $(0, n - 2)$ from any run when the number of hot runs is even, and $(2, n - 4)$ from a hot run otherwise.

Consistency checks. For a single interval the theorem gives $A(\{n\}) = \pi(n) + h(n)$ and $B(\{n\}) = \pi(n) - h(n)$, that is, in terms of $r = n \bmod 7$,

$$A(\{n\}) = \left\lfloor \tfrac{n}{7} \right\rfloor + (0, 1, 0, 1, 2, 1, 2)_r, \qquad B(\{n\}) = \left\lfloor \tfrac{n}{7} \right\rfloor + (0, 1, 0, 1, 0, 1, 0)_r,$$

which one can verify directly for $n \leq 6$: for example $A(\{4\}) = 2$ because Alice splits 4 as $(1, 1)$, while $B(\{4\}) = 0$ because Bob splits 4 as $(0, 2)$ and the remaining 2 is forced. Also $A(\{n\}) \equiv B(\{n\}) \equiv n \pmod 2$, as the Parity Lemma requires and as the covering argument demands, since every tile removes two squares.

Layer 1: WHAT

Block 1. Abstract the board into a multiset of run lengths; a move is $n \mapsto (i, n - 2 - i)$; terminal score is the number of 1s.

Block 2. Note the game is a scoring game on a disjunctive sum, so component values do not simply add and Grundy theory does not apply.

Block 3. Compute small single-interval values and observe the period 7 pattern, then guess the correct general statistics: a mean π and a hot indicator h.

Block 4. State the closed form $A = \Pi + \epsilon$, $B = \Pi - \epsilon$ for every position, where ϵ is the parity of the number of hot components.

Block 5. Prove almost additivity of π, by writing $\pi(n) = (n + c_{n \bmod 7})/7$ with all $c_r \in [-2, 6]$: the difference is a multiple of 7 trapped in $[-12, 12]$.

Block 6. Prove the parity lemma $\pi + h \equiv n$, which upgrades $|\Delta\Pi| \leq 1$ to $|\Delta\Pi| \leq \delta$.

Block 7. Exhibit the four attainment splits $(1, n - 3)$, $(0, n - 2)$, $(2, n - 4)$ and run the induction, then evaluate at $n = 2022$.

Juxtapose with the nominal route. The zombie fixes on the single interval, defines $a(n)$ and $b(n)$ only for intervals, and then discovers that after the first move he has two intervals and no theory for them. He patches this with a following strategy, discovers it breaks when one interval is exhausted, patches that with a pass convention, and then owes a proof that passing is worthless. Every patch is forced by the original decision to define values only for intervals.

The bifurcation point is the moment you decide what object to compute a value for. If you compute values for intervals, you are permanently fighting the disjunctive sum. If you compute values for all positions, the sum structure works for you, because the value of a position turns out to be a sum of per-component numbers plus a one-bit correction.

Layer 2: HOW

Block 1. **Cue.** "A tile must not cover a square already covered" and the board is a row. **Why natural.** Covered squares partition the uncovered ones into runs, and a tile lives inside exactly one run. Nothing about a run matters except its length, and nothing about the arrangement of runs matters at all. Reducing to a multiset is the definition-level move: two positions with the same multiset have identical game trees. **Link to the next block.** A move on a multiset is a split, so the game is a splitting game.

Block 2. **Cue.** The goal is a number, not the last move. **Why natural.** Combinatorial game theory splits sharply into normal play (last move wins, Sprague-Grundy applies) and scoring play (Grundy values are meaningless). Naming which one you are in prevents twenty minutes spent computing nim-values for Dawson's Kayles, which is a real and famous table that answers a different question. **Link to the next block.** In scoring play the right tools are per-component mean values and temperatures.

Block 3. **Cue.** You cannot guess the answer for 2022 without data. **Why natural.** Small case computation here is not fishing, it is the only way to discover the modulus 7. Compute $A(\{n\})$ and $B(\{n\})$ for $n \leq 15$ by hand or by systematic recursion, notice $A(\{n\}) = A(\{n-7\}) + 1$ and the residue patterns $(0,1,0,1,2,1,2)$ and $(0,1,0,1,0,1,0)$, and then read them as mean plus or minus temperature: $\pi = (A+B)/2$, $h = (A-B)/2$. That last step is the important one, because π and h are the objects that behave well under disjunctive sums, whereas A and B are not. **Link to the next block.** A mean and a $0/1$ temperature per component is exactly the data of a switch, and sums of switches are governed by parity.

Block 4. **Cue.** Each component is worth $\pi \pm 1$ depending on who takes it. **Why natural.** A component with $h = 1$ behaves like a two-sided option: whoever moves in it first swings the value by one in his own favour. In a sum of such switches the players alternately claim them, so the maximiser claims $\lceil t/2 \rceil$ of the t hot components and the minimiser claims the rest, and the net effect is exactly ± 1 according to the parity of t. Guessing the closed form $A = \Pi + \epsilon$ is therefore not a leap; it is the standard behaviour of a sum of switches of equal temperature. **Link to the next block.** A guessed closed form must now be proved by induction, and the induction needs to know how π and h change under a split.

Block 5. **Cue.** π is a floor function plus a bounded residue correction. **Why natural.** Any function of the form $\lfloor n/m \rfloor + (\text{table in } n \bmod m)$ can be written as $(n + c_{n \bmod m})/m$ with c bounded, and then differences of π along a relation like $i + j = n - 2$ are multiples of $1/m$ with an explicit bound. The trap of doing casework over the 49 residue pairs is avoided entirely: a multiple of 7 in $[-12, 12]$ has only three possible values. This is the laziness principle at its purest, and it is the technical heart of the solution. **Link to the next block.** Almost additivity gives $|\Delta\Pi| \leq 1$, which is not yet enough; you need to know when $\Delta\Pi$ can be nonzero.

Block 6. **Cue.** The score is always congruent to n modulo 2. **Why natural.** Every tile removes two squares, so the parity of the number of uncovered squares is invariant. In the language of the statistics this says $\pi + h \equiv n$, and combining it with $|\Delta\Pi| \leq 1$ gives $|\Delta\Pi| \leq \delta$: a split that does not change the parity of the hot count cannot change Π at all. That is the sharp statement the induction consumes. **Link to the next block.** Bounds in hand, produce the moves that attain them.

Block 7. **Cue.** Bounds without witnesses prove only one inequality. **Why natural.** Every optimal value statement needs both a bound over all moves and a move attaining it, and the attaining moves should be simple and uniform: split off one square, split off nothing, split off a pair. Checking these three splits is seven evaluations each of $c_s + c_u - c_r - 2$, which is arithmetic, not casework on the game. **Link to the next block.** The induction closes, and $2022 \equiv 6 \pmod 7$ gives 290.

Layer 3: WHY

The deep reason the answer has the form it does is that this game is, in the language of combinatorial game theory, a sum of *switches* all of temperature 1. A component of length n is worth $\pi(n)$ to both players if it is cold ($h = 0$), and worth $\pi(n) + 1$ to whoever moves in it first if it is hot ($h = 1$). In a sum of switches of equal temperature the correct play is greedy: take a hot component, because the value of doing so is exactly the temperature and nothing later can be worth more. The players alternate taking hot components, so the maximiser gains one net unit precisely when the number of hot components is odd. Everything about the 7 is contained in the two residue tables; everything about the game dynamics is contained in the word "switch".

Why 7? Honestly: because the small-case computation says so. There is no shortcut that produces 7 from the rules without computing; what the theory provides is the certainty that some such periodic pattern must exist (the value function of an interval grows linearly with a bounded correction, so it is eventually periodic in n modulo something) and the method to verify a guessed pattern in a few lines once you have it. Do not pretend the 7 was deduced. Name it as a computed input, verify it rigorously, and move on. That is what a knowledge gap looks like when handled honestly.

The discernment mechanism: in any scoring game on a disjunctive sum, do not compute values of positions; compute two numbers per component, the mean and the temperature, and then ask how the temperatures combine. If all temperatures are equal, parity decides. If they differ, the greedy rule "move in the hottest component" is the standard heuristic and is provably correct for sums of switches. Train it by taking any splitting or removal game with a numerical payoff, computing A and B for small components, forming $\pi = (A + B)/2$ and $h = (A - B)/2$, and looking for a pattern in π and h separately. Patterns in A and B separately are usually invisible; patterns in π and h usually are not.

What the examiners nudged with: they chose 2022, and $2022 = 7 \cdot 288 + 6$, so the residue is 6, one of the two hot residues, which guarantees that the answer is not simply $\lfloor n/7 \rfloor$ and that a solver who found the period but not the residue table will be off by two. They also phrased the goals asymmetrically ("Alice's goal is to maximize, Bob's to minimize") to make clear that this is a scoring game and to warn you off last-move theory.

Revolving concepts

Scoring games versus normal play. In normal play the last player to move wins, and every position has a Sprague-Grundy value; the value of a disjunctive sum is the exclusive-or of the values. In scoring play the payoff is a number and Grundy theory does not apply; the relevant invariants are the pair of optimal values (A, B) with each player to move, from which one forms the mean $(A + B)/2$ and the temperature $(A - B)/2$. See Book 1, field: Games and invariants, topic: scoring games, means and temperatures.

Switches and sums of switches. A switch is a position worth $m + \tau$ to the player who moves there first and $m - \tau$ to the other, with mean m and temperature τ. In a sum of switches with equal temperature τ, the value with the maximiser to move is $\sum m_i + \tau \cdot (t \bmod 2)$ where t is the number of switches with $\tau > 0$. That is precisely the theorem proved above, with $\tau = 1$. See Book 1, field: Games and invariants, topic: switches and the greedy hot-move principle.

Splitting games and their move rule. A move $n \mapsto (i, n-2-i)$ with $i + j = n - 2$ is the octal game move rule of Dawson's Kayles; in normal play its Grundy sequence is eventually periodic with period 34. Knowing this and knowing it is irrelevant here is worth more than not knowing it. See Book 1, field: Games and invariants, topic: octal games and Grundy periodicity.

Parity invariants. Every tile covers two squares, so the number of uncovered squares is invariant modulo 2 throughout; equivalently the number of odd runs never decreases and changes only by $+2$. The general principle: find a quantity that every legal move changes in a restricted way, and it will bound the outcome. Here it gives the free bound "the final score is at least the current number of odd runs". See Book 1, field: Games and invariants, topic: monovariants and parity.

Writing $\lfloor n/m \rfloor + f(n \bmod m)$ as $(n + c_{n \bmod m})/m$, and the recursion it encodes. Any function of this shape satisfies the recursion $\pi(n) = \pi(n-m) + 1$, whose general solution is exactly $\lfloor n/m \rfloor$ plus an arbitrary function of the residue; the constants $c_r = mf(r) - r$ are bounded, and differences along any linear relation among the arguments are then multiples of $1/m$ with an explicit range. The general lesson: a quantity satisfying $\pi(n) = \pi(n-m) + 1$ should be linearised in exactly this way before you compare it at several arguments, because it converts m^2 residue cases into one interval bound. See Book 1, field: Number theory, topic: floor functions and periodic corrections.

Circuit Bank

- **WHEN** you see a combinatorial game whose payoff is a number rather than who moves last **DO** compute the pair of values (A, B) for small components and immediately form the mean $(A + B)/2$ and the temperature $(A - B)/2$ **BECAUSE** means add over disjunctive sums and temperatures decide by parity, whereas A and B individually obey no addition rule at all, which is why raw value tables look patternless
- **WHEN** a game position decomposes into non-interacting components **DO** define the value function on multisets of components, never only on the starting shape **BECAUSE** a theory defined only on single components forces following strategies, pass conventions and extra lemmas, all of which are patches for a bad choice of state space
- **WHEN** you must compare $\lfloor n/m \rfloor + f(n \bmod m)$ at several related arguments **DO** write it as $(n + c_{n \bmod m})/m$ with $c_r = mf(r) - r$ and bound the c_r **BECAUSE** the comparison becomes a multiple of m trapped in a small interval, which replaces m^2 residue cases by one line
- **WHEN** you have proved a bound on every move **DO** produce explicit attaining moves, uniform in the parameter, before declaring the value **BECAUSE** an optimal-value claim is two inequalities; bounds without witnesses prove only that the value is at most (or at least) the claimed one, which is half the marks
- **WHEN** every move changes some count by a fixed amount **DO** name the invariant and read off the free bound it gives **BECAUSE** here each tile removes two squares, so the score parity is fixed and the number of odd runs is a monovariant, which immediately gives the lower bound that Bob can never beat

Backtesting

1. First useful cue: the board decomposes into independent runs, so the state is a multiset and the game is a disjunctive sum with a numerical payoff.

2. Method the expression suggested: compute (A, B) for small single runs, convert to mean and temperature, guess the closed form for all positions, prove it by induction on the total length.
3. Where you would hesitate, and the thought to reinforce: at the temptation to define values only for a single interval. Reinforce that in a splitting game the very first move creates two components, so any theory not defined on multisets will need repairs; choose the larger state space at the start.
4. The trap the question sets: assuming the value of a sum is the sum of the values. It is not: with three runs of length 4, the value with Bob to move is 2, not the sum of the individual Bob values. Only the means add; the temperatures interact through parity.
5. What makes you recognise it faster next time: a scoring game with independent components is a sum of switches; look for the temperature first and the mean second.
6. The reusable decision rule: for scoring games, tabulate (A, B) for small components, take half the sum and half the difference, and look for a pattern in those two sequences rather than in A and B.

Mirror drills

1. Compute $A(\{4\})$ and $B(\{4\})$ directly and check them against the formula. *Answer:* Alice splits 4 as $(1, 1)$ and scores 2; Bob splits 4 as $(0, 2)$, the forced reply exhausts the 2, and the score is 0. The formula gives $\pi(4) = 1$, $h(4) = 1$, so $A = 2$ and $B = 0$.
2. In the same game, what is the value with Bob to move on a position of three runs of length 4? *Answer:* $\Pi = 3$, $t = 3$ so $\epsilon = 1$, giving $B = 3 - 1 = 2$. Note this is not $b(4) + b(4) + b(4) = 0$, which is the whole point of the drill.
3. For which n does Alice moving first on a single run of length n do strictly better than Bob moving first? *Answer:* Exactly when n is hot, that is $n \equiv 4$ or $6 \pmod 7$; then $A - B = 2$, and otherwise $A = B$. Equivalently, exactly when the run is a genuine switch rather than a number.

4.6 A6. Odd power sums and interval lengths

Let n be a positive integer. Determine, in terms of n, the largest integer m with the following property: There exist real numbers $x_1, \ldots, x_{2n}$ with $-1 < x_1 < x_2 < \cdots < x_{2n} < 1$ such that the sum of the lengths of the n intervals

$$[x_1^{2k-1}, x_2^{2k-1}], [x_3^{2k-1}, x_4^{2k-1}], \ldots, [x_{2n-1}^{2k-1}, x_{2n}^{2k-1}]$$

is equal to 1 for all integers k with $1 \leq k \leq m$.

Read it out loud

Strip the geometry off first. The map $t \mapsto t^{2k-1}$ is strictly increasing on $\mathbb{R}$ for every $k \geq 1$, so each interval $[x_{2i-1}^{2k-1}, x_{2i}^{2k-1}]$ is genuinely an interval and its length is $x_{2i}^{2k-1} - x_{2i-1}^{2k-1}$. The condition is therefore

$$\sum_{i=1}^{n} \left(x_{2i}^{2k-1} - x_{2i-1}^{2k-1} \right) = 1 \qquad (1 \leq k \leq m),$$

that is, a system of m equations on the alternating odd power sums of the $2n$ numbers. So the intervals are decoration: this is a symmetric function problem in disguise, and it is asking how many odd power sums you can prescribe.

Now the move that turns it into a clean statement. The exponents are odd, so a minus sign in front of x^{2k-1} can be absorbed into the variable: $-x^{2k-1} = (-x)^{2k-1}$. That converts the alternating sum into an honest power sum of a modified list. And the right hand side is the constant 1, which is itself 1^{2k-1}, so it too can be absorbed as one more element of the list, with a sign. Define the multiset of $2n+1$ real numbers

$$R = \{ x_1,\ x_3,\ \ldots,\ x_{2n-1} \} \cup \{ -x_2,\ -x_4,\ \ldots,\ -x_{2n} \} \cup \{ 1 \}.$$

Then for every k the $(2k-1)$st power sum of R is

$$s_{2k-1}(R) = \sum_{i=1}^{n} x_{2i-1}^{2k-1} - \sum_{i=1}^{n} x_{2i}^{2k-1} + 1 = -1 + 1 = 0$$

precisely when the kth condition holds. So the problem says: how many consecutive odd power sums of a $(2n+1)$-element multiset of reals can vanish, when $2n$ of the elements lie in $(-1, 1)$ and one of them is 1?

That reformulation carries its own answer in embryo, because odd power sums measure the failure of a multiset to be symmetric under $x \mapsto -x$: if $R = -R$ then every odd power sum vanishes, and conversely you expect that enough vanishing odd power sums forces $R = -R$. But R contains 1 and every other element has modulus strictly less than 1, so R cannot be symmetric. The whole upper bound is the quantitative form of "enough".

The fields wired in are symmetric function theory (power sums, elementary symmetric functions, the Newton identities), polynomial parity, and, for the construction, roots of unity and the cosine parametrisation of Chebyshev nodes. Within thirty seconds you should have written the alternating sum, absorbed the signs into the variables, adjoined the element 1, and written "all odd power sums up to s_{2m-1} vanish".

Approaches, ranked worst to best

1. **Solve the system for small n numerically and guess.** *Cue:* "determine in terms of n". *Circuit:* small cases first. For $n = 1$ the system is $x_2 - x_1 = 1$ and $x_2^3 - x_1^3 = 1$; substituting $x_2 = x_1 + 1$ into the second gives $3x_1(x_1 + 1) = 0$, so $x_1 \in \{0, -1\}$ and hence $x_2 \in \{1, 0\}$, both excluded by the strict inequalities. So $m = 1$ when $n = 1$. This is worth doing, because it reveals that the obstruction is exactly that the extremal configuration wants to touch the endpoint 1. As a proof strategy it is hopeless for general n. Ranked last as a method, first as reconnaissance.

2. **Count equations against unknowns.** *Cue:* m equations in $2n$ unknowns. *Circuit:* dimension count. With $2n$ free variables one expects to satisfy $2n$ conditions, suggesting $m = 2n$. The answer is n, so the count is not merely imprecise, it is off by a factor of two. The reason is that a naive count ignores the constraint $|x_j| < 1$: the system does have solutions with $2n$ conditions, but they force some $|x_j| \geq 1$, exactly as in the case $n = 1$. A dimension count can never see a boundary. Ranked here as a warning: it is the argument that makes people confidently write the wrong answer.

3. **Generating function of odd power sums plus residues.** *Cue:* power sums suggest a generating function. *Circuit:* recover a multiset from the poles of a rational function. Set $f(z) = \sum_{x \in R} \frac{xz}{1-x^2z^2} = \sum_{k \geq 1} s_{2k-1}(R) z^{2k-1}$. Vanishing of enough coefficients forces $f \equiv 0$ if the pole count is controlled, and the residue of f at $z = 1/x$ recovers both x and its multiplicity. This works, and it is the route that generalises to a comparison of two arbitrary multisets, but it needs a preliminary reduction (cancel pairs $\{x, -x\}$, which contribute nothing to odd power sums, until none remain) and careful bookkeeping of pole orders against the order of vanishing at $z = 0$. Ranked third only because that bookkeeping is where a script under time pressure springs a leak.

4. **Newton identities on the monic polynomial with root multiset R.** *Cue:* power sums with a bound on how many are prescribed, and a fixed number of elements. *Circuit:* convert power sums to elementary symmetric functions, then read off polynomial parity. Vanishing of $s_1, s_3, \ldots, s_{2m-1}$ propagates through the Newton identities to $e_1 = e_3 = \cdots = e_{2m-1} = 0$, and for $m \geq n+1$ that kills every odd elementary symmetric function of the $2n+1$ roots, which says exactly that the polynomial is odd. An odd polynomial with root 1 has root -1, and $-1 \notin R$. This is the ideal route: it is fully elementary, it needs no reduction step, and the final contradiction is a single evaluation.

The ideal solution

The answer is $\boxed{m = n}$.

Reformulation. Since $t \mapsto t^{2k-1}$ is strictly increasing, the sum of the lengths of the n intervals equals $\sum_{i=1}^{n} \left(x_{2i}^{2k-1} - x_{2i-1}^{2k-1} \right)$, so the requirement is

$$\sum_{i=1}^{n} x_{2i}^{2k-1} - \sum_{i=1}^{n} x_{2i-1}^{2k-1} = 1 \qquad (1 \leq k \leq m). \tag{$*$}$$

Part 1: $m \leq n$.

Suppose real numbers $x_1, \ldots, x_{2n}$ with $|x_j| < 1$ satisfy $(*)$ for $k = 1, \ldots, m$ (the ordering is not needed for this half). Define the monic polynomial of degree $N := 2n+1$

$$p(x) = (x-1) \prod_{i=1}^{n} (x - x_{2i-1})\,(x + x_{2i}),$$

whose roots, listed with multiplicity, form the multiset

$$R = \{1\} \cup \{x_1, x_3, \ldots, x_{2n-1}\} \cup \{-x_2, -x_4, \ldots, -x_{2n}\}.$$

Let s_j denote the jth power sum of R and e_j its jth elementary symmetric function, so that

$$p(x) = \sum_{j=0}^{N} (-1)^j e_j\, x^{N-j}, \qquad e_0 = 1.$$

Because $2k-1$ is odd we have $(-x_{2i})^{2k-1} = -x_{2i}^{2k-1}$, so for $1 \le k \le m$,

$$s_{2k-1} = 1 + \sum_{i=1}^{n} x_{2i-1}^{2k-1} - \sum_{i=1}^{n} x_{2i}^{2k-1} = 1 - 1 = 0,$$

using $(*)$.

Lemma 4.6.1. *If $s_j = 0$ for every odd j with $1 \le j \le J$, then $e_j = 0$ for every odd j with $1 \le j \le \min(J, N)$.*

Proof. The Newton identities for a monic polynomial with N roots state that for $1 \le j \le N$,

$$j\, e_j = \sum_{i=1}^{j} (-1)^{i-1} e_{j-i}\, s_i.$$

Argue by strong induction on odd $j \le \min(J, N)$. In the sum on the right, split by the parity of i. If i is odd then $i \le j \le J$, so $s_i = 0$ and the term vanishes. If i is even then $j - i$ is odd and $1 \le j - i < j$, so $e_{j-i} = 0$ by the inductive hypothesis and the term vanishes. Hence $j\, e_j = 0$, and since $j \ge 1$ we get $e_j = 0$. □

Now suppose, for contradiction, that $m \ge n+1$. Then $s_j = 0$ for all odd $j \le 2m-1$, and $2m - 1 \ge 2n + 1 = N$, so the lemma gives $e_j = 0$ for *every* odd j with $1 \le j \le N$. In the expansion $p(x) = \sum_{j=0}^{N} (-1)^j e_j x^{N-j}$, the term of index j has degree $N - j = 2n + 1 - j$, which is even exactly when j is odd. Therefore every even-degree coefficient of p vanishes, that is, p is an odd polynomial:

$$p(-x) = -p(x) \qquad \text{for all } x.$$

But $p(1) = 0$ by construction, so $p(-1) = -p(1) = 0$ and -1 is a root of p. The roots of p are 1 and the $2n$ numbers $x_1, x_3, \ldots, x_{2n-1}, -x_2, -x_4, \ldots, -x_{2n}$, all of which have modulus strictly less than 1. So -1 is not a root, a contradiction. Hence $m \le n$.

Part 2: $m = n$ is attained.

Take

$$x_j = \cos \frac{(2n+1-j)\pi}{2n+1} \qquad (j = 1, \ldots, 2n).$$

As j runs from 1 to $2n$ the angle $\frac{(2n+1-j)\pi}{2n+1}$ decreases strictly from $\frac{2n\pi}{2n+1}$ to $\frac{\pi}{2n+1}$, staying in the open interval $(0, \pi)$ on which the cosine is strictly decreasing and takes values in $(-1, 1)$. Hence $-1 < x_1 < x_2 < \cdots < x_{2n} < 1$, as required.

Fix k with $1 \le k \le n$. Since $2k-1$ is odd, $(-1)^{j(2k-1)} = (-1)^j$, so the sum of the lengths is

$$L_k := \sum_{i=1}^{n} \left(x_{2i}^{2k-1} - x_{2i-1}^{2k-1} \right) = \sum_{j=1}^{2n} (-1)^j x_j^{2k-1} = \sum_{j=1}^{2n} \left((-1)^j x_j \right)^{2k-1}.$$

Substitute $\ell = 2n + 1 - j$, so that ℓ runs over $1, \ldots, 2n$ and $(-1)^j = (-1)^{2n+1-\ell} = -(-1)^\ell$. Using $\cos(\ell\pi + \theta) = (-1)^\ell \cos\theta$,

$$(-1)^j x_j = -(-1)^\ell \cos \frac{\ell\pi}{2n+1} = -\cos\left(\ell\pi + \frac{\ell\pi}{2n+1} \right) = -\cos \frac{2\pi(n+1)\ell}{2n+1}.$$

Let $\zeta = e^{2\pi i (n+1)/(2n+1)}$. Since $2(n+1) - (2n+1) = 1$, we have $\gcd(n+1, 2n+1) = 1$, so ζ is a primitive $(2n+1)$st root of unity, and $\cos \frac{2\pi(n+1)\ell}{2n+1} = \frac{\zeta^\ell + \zeta^{-\ell}}{2}$. Therefore, using that $2k-1$ is odd to pull out the minus sign,

$$L_k = -\sum_{\ell=1}^{2n} \left(\frac{\zeta^\ell + \zeta^{-\ell}}{2} \right)^{2k-1} = -\frac{1}{2^{2k-1}} \sum_{t=0}^{2k-1} \binom{2k-1}{t} \sum_{\ell=1}^{2n} \zeta^{\ell(2k-1-2t)},$$

after expanding by the binomial theorem and exchanging the two finite sums.

For each t, put $u = 2k-1-2t$. Then u is odd, so $u \neq 0$, and $|u| \leq 2k-1 \leq 2n-1 < 2n+1$; hence $u \not\equiv 0 \pmod{2n+1}$ and ζ^u is a root of unity different from 1. Consequently

$$\sum_{\ell=1}^{2n} \zeta^{\ell u} = \left(\sum_{\ell=0}^{2n} \zeta^{\ell u}\right) - 1 = 0 - 1 = -1.$$

Substituting,

$$L_k = -\frac{1}{2^{2k-1}} \sum_{t=0}^{2k-1} \binom{2k-1}{t} \cdot (-1) = \frac{1}{2^{2k-1}} \cdot 2^{2k-1} = 1.$$

So the configuration satisfies $(*)$ for every k with $1 \leq k \leq n$, and $m = n$ is attained. Combining the two parts, the largest such m is n. ■

Where the construction stops, and why. The only step that used $k \leq n$ was the bound $|u| \leq 2k-1 < 2n+1$. At $k = n+1$ the extreme terms $t = 0$ and $t = 2k-1$ give $u = \pm(2n+1) \equiv 0$, so those two inner sums equal $2n$ instead of -1, and $L_{n+1} = 1 - \frac{(2n+1)\cdot 2}{2^{2n+1}} \neq 1$. For example at $n = 1$ the configuration is $x_1 = -\frac{1}{2}$, $x_2 = \frac{1}{2}$, with $L_1 = 1$ and $L_2 = \frac{1}{4}$; at $n = 2$ one gets $L_1 = L_2 = 1$ and $L_3 = \frac{11}{16}$. The construction is tight, not merely sufficient.

Remark: what the upper bound really says. A multiset R satisfies $R = -R$ if and only if all of its odd power sums vanish. Part 1 is the statement that for a multiset of size $2n+1$, vanishing of the first $n+1$ odd power sums already forces this symmetry, which then contradicts $1 \in R$ and $|x| < 1$ for all other elements. The number $n+1$ is exactly what is needed because the polynomial has $n+1$ odd-index elementary symmetric functions among $e_1, \ldots, e_{2n+1}$.

Layer 1: WHAT

Block 1. Strip the geometry: interval lengths are differences of odd powers, so the condition is an alternating odd power sum equal to 1.

Block 2. Absorb the alternating signs into the variables, legitimate because the exponents are odd, and absorb the constant 1 as an extra element 1 of the list.

Block 3. Restate: the odd power sums $s_1, s_3, \ldots, s_{2m-1}$ of a $(2n+1)$-element multiset R all vanish.

Block 4. Convert power sums to elementary symmetric functions with the Newton identities: all odd-index e_j vanish up to index $2m-1$.

Block 5. If $m \geq n+1$ this covers every odd index up to the degree, so p has only odd-degree terms: p is an odd polynomial.

Block 6. An odd polynomial with root 1 has root -1; but every element of R other than 1 has modulus below 1. Contradiction, so $m \leq n$.

Block 7. For the construction, take the $2n$ interior Chebyshev-type nodes $\cos\frac{(2n+1-j)\pi}{2n+1}$, convert the alternating sum to a sum over $(2n+1)$st roots of unity, and use $\sum_{\ell=1}^{2n} \zeta^{\ell u} = -1$ for $u \not\equiv 0$.

Juxtapose with the nominal route. The zombie counts m equations against $2n$ unknowns, concludes $m = 2n$, and either stops or wastes the session trying to build a configuration. If he does get as far as suspecting $m = n$, he tries to prove it by manipulating the m equations directly, subtracting them from one another and hoping for a factorisation, which never comes because the equations are not polynomial identities in any small number of quantities: they are m separate statements about $2n$ variables that only become tractable in the language of symmetric functions.

The bifurcation point is the sentence where you decide what a "sum of odd powers with signs" is. The zombie sees m constraints. You see a power sum of one multiset, because odd exponents absorb signs, and once it is a power sum the entire theory of symmetric functions is available.

Layer 2: HOW

Block 1. Cue. Intervals with endpoints x^{2k-1}, and the exponent $2k-1$ is odd. **Why natural.** $t \mapsto t^{2k-1}$ is strictly increasing on all of $\mathbb{R}$, which is the only reason $[x_{2i-1}^{2k-1}, x_{2i}^{2k-1}]$ is a legitimate

interval; the odd exponent was chosen by the setters for exactly that purpose and for the sign absorption to come. So write the length as a difference immediately and forget the geometry. **Link to the next block.** A signed sum of odd powers is asking to be turned into an unsigned one.

Block 2. **Cue.** $-x^{2k-1} = (-x)^{2k-1}$, valid for every odd exponent simultaneously. **Why natural.** This is the definition-level fact that makes the whole problem uniform in k. Any device that works for one k but not all is useless here; sign absorption works for all odd exponents at once, so it does not disturb the family of conditions. Likewise $1 = 1^{2k-1}$ for all k, so the constant can be moved into the list as an element rather than sitting on the right hand side. **Link to the next block.** You now have a single multiset whose odd power sums all vanish.

Block 3. **Cue.** "All odd power sums vanish" is a symmetry statement. **Why natural.** If a multiset is invariant under negation then odd power sums cancel in pairs. The converse is the substance. Recognising the target as "prove the multiset is negation-symmetric" tells you exactly what contradiction to look for at the end, namely an element that has no negative partner. The element 1 is that partner-less element, and it is partner-less precisely because the problem confined all the x_j to $(-1, 1)$. **Link to the next block.** To get from power sums to a structural statement about the multiset, pass to the polynomial with those roots.

Block 4. **Cue.** Finitely many power sums of finitely many numbers. **Why natural.** Power sums and elementary symmetric functions are two coordinate systems on the same object, and the Newton identities are the change of coordinates. The identities are triangular, so vanishing propagates: the parity split in the sum is not a computation, it is the observation that odd plus even is odd. Notice the shape of the induction: it needs only the terms with i odd (killed by hypothesis) and those with i even (killed by the inductive hypothesis on a smaller odd index). **Link to the next block.** Vanishing odd elementary symmetric functions is a statement about which coefficients of p are zero.

Block 5. **Cue.** $p(x) = \sum_j (-1)^j e_j x^{N-j}$ with $N = 2n + 1$ odd. **Why natural.** The index j and the degree $N - j$ have opposite parities when N is odd, so "all odd-index e_j vanish" is literally "all even-degree coefficients vanish", which is literally "p is an odd function". Choosing N odd is therefore not an accident of the construction: including the extra element 1 made the degree $2n + 1$, and that is what turns a symmetric function statement into a parity statement. **Link to the next block.** An odd polynomial has a negation-symmetric root multiset.

Block 6. **Cue.** p odd and $p(1) = 0$. **Why natural.** $p(-1) = -p(1) = 0$ needs no theory. This is why the extra element was chosen to be 1 and not some other constant: the right hand side of the problem is 1, and 1 sits exactly on the boundary of the forbidden region for the x_j. The strict inequality $x_{2n} < 1$ in the statement is therefore load-bearing, not cosmetic, and the $n = 1$ computation shows what happens when it is relaxed: the solution degenerates to $\{0, 1\}$. **Link to the next block.** The bound is n; now construct.

Block 7. **Cue.** You need $2n$ numbers in $(-1, 1)$ with n prescribed alternating odd power sums. **Why natural.** Prescribing many power sums at once is what roots of unity do best, because $\sum_{\ell=1}^{N-1} \zeta^{\ell u} = -1$ for every $u \not\equiv 0 \pmod N$, uniformly in u. So look for the x_j as cosines of equally spaced angles, whose odd powers expand by the binomial theorem into exactly such sums; then the binomial coefficients sum to 2^{2k-1} and cancel the normalising power of 2. The alternating signs and the reversal $\ell = 2n + 1 - j$ are there to convert $(-1)^\ell \cos \frac{\ell\pi}{2n+1}$ into a single cosine of a multiple angle, using $\cos(\ell\pi + \theta) = (-1)^\ell \cos\theta$. **Link to the next block.** The uniformity in u holds precisely while $|u| \le 2k - 1 < 2n + 1$, which is the constraint $k \le n$, and it fails at $k = n + 1$, matching the upper bound exactly.

Layer 3: WHY

Three truths make this route ideal. First, odd power sums are exactly the coordinates that detect the failure of a finite multiset of reals to be symmetric about the origin; a multiset is negation-symmetric if and only if all its odd power sums vanish, and finitely many of them suffice once you have as many as there are odd-index elementary symmetric functions. Second, the Newton identities are a triangular change of coordinates between power sums and elementary symmetric functions, so vanishing conditions transfer between the two systems with an induction that respects parity. Third, for a monic polynomial of odd degree, "all odd-index elementary symmetric functions vanish" and "the polynomial is an odd function" are the same statement, which converts algebra into a one-line evaluation at $x = -1$.

The discernment mechanism to install: whenever a problem prescribes several power sums, or several moments, or several integrals of powers, do not manipulate the equations. Encode the data as a polynomial (or a generating function) whose roots are the objects, and translate the prescriptions into vanishing coefficients. Then the question "how many conditions can hold" becomes "how many coefficients can vanish before the polynomial degenerates", and degeneration is always visible. The same reflex solves problems about moments determining a measure, about Vandermonde systems, and about equal power sums of two sets (the Prouhet, Tarry and Escott problem, whose whole content is that equal power sums up to a high enough order force equality of the multisets).

Train it by taking any statement of the form "the first r power sums of these numbers are $c_1, \dots, c_r$" and immediately writing the first r elementary symmetric functions via the Newton identities, then asking what the resulting polynomial looks like. If a pattern of zeros appears, name the corresponding structural property (odd, even, palindromic, divisible by x^d), because that property is the real content.

What the examiners nudged with. Every constant in the statement is doing work: the odd exponents $2k-1$ permit sign absorption; the target value 1 matches the excluded endpoint of the interval $(-1, 1)$ so that the contradiction is "-1 is a root"; the count $2n$ of variables makes the auxiliary polynomial have odd degree $2n+1$; and the strictness of $-1 < x_1$ and $x_{2n} < 1$ is what makes the extremal configuration unattainable at $m = n+1$. A statement in which every numeral is load-bearing is a statement engineered around a single mechanism, and finding that mechanism is the whole task.

Knowledge gaps, stated plainly. This problem is not approachable at all without three things installed. (i) The elementary symmetric functions e_j and power sums s_j of a multiset, and the relation $p(x) = \sum_j (-1)^j e_j x^{N-j}$ between e_j and the coefficients. (ii) The Newton identities $je_j = \sum_{i=1}^{j} (-1)^{i-1} e_{j-i} s_i$ for $1 \le j \le N$; without them there is no bridge from the given data (power sums) to the usable data (coefficients). (iii) The geometric series of roots of unity, $\sum_{\ell=0}^{N-1} \zeta^{\ell u} = 0$ for ζ a primitive Nth root of unity and $u \not\equiv 0 \pmod N$; without it the construction cannot be verified. None of these is in A-level Further Mathematics. A fourth item, partial fractions and residues of rational functions, is needed only for the alternative route through the generating function $\sum \frac{xz}{1-x^2z^2}$, and can be skipped if you take the Newton route. Do not attempt this problem in the arena until (i), (ii) and (iii) are automatic.

Revolving concepts

Power sums, elementary symmetric functions, and the Newton identities. For a multiset $\{r_1, \dots, r_N\}$ with e_j the jth elementary symmetric function and $s_j = \sum_i r_i^j$, the identities

$$j\,e_j = \sum_{i=1}^{j} (-1)^{i-1} e_{j-i} s_i \quad (1 \le j \le N), \qquad s_j = \sum_{i=1}^{N} (-1)^{i-1} e_i\, s_{j-i} \quad (j > N)$$

let you pass freely between the two coordinate systems. The second form is itself a linear recursion: once $e_1, \dots, e_N$ are known, the power sums satisfy a linear recurrence of order N with those

coefficients, whose general solution is $s_j = \sum_i c_i r_i^j$. Generalise the recursion this way: any sequence defined by a linear recurrence with characteristic polynomial p is a combination of jth powers of the roots of p, and conversely power sums of roots satisfy the recurrence read off from the coefficients. See Book 1, field: Polynomials, topic: symmetric functions and the Newton identities.

Negation symmetry and odd power sums. A finite multiset $R \subset \mathbb{R}$ satisfies $R = -R$ if and only if $s_j(R) = 0$ for every odd j, if and only if the monic polynomial with root multiset R is an even or an odd function according to the parity of $|R|$. The quantitative version, that finitely many odd power sums suffice, is what Part 1 proves. See Book 1, field: Polynomials, topic: parity of polynomials and root symmetry.

Equal power sums force equal multisets. If two multisets of complex numbers of sizes at most N have equal jth power sums for $j = 1, \ldots, N$, they are equal. This is the Prouhet, Tarry and Escott circle of ideas and is the same statement as invertibility of the Vandermonde matrix (r_i^j) for distinct r_i, whose determinant is $\prod_{i<j}(r_j - r_i)$. See Book 1, field: Polynomials, topic: Newton identities and Vandermonde.

Roots of unity sums. For ζ a primitive Nth root of unity, $\sum_{\ell=0}^{N-1} \zeta^{\ell u}$ equals N if $N \mid u$ and 0 otherwise. This is the discrete orthogonality relation and the engine of every explicit construction of this type. Combined with $\cos\theta = \frac{e^{i\theta}+e^{-i\theta}}{2}$ and the binomial theorem, it evaluates $\sum_\ell (\cos \alpha\ell)^d$ in closed form. See Book 1, field: Complex numbers, topic: roots of unity and orthogonality.

Chebyshev nodes. The numbers $\cos \frac{j\pi}{N}$ are the extremal nodes of the Chebyshev polynomial T_N, and $\cos \frac{(2j-1)\pi}{2N}$ are its roots. Configurations of equally spaced angles are the default guess whenever many symmetric conditions must hold at once, because their power sums collapse via roots of unity. See Book 1, field: Polynomials, topic: Chebyshev polynomials and node sets.

Generating function of odd power sums. $\sum_{k\geq 1} s_{2k-1} z^{2k-1} = \sum_{x\in R} \frac{xz}{1-x^2z^2}$, a rational function whose poles at $z = \pm 1/x$ have residues determining x and its multiplicity. This is the alternative route and the one that generalises to comparing two multisets directly. See Book 1, field: Generating functions, topic: power sums and partial fractions.

Circuit Bank

- **WHEN** you see a signed sum of odd powers of several variables **DO** absorb every sign into its variable, since $-x^{2k-1} = (-x)^{2k-1}$, and absorb any constant right hand side as an extra element of the list **BECAUSE** the family of conditions then becomes 'these power sums of one multiset vanish', which puts the whole of symmetric function theory at your disposal, uniformly in the exponent
- **WHEN** a problem prescribes several power sums of an unknown finite set **DO** form the monic polynomial with those roots and translate the prescriptions into its coefficients via the Newton identities **BECAUSE** power sums and coefficients are two coordinate systems linked by a triangular change of variables, and structural facts (parity, divisibility, degeneration) are visible only in the coefficient system
- **WHEN** all odd-index elementary symmetric functions of a monic polynomial of odd degree vanish **DO** conclude that the polynomial is an odd function and evaluate at a known root and its negative **BECAUSE** for odd degree N, the index j and the degree $N - j$ have opposite parity, so vanishing odd-index e_j is exactly vanishing even-degree coefficients, and an odd polynomial has a negation-symmetric root multiset
- **WHEN** you must construct a configuration satisfying many power sum conditions at once **DO** try equally spaced angles, so that the powers expand into sums $\sum_\ell \zeta^{\ell u}$ over roots of unity **BECAUSE** those sums take the same value -1 for every $u \not\equiv 0$, so the binomial expansion collapses uniformly in k, and the range of k for which it works is read off from the condition $|u| < N$

- **WHEN** a dimension count suggests more conditions can be met than the answer allows **DO** suspect a boundary constraint and test the smallest case explicitly **BECAUSE** counting equations against unknowns is blind to inequalities; here the extremal solution for $n = 1$ is $(0, 1)$, which sits exactly on the forbidden endpoint, and that is the whole obstruction

Backtesting

1. First useful cue: the exponents are odd, so signs absorb into variables and the alternating sum of lengths is a single power sum of a modified multiset; the constant 1 joins the multiset as the element 1.
2. Method the expression suggested: form the monic polynomial with that root multiset, push the vanishing power sums through the Newton identities to vanishing odd-index elementary symmetric functions, and read the result as polynomial parity.
3. Where you would hesitate, and the thought to reinforce: at the parity bookkeeping in the Newton induction. Reinforce the split by parity of the summation index: odd i kills s_i by hypothesis, even i leaves $j - i$ odd and smaller, killed by induction. Written that way it is two clauses, not a computation.
4. The trap the question sets: the equation count. With $2n$ unknowns it is natural to expect $2n$ conditions to be satisfiable, and the true answer is half of that. The gap is caused entirely by the open interval $(-1, 1)$, which a dimension count cannot see.
5. What makes you recognise it faster next time: every numeral in the statement is load-bearing. Odd exponents permit sign absorption, the value 1 equals the excluded endpoint, and $2n$ variables give an auxiliary polynomial of odd degree. When a statement is that tightly engineered, look for a single mechanism.
6. The reusable decision rule: prescribed power sums become prescribed coefficients; then structural degeneration of the polynomial is the obstruction, and the number of conditions you can impose is the number of coefficients you can kill before it degenerates.

Mirror drills

1. Show that if the multiset $\{r_1, \ldots, r_N\}$ of complex numbers has $s_j = 0$ for $j = 1, \ldots, N$, then all $r_i = 0$. *Answer:* By the Newton identities and induction, $e_j = 0$ for $j = 1, \ldots, N$, so the monic polynomial is x^N and every root is 0. Same mechanism, with no parity refinement.
2. Solve the case $n = 1$ of the problem by hand: find all $-1 < x_1 < x_2 < 1$ with $x_2 - x_1 = 1$ and $x_2^3 - x_1^3 = 1$. *Answer:* Substituting $x_2 = x_1 + 1$ into the second equation gives $3x_1^2 + 3x_1 + 1 = 1$, so $x_1 \in \{0, -1\}$ and $x_2 \in \{1, 0\}$; both violate the strict inequalities, so $m = 1$ for $n = 1$. The degenerate solution $\{0, 1\}$ shows that the boundary is the obstruction.
3. Evaluate $\sum_{\ell=1}^{2n} \cos \frac{2\pi\ell}{2n+1}$ and $\sum_{\ell=1}^{2n} \cos^3 \frac{2\pi\ell}{2n+1}$ for $n \geq 2$. *Answer:* Both equal -1: the first is $\sum_{\ell=1}^{2n} \frac{\zeta^\ell + \zeta^{-\ell}}{2} = \frac{-1-1}{2} = -1$, and expanding the cube gives $\frac{1}{8}\left(\binom{3}{0} + \binom{3}{1} + \binom{3}{2} + \binom{3}{3}\right)(-1) = -1$, using that each exponent $\pm 3, \pm 1$ is nonzero modulo $2n + 1$ when $2n + 1 > 3$. This is the construction's computation in miniature.

4.7 B1. Parity of exponential series coefficients

Suppose that $P(x) = a_1x + a_2x^2 + \cdots + a_nx^n$ is a polynomial with integer coefficients, with a_1 odd. Suppose that $e^{P(x)} = b_0 + b_1x + b_2x^2 + \cdots$ for all x. Prove that b_k is nonzero for all $k \geq 0$.

Read it out loud

An exponential of an integer polynomial with no constant term, expanded as a power series; prove that no coefficient dies. Three fields are wired in: generating functions (the object $e^{P(x)}$ is an exponential generating function in disguise), elementary number theory (the hypotheses are integrality and the parity of a_1), and one line of calculus (the exponential is the function whose logarithmic derivative is P').

What is really being tested is whether you look at the right object. The coefficients b_k are rational numbers with denominators dividing $k!$, and a rational number is a poor thing to prove nonzero: there is no modulus to work in. The hypotheses are the guiding lights. "Integer coefficients" and "a_1 odd" are parity hypotheses, and a parity hypothesis is planted so that you prove something is odd. An odd integer is nonzero. Thus the statement you should actually prove is stronger and discrete: $k!\,b_k$ is an odd integer for every k.

Within thirty seconds you should have written $c_k = k!\,b_k$, checked $c_0 = e^{P(0)} = 1$ and $c_1 = a_1$, and asked how c_{k+1} is built from $c_0, \ldots, c_k$. The cleanest engine for "how are the coefficients of e^P built" is not the series $\sum_m P^m/m!$; it is the differential equation $y' = P'(x)\,y$, because that equation is what e^P is, definitionally, and a first-order linear equation with polynomial coefficient turns into a finite linear recursion.

Approaches, ranked worst to best

1. **Multinomial grind.** *Cue:* the explicit series $e^P = \sum_m P(x)^m/m!$. *Circuit:* expand and track coefficients. (zombie route: b_k becomes a sum over compositions of k of multinomial coefficients divided by $m!$; you cannot see the denominators cancel, let alone the parity, without first normalising by $k!$, and once you have normalised you should be using a better engine anyway)

2. **Exponential formula and involutions.** *Cue:* e^P as the generating function of set partitions with coloured blocks. *Circuit:* count, then cancel in pairs with a sign-reversing involution. (correct: $k!\,b_k$ is a signed count of set partitions of $\{1, \ldots, k\}$ whose blocks of size j carry one of $|a_j|$ colours, and a fixed-point-free involution on the non-trivial partitions leaves only the all-singletons partition, which is odd; but it needs the exponential formula plus a carefully checked involution, the most theory for the least ink saved)

3. **Multiplicative decomposition.** *Cue:* $e^P = e^{a_1x}\,e^{a_2x^2}\cdots e^{a_nx^n}$. *Circuit:* show each factor other than e^x lies in a multiplicatively closed class of series with even normalised coefficients. (works: series $\sum c_kx^k/k!$ with $c_0 = 1$ multiply by $e_k = \sum_m \binom{k}{m} c_m d_{k-m}$, so "all c_k even for $k \geq 1$" is preserved; you then need $2^k/k!$ to have even numerator, which is Legendre's formula $v_2(k!) < k$, and $(mj)!/m!$ even for $j \geq 2$; three small lemmas where one would do)

4. **Truncated series at the top degree.** *Cue:* $k!\,b_k = [x^k]\sum_{m\leq k} \frac{k!}{m!}P^m$. *Circuit:* the $m = k$ term contributes a_1^k, every $\frac{k!}{m!}$ with $m \leq k-2$ is even. (the official first solution: two lines, but with a boundary case, k odd and $m = k-1$, where $k!/m! = k$ is odd and you must compute the x^k coefficient of $k\,P^{k-1}$ by hand as $k(k-1)a_1^{k-2}a_2$; a place to drop a point under time pressure)

5. **Differential equation to recursion.** *Cue:* e^P is the solution of $y' = P'(x)\,y$ with $y(0) = 1$. *Circuit:* convert the equation into a recursion for $c_k = k!\,b_k$ and reduce mod 2. (ideal: the

recursion has integer coefficients that are falling factorials, every term except $a_1 c_k$ is visibly even, one induction, no boundary cases)

The ideal solution

Write $y(x) = e^{P(x)}$. Since P is a polynomial, y is entire, so its Taylor series $\sum_{k\geq 0} b_k x^k$ converges for every real x and may be differentiated term by term. The chain rule gives

$$y'(x) = P'(x)\, y(x), \qquad P'(x) = \sum_{j=1}^{n} j a_j x^{j-1}.$$

Comparing the coefficient of x^k on both sides, with the convention $b_m = 0$ for $m < 0$,

$$(k+1)\, b_{k+1} = \sum_{j=1}^{n} j a_j\, b_{k+1-j} \qquad (k \geq 0).$$

Set $c_k = k!\, b_k$. Multiply the display by $k!$ and use $k!/(k+1-j)! = k(k-1)\cdots(k+2-j)$, a product of $j-1$ consecutive integers (empty for $j = 1$):

$$c_{k+1} = a_1 c_k + \sum_{j=2}^{n} j a_j\, k(k-1)\cdots(k+2-j)\; c_{k+1-j},$$

where terms with $k+1-j < 0$ vanish.

Claim 4.7.1. *For every $k \geq 0$, c_k is an odd integer.*

Proof. Induction on k. First $c_0 = b_0 = e^{P(0)} = 1$. Suppose $c_0, \ldots, c_k$ are odd integers. Every term of the recursion for c_{k+1} is then an integer. The term $a_1 c_k$ is odd. For $j = 2$ the term is $2a_2 k\, c_{k-1}$, even. For $j \geq 3$ the factor $k(k-1)\cdots(k+2-j)$ is a product of $j-1 \geq 2$ consecutive integers, one of which is even, so the term is even. Hence $c_{k+1} \equiv a_1 c_k \equiv 1 \pmod 2$. □

Therefore $b_k = c_k/k!$ is a nonzero rational number for every $k \geq 0$. In fact $k!\, b_k$ is an odd integer, which is the statement worth remembering.

Layer 1: WHAT

Block 1: strengthen the target. "$b_k \neq 0$" becomes "$k!\, b_k$ is an odd integer", a discrete statement with a modulus to work in. Block 2: choose the engine. e^P is characterised by $y' = P'y$, $y(0) = 1$; write that, not the series $\sum P^m/m!$. Block 3: read off the recursion $(k+1)b_{k+1} = \sum_j j a_j b_{k+1-j}$ and normalise to $c_k = k!\, b_k$, which clears every denominator and produces falling factorials as coefficients. Block 4: reduce mod 2. Every term except $a_1 c_k$ carries an even factor: the explicit 2 when $j = 2$, or a product of at least two consecutive integers when $j \geq 3$. Block 5: close by induction from $c_0 = 1$.

Juxtaposition. The nominal route expands $e^P = \sum_m P^m/m!$ and tries to compute b_k; it is not wrong, and pushed correctly it becomes approach 4, but it forces a boundary case and it never tells you why the parity behaves. The bifurcation point is Block 1 combined with Block 2: the moment you decide to study $k!\, b_k$ rather than b_k, and to let the differential equation, not the series, generate the coefficients. After that the proof writes itself.

Layer 2: HOW

Block 1. **Cue.** "Integer coefficients", "a_1 odd", "prove nonzero". Integrality plus a parity hypothesis is a request for a parity conclusion. **Why natural.** A rational number has no arithmetic to exploit; an integer does. Denominators of b_k divide $k!$ because e^P is a sum of $P^m/m!$, so $k!\, b_k$ is the natural integer candidate. Odd implies nonzero, so proving the stronger discrete statement is not extra work, it is the only route that has a chance. **Link to the next block.** Now you need a description of $k!\, b_k$ that shows integrality and parity together; that means a recursion.

Block 2. **Cue.** The function is $e^{P(x)}$, and P is a polynomial. **Why natural.** The exponential of a polynomial is the unique solution of $y' = P'(x)\,y$ with $y(0) = 1$. A linear differential equation with polynomial coefficient is a finite linear recursion on Taylor coefficients: that is what Further Maths series solutions of differential equations are for. The series $\sum P^m/m!$ hides the same recursion behind multinomial sums. **Link to the next block.** Differentiate termwise (legitimate: y is entire) and compare coefficients.

Block 3. **Cue.** The recursion $(k+1)b_{k+1} = \sum_j j a_j b_{k+1-j}$ has a factor $k+1$ on the left. **Why natural.** Multiplying by $k!$ converts $(k+1)b_{k+1}$ into c_{k+1} and each b_{k+1-j} into c_{k+1-j} times $k!/(k+1-j)!$, a falling factorial with $j-1$ factors. Falling factorials are integers, so $c_k \in \mathbb{Z}$ falls out for free. **Link to the next block.** Look at each coefficient mod 2.

Block 4. **Cue.** Products of consecutive integers. **Why natural.** A product of m consecutive integers equals $m!$ times a binomial coefficient, hence is divisible by $m!$; for $m \geq 2$ it is even. The $j = 2$ term has no such product (only one factor, k), but it carries the explicit factor 2 from $j a_j = 2a_2$. So the only odd term is $a_1 c_k$. **Link to the next block.** Induction from $c_0 = 1$ needs nothing else.

Block 5. **Cue.** A recursion with all lower terms even except one. **Why natural.** $c_{k+1} \equiv a_1 c_k \pmod 2$ and a_1 is odd, so parity is inherited. This is also why a_1 odd is exactly the right hypothesis: with a_1 even, c_k is even for $k \geq 1$ and the conclusion can fail (e^{x^2} has every odd coefficient zero). **Link to the next block.** Translate back: $b_k = c_k/k! \neq 0$.

Layer 3: WHY

The mathematical truth underneath is that e^P for an integer polynomial P is an exponential generating function with integer coefficients, and those coefficients satisfy a linear recursion with polynomial (falling factorial) coefficients because e^P satisfies a first-order linear differential equation. Any series satisfying such an equation has this property; the exponential is only the simplest case. Once the recursion is written, parity is a matter of looking at which coefficients are even, and falling factorials of length at least two are always even.

The discernment mechanism is the question "what modulus?". When a problem asks you to prove that a quantity is nonzero, and the hypotheses are arithmetic (integers, odd, prime), the examiners are telling you to find an integer-valued normalisation and a modulus in which the quantity is a unit. Here the normalisation is $k!$ and the modulus is 2. To train this, take every "prove nonzero" statement you meet and ask: nonzero in which ring, and what is the cheapest congruence that implies it?

The nudge was explicit. They did not write $P(x) = x + a_2x^2 + \cdots$; they wrote "$a_1$ odd", and they wrote "$e^{P(x)} = b_0 + b_1 x + \cdots$ for all x" to make you think analytically about something that is arithmetic. Seeing through the analytic costume to the parity statement is the whole problem.

Revolving concepts

Exponential generating functions. For a sequence (c_k), the series $\sum c_k x^k/k!$ is its exponential generating function; products of such series correspond to binomial convolutions $e_k = \sum_m \binom{k}{m} c_m d_{k-m}$, which is why integrality and parity classes are preserved under multiplication. The series $e^{P(x)}$ with P a polynomial without constant term is the exponential generating function of "structures built from connected pieces", the exponential formula: $k!\,[x^k]\,e^P$ counts set partitions of a k-set with each block of size j weighted by a_j. See Book 1, field: Generating functions, topic: exponential generating functions and the exponential formula.

Differential equations to recursions (the generalised recursion). If $y = \sum b_k x^k$ satisfies $y' = Q(x)\,y$ with $Q(x) = \sum_{i \geq 0} q_i x^i$ a polynomial, then $(k+1)b_{k+1} = \sum_i q_i b_{k-i}$, and with $c_k = k!\,b_k$

this becomes $c_{k+1} = \sum_i q_i\, k(k-1)\cdots(k-i+1)\, c_{k-i}$. Special cases you should recognise on sight: $Q = 1 + x$ gives $c_{k+1} = c_k + kc_{k-1}$, the involution numbers $1, 1, 2, 4, 10, 26, \ldots$; $Q = e^x$ gives $c_{k+1} = \sum_m \binom{k}{m} c_m$, the Bell numbers; $Q = 2x$ gives $c_{k+1} = 2kc_{k-1}$, the coefficients of e^{x^2}. The general solution method is always the same: the recursion is linear with polynomial coefficients, so any arithmetic property (integrality, congruences, growth rate) is proved by induction along it. See Book 1, field: Sequences and recurrences, topic: linear recursions with polynomial coefficients.

Falling factorials and divisibility. $k(k-1)\cdots(k-m+1) = m!\binom{k}{m}$ is divisible by $m!$; in particular any product of two consecutive integers is even. The 2-adic valuation of $k!$ is $v_2(k!) = k - s_2(k)$, where $s_2(k)$ is the number of ones in the binary expansion of k (Legendre's formula); this is the lemma behind approach 3. See Book 1, field: Number theory, topic: valuations of factorials.

Circuit Bank

- **WHEN** you see "prove nonzero" with integer and parity hypotheses **DO** write an integer normalisation of the quantity and prove it is odd, or a unit mod a well-chosen prime **BECAUSE** because a rational number has no modulus to work in and an odd integer is automatically nonzero
- **WHEN** you see the coefficients of $e^{P(x)}$, or of any y with $y' = Q(x)\, y$ **DO** write the recursion $(k+1)b_{k+1} = \sum_i q_i b_{k-i}$, then pass to $c_k = k!\, b_k$ **BECAUSE** because a first-order linear differential equation with polynomial coefficient is a finite linear recursion, and the $k!$ normalisation turns its coefficients into integer falling factorials
- **WHEN** you see a product of consecutive integers inside a recursion **DO** mark it as divisible by the factorial of its length **BECAUSE** because it equals that factorial times a binomial coefficient, so it is even as soon as it has two factors

Backtesting

1. First useful cue: "integer coefficients, a_1 odd, prove $b_k \neq 0$". Parity in, parity out.
2. Method the expression suggested: e^P satisfies $y' = P'y$, so read the coefficients from the differential equation and normalise by $k!$.
3. Where you would hesitate, and the thought to reinforce: whether $k!\, b_k$ is even an integer. Do not stop to prove it separately; the recursion proves integrality and parity in the same induction.
4. The trap the question sets: the analytic phrasing "for all x" invites you to think about convergence or about e^P as a function; nothing about the function matters beyond the one differentiation.
5. What makes you recognise it faster next time: any exponential of a polynomial, or any e^f with f having integer Taylor coefficients, is an exponential generating function of integers, and its coefficients obey a recursion you can write in one line.
6. The reusable decision rule: to prove a Taylor coefficient is nonzero, multiply by $k!$ and prove a congruence.

Mirror drills

1. (drill) The involution numbers $I_k = k!\,[x^k]\, e^{x+x^2/2}$ satisfy $I_{k+1} = I_k + kI_{k-1}$. Explain why the parity argument of B1 breaks and why I_k is even for all $k \geq 2$. *Answer:* $a_2 = 1/2$ is not an integer, so the $j = 2$ term is $k\, c_{k-1}$ with no factor 2; then $I_2 = 2$ and $I_{k+1} \equiv I_k + kI_{k-1}$ gives even for ever by induction on pairs.

2. (drill) Let P have integer coefficients with $P(0) = 0$ and a_1 even. Show $k!\,b_k$ is even for all $k \geq 1$, and give a P with some $b_k = 0$. *Answer:* $c_{k+1} \equiv a_1 c_k \equiv 0$; take $P = x^2$, where every odd coefficient vanishes.

3. (drill) Let p be an odd prime and $P(x) = x + x^p$. Prove $k!\,b_k \equiv 1 \pmod{p}$ for all $k \geq 0$. *Answer:* the recursion is $c_{k+1} = c_k + p\,k(k-1)\cdots(k+2-p)\,c_{k+1-p}$, and the second term carries the factor $ja_j = p$, so $c_{k+1} \equiv c_k \pmod{p}$ and $c_0 = 1$; in fact $c_k = 1$ exactly for $k < p$.

4.8 B2. Finite sets closed under the cross product

Let $\times$ represent the cross product in $\mathbb{R}^3$. For what positive integers n does there exist a set $S \subset \mathbb{R}^3$ with exactly n elements such that

$$S = \{v \times w : v, w \in S\}?$$

Read it out loud

A finite set of vectors in three dimensions that reproduces itself exactly under all pairwise cross products. The fields wired in are vector algebra (the cross product and its two defining properties), a scrap of linear algebra (orthogonal sets and spanning), and a finiteness argument of the kind that appears in group theory: a set closed under an operation cannot contain anything whose "size" grows under that operation.

What is really being tested is whether you know what the cross product controls. It is not associative, it has no identity, and it is not a group operation, so the algebraic reflexes you would use for a multiplicative closure problem do not transfer. What it does have is exactly three facts: $v \times v = 0$, the output is orthogonal to both inputs, and $\|v \times w\| = \|v\|\|w\| \sin\theta$. That last one is the only scalar law available, and a scalar law plus finiteness is a rigidity statement waiting to happen.

Within thirty seconds you should have written two lines. First, S is nonempty, so pick any $v \in S$ and note $0 = v \times v \in S$: the zero vector is forced. Second, the norm identity, with the observation that if u and z are perpendicular then $\|u \times z\| = \|u\|\|z\|$ exactly, with no sine factor to spoil it. Multiplication by a fixed constant, applied over and over inside a finite set, is a contradiction unless the constant is 1. That sentence is the whole solution.

The answer, once you see the shape, is the unit octahedron plus its centre: $\{0, \pm v_1, \pm v_2, \pm v_3\}$ for an orthonormal basis, giving $n = 7$, together with the degenerate $S = \{0\}$, giving $n = 1$.

Approaches, ranked worst to best

1. **Coordinate brute force.** *Cue:* the operation is given by an explicit bilinear formula in coordinates. *Circuit:* write everything in components and solve. (zombie route: $3n$ unknowns and n^2 vector equations with no structure imposed; you cannot even write down the condition $S = \{v \times w\}$ without choosing which product equals which element, so the case count explodes before any algebra happens)
2. **Small case hunting.** *Cue:* the phrase "for what positive integers n". *Circuit:* compute $n = 1, 2, 3, \ldots$ by hand and guess. (useful reconnaissance only: you quickly find $\{0\}$ and the seven element octahedral set, but the entire difficulty is proving nothing else exists, and enumeration gives you no leverage on that)
3. **Identify the algebra.** *Cue:* a bilinear antisymmetric product on $\mathbb{R}^3$. *Circuit:* recognise the Lie algebra $\mathfrak{so}(3)$, or the imaginary quaternions. (correct and illuminating: the answer set is the image of the quaternion group $\{\pm 1, \pm i, \pm j, \pm k\}$, and the Jacobi identity explains why the structure is rigid; but no amount of structure theory removes the need for the finiteness argument, so this is theory bought at full price and used at a discount)
4. **Orthogonality first.** *Cue:* $v \times w$ is perpendicular to both v and w. *Circuit:* force all pairs of elements to be perpendicular, then count. (the right second move made first: to convert "$v \times w \in S$" into "$v \perp w$" you need to know that $\|v \times w\| = 1$, which requires the norm classification you have not yet done, so starting here stalls immediately)
5. **Norms first.** *Cue:* "exactly n elements" (finiteness) sitting next to an operation with a multiplicative norm law. *Circuit:* iterate the operation to build a geometric progression of norms, and let finiteness kill it. (ideal: one induction shows every nonzero element is a unit vector, after which orthogonality is a one line consequence of $\sin\theta = 1$ and the count is forced)

The ideal solution

The answers are $n = 1$ and $n = 7$.

Throughout, write $\|\cdot\|$ for the Euclidean norm and use the two defining properties of the cross product: $v \times w$ is orthogonal to both v and w, and $\|v \times w\| = \|v\|\|w\| \sin\theta$ where $\theta \in [0, \pi]$ is the angle between v and w. In particular $v \times w = 0$ exactly when v and w are linearly dependent.

Suppose S has exactly $n \geq 1$ elements and $S = \{v \times w : v, w \in S\}$. Since S is nonempty, choose $v \in S$; then $0 = v \times v \in S$. So $0 \in S$ always.

Case 1: every pair of elements of S is linearly dependent. Then every cross product of elements of S vanishes, so $S = \{0\}$ and $n = 1$. Conversely $S = \{0\}$ does satisfy $S = \{v \times w\}$, so $n = 1$ occurs.

Case 2: S contains two linearly independent vectors.

Claim 4.8.1. *Every nonzero $u \in S$ satisfies $\|u\| = 1$.*

Proof. Suppose $u \in S$ is nonzero with $\|u\| \neq 1$. Since S contains two linearly independent vectors, at least one of them, call it z, is not a scalar multiple of u. Define

$$u_1 = u \times z, \qquad u_{k+1} = u \times u_k \quad (k \geq 1).$$

Every u_k lies in S, because S is closed under cross products of its own elements. We show by induction that $u_k \neq 0$ and $u_k \perp u$ for all $k \geq 1$. For $k = 1$: u and z are independent, so $u_1 \neq 0$, and $u_1 \perp u$ by construction. If $u_k \neq 0$ and $u_k \perp u$, then u and u_k are independent (a nonzero vector orthogonal to u is not a multiple of u), so $u_{k+1} = u \times u_k \neq 0$, and $u_{k+1} \perp u$ by construction.

Because $u \perp u_k$ for $k \geq 1$, the sine factor is 1 and the norms satisfy exactly

$$\|u_{k+1}\| = \|u\|\,\|u_k\|, \qquad \text{so} \qquad \|u_k\| = \|u\|^{k-1}\|u_1\|.$$

Since $\|u_1\| > 0$ and $\|u\| \neq 1$, the numbers $\|u_k\|$ are pairwise distinct, so the vectors u_k are pairwise distinct. Thus S contains infinitely many elements, contradicting $|S| = n$. □

Claim 4.8.2. *Any two nonzero elements of S are either equal up to sign or orthogonal.*

Proof. Let $u, z \in S$ be nonzero; by the previous claim both are unit vectors. If they are linearly dependent then $z = \pm u$. If they are independent then $u \times z$ is a nonzero element of S, hence a unit vector, so

$$1 = \|u \times z\| = \|u\|\|z\| \sin\theta = \sin\theta,$$

forcing $\theta = \pi/2$, that is $u \perp z$. □

Now pick $v_1, v_2 \in S$ linearly independent, and set $v_3 = v_1 \times v_2 \in S$. By the claims, v_1 and v_2 are orthogonal unit vectors, so v_3 is a unit vector orthogonal to both, and (v_1, v_2, v_3) is an orthonormal basis of $\mathbb{R}^3$ with

$$v_1 \times v_2 = v_3, \quad v_2 \times v_3 = v_1, \quad v_3 \times v_1 = v_2.$$

Reversing the order of each product changes the sign, so S contains all seven of

$$0, \quad v_1, \quad v_2, \quad v_3, \quad -v_1 = v_3 \times v_2, \quad -v_2 = v_1 \times v_3, \quad -v_3 = v_2 \times v_1,$$

and these are pairwise distinct. Conversely, let $u \in S$ be nonzero. By the second claim u is, for each i, either $\pm v_i$ or orthogonal to v_i. If u were orthogonal to all of v_1, v_2, v_3, then u would be orthogonal to a spanning set of $\mathbb{R}^3$, forcing $u = 0$; so $u = \pm v_i$ for some i. Therefore

$$S = \{0, \pm v_1, \pm v_2, \pm v_3\}, \qquad n = 7.$$

It remains to confirm that such an S really does satisfy the condition, since the problem demands equality and not merely closure. Take any orthonormal basis (v_1, v_2, v_3) with $v_3 = v_1 \times v_2$ and put $T = \{0, \pm v_1, \pm v_2, \pm v_3\}$. A product with 0, or of two parallel elements, gives $0 \in T$. A product

$(\varepsilon_1 v_i) \times (\varepsilon_2 v_j)$ with $i \neq j$ and $\varepsilon_1, \varepsilon_2 \in \{1, -1\}$ equals $\pm v_k$ where k is the third index, and as the signs and the order of i and j vary, both v_k and $-v_k$ are attained. Hence $\{v \times w : v, w \in T\} = T$ exactly.

The possible values are therefore

$$\boxed{n = 1 \text{ and } n = 7}.$$

Layer 1: WHAT

Block 1: S is nonempty, and $v \times v = 0$, so $0 \in S$ with no work at all.

Block 2: split on the only structural dichotomy available: either all of S lies on one line through the origin, in which case every product dies and $S = \{0\}$, or S contains two independent vectors.

Block 3: ask what quantity the cross product controls, and answer: the norm, multiplicatively, exactly when the arguments are perpendicular. Build the orbit $u_1 = u \times z$, $u_{k+1} = u \times u_k$, which stays perpendicular to u forever, so the norms form a geometric progression with ratio $\|u\|$.

Block 4: finiteness forbids a nonconstant geometric progression, so $\|u\| = 1$ for every nonzero $u \in S$.

Block 5: with all nonzero elements on the unit sphere, $u \times z \in S$ forces $\sin\theta = 1$, so distinct directions in S are perpendicular.

Block 6: perpendicular unit vectors in $\mathbb{R}^3$ come in at most three directions, each contributing two elements; adding 0 gives exactly seven, and there is no room for an eighth.

Block 7: verify both directions of the equality for the seven element set.

The nominal route goes: "finite set, explicit operation, let me parametrise the elements and solve". It writes $v_i = (x_i, y_i, z_i)$, expands determinants, and drowns. The bifurcation point is Block 3, at the question *which scalar function of a vector does this operation multiply?* The zombie answers "components"; components are not multiplied by anything. The ideal answer is "the norm", and it is multiplied exactly, with no error term, precisely in the situation the operation itself manufactures (perpendicular arguments). Once you have a multiplicative quantity inside a finite set, the problem is over.

Layer 2: HOW

Block 1. **Cue.** $S = \{v \times w : v, w \in S\}$ with v and w ranging independently, so in particular $w = v$ is allowed. **Why natural.** Closure conditions are always tested first on the diagonal, because $v * v$ is the cheapest element you can manufacture. Here $v \times v = 0$ by antisymmetry, so the zero vector is in S for free. This also tells you $n = 1$ is a live candidate rather than a formality. **Link to the next block.** Knowing $0 \in S$, the real question is what the nonzero elements can be.

Block 2. **Cue.** The cross product of dependent vectors vanishes. **Why natural.** The operation has a large "kernel": any set of pairwise parallel vectors produces only 0. That is a genuinely different regime from the general one, so it must be split off before you argue about norms; otherwise the phrase "choose z not parallel to u" is unjustified. **Link to the next block.** In the nondegenerate case you now have two independent elements to feed the machine.

Block 3. **Cue.** "Exactly n elements" sitting next to a norm law. **Why natural.** Finiteness is never decoration. It is there because some construction inside the problem generates an infinite family unless a parameter is pinned. The only parameter in sight is $\|u\|$, and the only law is $\|u \times z\| = \|u\|\|z\| \sin\theta$. The sine is a nuisance in general, so you engineer it away: cross with u repeatedly, and after the first step every vector in the orbit is perpendicular to u, so $\sin\theta = 1$ permanently. **Link to the next block.** The orbit has norms $\|u\|^{k-1}\|u_1\|$, which is a geometric progression.

Block 4. Cue. A geometric progression of distinct positive numbers inside a finite set. **Why natural.** Distinct norms mean distinct vectors, and infinitely many of them. The ratio must therefore be 1. This is the same mechanism that forces a finite multiplicative subgroup of the positive reals to be trivial, and it is why every element of a finite set closed under a norm multiplicative operation lies on the unit sphere or at the origin. **Link to the next block.** All nonzero elements are unit vectors; now the sine factor becomes readable.

Block 5. Cue. $\|u \times z\| = \sin\theta$ once u and z are unit vectors, and the left side must be 1 because $u \times z$ is a nonzero element of S. **Why natural.** An equation between a norm and a sine converts algebra into geometry with no intermediate steps. $\sin\theta = 1$ has the unique solution $\theta = \pi/2$ in $[0, \pi]$. **Link to the next block.** Distinct directions are now orthogonal, which is a counting constraint.

Block 6. Cue. Pairwise orthogonal nonzero vectors in $\mathbb{R}^3$. **Why natural.** They are linearly independent, so there are at most three of them; each direction contributes exactly the two unit vectors $\pm v_i$; and any further element would have to be orthogonal to a spanning set, hence zero. The count $1 + 6 = 7$ is forced, not chosen. **Link to the next block.** Only the verification remains.

Block 7. Cue. The problem says $S = \{v \times w\}$, an equality of sets. **Why natural.** Everything so far proves the inclusion "S is contained in the octahedral set" and that the seven elements are produced. A grader will want the reverse inclusion checked explicitly, that is, that every one of the seven elements arises as a product and that no product escapes the set. Both are one line each, and skipping them is how a full solution becomes a nine.

Layer 3: WHY

The mathematical truth underneath is that the cross product carries a *multiplicative valuation*. Whenever an operation $*$ on a set admits a function N into the positive reals with $N(a * b) = N(a)N(b)$ on the relevant part of the domain, any finite $*$ closed set must have all its values of N equal to 1, because $N(a), N(a)^2, N(a)^3, \ldots$ would otherwise be infinitely many distinct values. You have met this before in three costumes: a finite subgroup of $\mathbb{R}^{>0}$ is trivial; a finite set of complex numbers closed under multiplication lies in $\{0\} \cup$ (roots of unity); a finite set of monic integer polynomials closed under multiplication must consist of degree zero elements. The cross product is a fourth costume, with the twist that its valuation is multiplicative only under a side condition (perpendicularity), and the operation itself supplies that side condition after one application. That is the reason the orbit $u_{k+1} = u \times u_k$ is the natural object rather than an arbitrary product of elements.

The discernment mechanism is a question you should ask automatically whenever the words "finite" and "closed" appear together: *what does this operation do to size?* If the answer is "multiplies it", finiteness forces size 1. If the answer is "adds to it" (degree, length, number of prime factors), finiteness forces the additive quantity to be zero. If the answer is "does not change it", you learn nothing and must find another invariant. Training this is a matter of building a reflex list of size functions: modulus, norm, determinant, degree, trace, order, cardinality of support.

What the examiners nudged toward is visible in the phrasing. They wrote "with exactly n elements" rather than "finite", which puts the cardinality in your face; and they wrote the condition as an equality of sets rather than as closure, which is the hint that the answer will be a rigid, self reproducing configuration rather than anything you can pad. The rigidity itself is not an accident: $\{0, \pm v_1, \pm v_2, \pm v_3\}$ is the set of imaginary parts of the quaternion group $\{\pm 1, \pm i, \pm j, \pm k\}$, and the reason no other configuration survives is that $(\mathbb{R}^3, \times)$ is a simple Lie algebra whose only finite self reproducing subsets are the trivial one and the standard octahedron.

Revolving concepts

The cross product. For $v, w \in \mathbb{R}^3$, $v \times w$ is the unique vector with $v \times w \perp v, w$, with $\|v \times w\| = \|v\|\|w\| \sin\theta$, and with $(v, w, v \times w)$ right handed. It is bilinear and antisymmetric, so $v \times v = 0$; it is not associative, and instead satisfies the Jacobi identity $u \times (v \times w) + v \times (w \times u) + w \times (u \times v) = 0$ and the triple product expansion $u \times (v \times w) = v(u \cdot w) - w(u \cdot v)$. See Book 1, field: Geometry, topic: vector product.

The map $L_u(x) = u \times x$ and its recursion. Fix $u \neq 0$. Then L_u kills the line $\mathbb{R}u$ and maps $u^\perp$ to itself; on that plane it is the composition of a rotation by $\pi/2$ about u with a scaling by $\|u\|$. The recursion $u_{k+1} = L_u(u_k)$ is therefore a linear recursion with matrix $\|u\|R$, R a rotation by a quarter turn, so in general

$$u_k = \|u\|^{k-1} R^{k-1} u_1, \qquad \|u_k\| = \|u\|^{k-1}\|u_1\|.$$

Generalise the pattern: for any linear map A acting on a subspace as a similarity of ratio r, the orbit of a nonzero vector has norms $r^k\|u_1\|$, so a finite orbit forces $r = 1$, and when $r = 1$ the orbit is finite exactly when the rotation part has rational angle. Here $r = 1$ gives $L_u^4 = \mathrm{id}$ on $u^\perp$, period 4, which is precisely why the answer set has $\pm$ pairs. See Book 1, field: Linear algebra, topic: orthogonal maps and orbits.

Multiplicative valuations and finiteness. If $N : X \to \mathbb{R}^{>0}$ satisfies $N(a * b) = N(a)N(b)$ and X is finite and closed under $*$, then $N \equiv 1$. Standard companions: a finite subgroup of the multiplicative group of a field is cyclic; a finite set of complex numbers closed under multiplication is μ_m or $\mu_m \cup \{0\}$. See Book 1, field: Abstract algebra, topic: finite closure arguments.

Orthogonal sets. Nonzero pairwise orthogonal vectors are linearly independent, so at most dim many; a vector orthogonal to a spanning set is zero. See Book 1, field: Linear algebra, topic: orthonormal bases.

Quaternions. For purely imaginary quaternions u, v one has $uv = -(u \cdot v) + u \times v$, so the cross product is the imaginary part of quaternion multiplication. The seven element answer is $\{0\} \cup \{\pm i, \pm j, \pm k\}$ in disguise. See Book 1, field: Abstract algebra, topic: quaternions.

Circuit Bank

- **WHEN** a problem gives a finite set closed under an operation **DO** ask at once what scalar quantity the operation multiplies, and iterate the operation on one element **BECAUSE** finiteness forbids a nonconstant geometric progression, so that quantity is pinned to 1 and the problem collapses to a rigidity statement
- **WHEN** an operation satisfies $v * v = e$ for a distinguished element e, and a set equals its own image **DO** write e into the set immediately **BECAUSE** the diagonal $w = v$ is always legal in a closure condition and is the cheapest element you can manufacture
- **WHEN** a cross product is forced to be a unit vector **DO** read the angle straight off $\|v \times w\| = \|v\|\|w\| \sin\theta$ **BECAUSE** the norm identity converts an algebraic membership condition into the geometric statement $\theta = \pi/2$ in a single line
- **WHEN** a norm law carries an awkward factor such as $\sin\theta$ **DO** engineer the factor to equal 1 by feeding the operation its own output **BECAUSE** the cross product outputs vectors perpendicular to its inputs, so the second application onwards is automatically in the clean case
- **WHEN** the problem states $S = \{\text{image}\}$ rather than image $\subseteq S$ **DO** verify both inclusions explicitly at the end **BECAUSE** an equality of sets is two statements, and the reverse inclusion is where constructed examples are usually checked or lost

Backtesting

1. First useful cue: the words "exactly n elements" next to an operation with a multiplicative norm law; finiteness is the active hypothesis, not the question.
2. Method the expression suggested: iterate $u \mapsto u \times u_k$ to manufacture perpendicular arguments, turning $\|v \times w\| = \|v\|\|w\| \sin\theta$ into an exact geometric progression of norms.
3. Where you would hesitate, and the thought to reinforce: at the start, when the problem looks like a search over configurations. Reinforce this: you are not searching, you are proving that a scalar is pinned. Configuration searches in $\mathbb{R}^3$ are hopeless; scalar rigidity arguments are three lines.
4. The trap the question sets: forgetting that the condition is an equality, so that a set which is merely closed under the cross product (for example any set of parallel vectors together with 0) looks like a counterexample; and, inside the norm argument, forgetting to check $u_k \neq 0$ at every step, without which the "distinct norms" claim is empty.
5. What makes you recognise it faster next time: the pairing of a finiteness hypothesis with any operation that has a size law. That pairing has exactly one purpose in every problem that contains it.
6. The reusable decision rule: finite plus closed plus multiplicative size equals size 1. Then use the structural properties (here orthogonality) to count.

Mirror drills

1. Find all finite sets $S \subset \mathbb{C}$ with $S = \{zw : z, w \in S\}$. *Answer:* the modulus is multiplicative, so finiteness forces every nonzero element onto the unit circle; the nonzero part is then a finite nonempty subset of the circle group closed under multiplication, hence a subgroup, hence μ_m. The answers are $\{0\}$, μ_m and $\mu_m \cup \{0\}$ for $m \geq 1$.
2. Suppose only that $S \subset \mathbb{R}^3$ is finite and $\{v \times w : v, w \in S\} \subseteq S$. Classify S. *Answer:* the same two claims apply verbatim, so either all elements of S are parallel (and then S is any such set that contains 0 if it has at least two elements, since all products vanish), or $S = \{0, \pm v_1, \pm v_2, \pm v_3\}$ for an orthonormal basis. The equality hypothesis was only ever used to rule out padding by parallel vectors.
3. For a unit vector u and any $x \perp u$, compute $u \times (u \times (u \times (u \times x)))$. *Answer:* x. On $u^\perp$ the map L_u is a quarter turn, so L_u^4 is the identity; this period 4 is exactly why the seven element set closes up after $\pm$ pairs.

4.9 B3. Iterated recolouring of the positive reals

Assign to each positive real number a colour, either red or blue. Let D be the set of all distances $d > 0$ such that there are two points of the same colour at distance d apart. Recolour the positive reals so that the numbers in D are red and the numbers not in D are blue. If we iterate this recolouring process, will we always end up with all the numbers red after a finite number of steps?

Read it out loud

A two colouring of the positive reals is fed into a machine that returns a new two colouring: a number is red in the output exactly when it occurs as the gap between two points of the same colour in the input. The question is whether every orbit of this machine reaches the all red colouring in finitely many steps. Three fields are wired in: colouring combinatorics of the Ramsey type (monochromatic pairs at prescribed distances), the elementary arithmetic of the reals under translation, and the dynamics of an iterated map on the space of colourings.

Notice the double role played by the positive reals. They are simultaneously the points being coloured and the distances being classified. That is the whole design of the problem: a statement about the colours of the points $x/2$ and $3x/2$ becomes a statement about the colour of the number x, because $3x/2 - x/2 = x$. Any solution has to exploit that self reference; nothing else is available.

The decisive cue is that the question asks about the colour red, which is defined by an existential statement ("there exist two points of the same colour at distance d"), and existential statements are weak. So chase the other side. A number d is blue exactly when

$$\chi(t) \neq \chi(t+d) \quad \text{for every } t > 0,$$

a statement quantified over all t, and therefore enormously strong: it says the input colouring is a perfect alternation along every arithmetic progression of common difference d. Within thirty seconds you should have written that line down, and then the immediate consequence: two colours means "different" composed with "different" is "same", so $\chi(t+2d) = \chi(t)$ for all t, and hence $2d$ is red in the output. Blue numbers are already fighting each other.

The answer is yes, and in fact two steps always suffice; one step does not, so the constant 2 is sharp.

Approaches, ranked worst to best

1. **Hunt for a counterexample colouring.** *Cue:* the phrasing "will we always". *Circuit:* construct a colouring whose orbit never turns all red. (zombie route: you find, in a minute, that the colouring "red if $\lfloor t \rfloor$ is even" leaves the number 1 blue after one step, and you then spend an hour trying to iterate that idea into a genuine counterexample; the search cannot terminate because there is no counterexample, and it teaches you nothing about why)

2. **Measure theoretic difference sets.** *Cue: D* is a union of difference sets of the colour classes. *Circuit:* apply the Steinhaus theorem: a set of positive measure has a difference set containing an interval about 0. (fails as stated: the colouring is completely arbitrary, so the colour classes need not be measurable, and the hypothesis of the Steinhaus theorem is unavailable; even after patching, it would only give an interval of red numbers, not all of them)

3. **Ramsey and van der Waerden machinery.** *Cue:* monochromatic configurations at prescribed gaps. *Circuit:* quote a theorem guaranteeing monochromatic arithmetic progressions. (heavy artillery aimed at a target that a three point pigeonhole hits: the classical theorems are about colourings of the integers and would need translation and care, and they still would not organise the two step structure)

4. **Doubling only.** *Cue: d* blue forces $2d$ red. *Circuit:* iterate the doubling relation to fill up the line. (a genuine and correct first lemma, and it does half the work, but doubling alone cannot reach a number from below; you can never conclude that a given x is red from statements about $2x, 4x, 8x, \ldots$, so the argument stalls one case short)
5. **Alternation plus the three point pigeonhole.** *Cue:* blue is a for all statement; three points and two colours force a monochromatic pair. *Circuit:* convert blue into perfect alternation, then split any blue gap at its midpoint. (ideal: two short lemmas, then a four point chain $x, 2x, 3x, 4x$ splits into exactly two cases, one killed by doubling and one killed by halving)

The ideal solution

The answer is yes: for every initial colouring, all positive reals are red after two steps, and they stay red thereafter.

Write a colouring as a function χ from $\mathbb{R}^+$ to $\{\text{red}, \text{blue}\}$. For a colouring χ let

$$D(\chi) = \{d > 0 : \chi(t) = \chi(t+d) \text{ for some } t > 0\},$$

which is exactly the set D of the problem, and let $\Phi(\chi)$ be the colouring whose red set is $D(\chi)$. Let χ_0 be the initial colouring, $\chi_n = \Phi^n(\chi_0)$, and write R_n and B_n for the red and blue sets of χ_n, so that $R_{n+1} = D(\chi_n)$ and B_{n+1} is its complement in $\mathbb{R}^+$.

Unwinding the definition gives the only fact we shall use about blue numbers:

$$d \in B_{n+1} \iff \chi_n(t) \neq \chi_n(t+d) \text{ for every } t > 0. \tag{$*$}$$

Lemma 4.9.1 (Doubling)**.** *If $d \in B_{n+1}$ then $2d \in R_{n+1}$.*

Proof. By $(*)$, $\chi_n(t) \neq \chi_n(t+d)$ and $\chi_n(t+d) \neq \chi_n(t+2d)$ for every $t > 0$. There are only two colours, so $\chi_n(t) = \chi_n(t+2d)$. Thus t and $t+2d$ are two points of the same colour at distance $2d$, so $2d \in D(\chi_n) = R_{n+1}$. □

Lemma 4.9.2 (Splitting)**.** *If $d \in B_{n+1}$ then for every s with $0 < s < d$, at least one of s and $d - s$ lies in R_{n+1}. In particular, taking $s = d/2$, we get $d/2 \in R_{n+1}$.*

Proof. Fix any $t > 0$ and look at the three points t, $t+s$, $t+d$. By $(*)$ the outer two have different colours, so the middle one has the same colour as exactly one of them. If $\chi_n(t+s) = \chi_n(t)$ then $s \in D(\chi_n)$; if $\chi_n(t+s) = \chi_n(t+d)$ then $d - s \in D(\chi_n)$. The special case $s = d/2$ makes the two alternatives identical, so no case split survives. □

Theorem 4.9.3. $R_2 = \mathbb{R}^+$.

Proof. Suppose for contradiction that $x \in B_2$ for some $x > 0$. By $(*)$ applied at level $n = 1$, $\chi_1(t) \neq \chi_1(t+x)$ for all $t > 0$. Applying this at $t = x, 2x, 3x$ gives

$$\chi_1(x) \neq \chi_1(2x), \qquad \chi_1(2x) \neq \chi_1(3x), \qquad \chi_1(3x) \neq \chi_1(4x),$$

so with two colours the four numbers split as $\chi_1(x) = \chi_1(3x)$ and $\chi_1(2x) = \chi_1(4x)$, and these two common colours are different. Exactly one of the following two cases holds.

Case A: $2x$ and $4x$ are blue. Apply the Doubling Lemma to $2x \in B_1$: it gives $4x \in R_1$, contradicting $4x \in B_1$.

Case B: x and $3x$ are blue. Apply the Splitting Lemma at the midpoint to each of them: $x/2 \in R_1$ and $3x/2 \in R_1$. So $x/2$ and $3x/2$ are two points of the same colour under χ_1, and their distance is

$$\frac{3x}{2} - \frac{x}{2} = x.$$

Hence $x \in D(\chi_1) = R_2$, contradicting $x \in B_2$.

Both cases are impossible, so B_2 is empty and $R_2 = \mathbb{R}^+$. □

Finally, the all red colouring is a fixed point: if every positive real is red, then for every $d > 0$ the points t and $t + d$ are both red, so $d \in D$ and the recolouring returns all red again. Hence $R_n = \mathbb{R}^+$ for every $n \geq 2$, and the answer to the question is

$$\boxed{\text{yes, and two steps always suffice}}.$$

The constant 2 cannot be improved. Colour t red when $\lfloor t \rfloor$ is even and blue when $\lfloor t \rfloor$ is odd. Then $\lfloor t+1 \rfloor = \lfloor t \rfloor + 1$ for every t, so t and $t+1$ always receive different colours and $1 \notin D(\chi_0)$; that is, $1 \in B_1$ and one step is not enough.

Layer 1: WHAT

Block 1: name the machine and unwind what blue means: d is blue in the output exactly when the input colouring alternates with step d, a statement quantified over all t.

Block 2: two colours turn alternation into periodicity, $\chi(t + 2d) = \chi(t)$, so a blue d forces $2d$ to be red. Blue numbers cannot contain a number together with its double.

Block 3: three points and two colours force a monochromatic pair, so a blue d forces at least one of s and $d - s$ to be red for each $s \in (0, d)$; choosing $s = d/2$, the fixed point of $s \mapsto d - s$, removes the ambiguity and gives $d/2$ red.

Block 4: assume x is blue after two steps. Alternation with step x splits $\{x, 2x, 3x, 4x\}$ into the pair $\{x, 3x\}$ and the pair $\{2x, 4x\}$, monochromatic and of opposite colours in χ_1.

Block 5: if $\{2x, 4x\}$ is the blue pair, doubling applied to $2x$ makes $4x$ red. Contradiction.

Block 6: if $\{x, 3x\}$ is the blue pair, halving makes $x/2$ and $3x/2$ both red; their difference is exactly x, so x is red at the next step. Contradiction.

Block 7: conclude, note stability of the all red colouring, and exhibit the floor parity colouring to show one step is genuinely not enough.

The nominal route reads "will we always" as an invitation to search for a counterexample, and spends its time constructing colourings. The bifurcation point is Block 1: the decision to argue about blue rather than red. Red is an existential property, so knowing a number is red gives you one point pair somewhere on the line, chosen by an adversary. Blue is a universal property, so knowing a number is blue gives you information at every single point of the line. In a problem where you must derive strong conclusions, you must chase the strong hypothesis, which means arguing by contradiction from the complement.

Layer 2: HOW

Block 1. **Cue.** "D is the set of all distances d such that there are two points...", an existential definition, and a question that asks for everything to become red. **Why natural.** To prove a set is everything, assume some element is missing and derive a contradiction. The missing element is blue, and negating the existential quantifier turns the definition inside out into a for all statement about the previous colouring. Writing $(*)$ down is not a step, it is a translation, and translations of quantifiers are always free. **Link to the next block.** You now have a functional equation for the colouring, $\chi_n(t) \neq \chi_n(t + d)$ for all t, and functional equations are things you compose with themselves.

Block 2. **Cue.** "either red or blue": exactly two colours. **Why natural.** With two colours, "different" is an involution: apply the alternation twice and you return to the original colour. So a colouring that alternates with step d is periodic with period $2d$, and periodicity manufactures monochromatic pairs at distance $2d$ for free. This is the only place in the entire solution where the number of colours matters, and it matters absolutely: with three colours the lemma is false. **Link to the next block.** Doubling gives you an upward mechanism; you will also need a downward one.

Block 3. **Cue.** Three points, two colours. **Why natural.** The pigeonhole in its smallest form. If you place a third point anywhere strictly between t and $t+d$, it must agree with one of the ends, and the two possible gaps are s and $d-s$. That is an "or", and an "or" is a nuisance. The way to remove it is to make the two alternatives coincide, which happens exactly at the midpoint $s = d/2$, the fixed point of the involution $s \mapsto d-s$. This is why $3x/2$ appears in the standard write ups: it is the midpoint of x and $2x$, nothing more. **Link to the next block.** You now have both a doubling and a halving rule for blue numbers.

Block 4. **Cue.** The assumption $x \in B_2$ gives alternation with step x for the colouring χ_1, and you have two rules that convert blue numbers into red ones. **Why natural.** Alternation with step x means the colours of $x, 2x, 3x, 4x, \ldots$ alternate, so the odd multiples share a colour and the even multiples share the other. Testing four consecutive multiples is the smallest window that contains both a doubling pair ($2x$ and $4x$) and a halving pair (x and $3x$) whose halves differ by x. You take four because the target distance is x and you need $3x/2 - x/2$. **Link to the next block.** The case split is now forced by the two colours, and each case has a rule waiting for it.

Block 5. **Cue.** $2x$ and $4x$ both blue. **Why natural.** The Doubling Lemma applied to the smaller one immediately says the larger is red. This is why doubling exists: it forbids a blue number and its double from coexisting, and the even multiples in an alternating chain are exactly such a pair. **Link to the next block.** One case down.

Block 6. **Cue.** x and $3x$ both blue, and you are trying to prove something about the number x itself. **Why natural.** The Splitting Lemma halves them, and $3x/2 - x/2 = x$ is exactly the distance you need. This is the self referential heart of the problem: the colours of two points produce the colour of a number, and the number produced is the very one you assumed blue. **Link to the next block.** Contradiction in both cases, so the assumption was false.

Block 7. **Cue.** The question says "after a finite number of steps". **Why natural.** A finite bound invites you to state the exact one and to show it is best possible. The all red colouring is a fixed point (trivially), and the floor parity example shows one step can fail, so 2 is the answer and the solution is complete rather than merely correct.

Layer 3: WHY

The mathematical truth beneath this problem is that being blue is almost impossible. A blue number d certifies that the colouring is a proper 2 colouring of the graph on $\mathbb{R}^+$ whose edges join points at distance d. That graph is a disjoint union of two way infinite paths, one for each coset of $d\mathbb{Z}$, so such colourings exist in abundance, which is why the first step can fail. But a blue number at the second stage demands that the colouring χ_1, which is itself already defined by a difference condition, be one of these rigid alternating colourings, and the alternating structure then forces relations between the colours of $x/2, x, 3x/2, 2x, 3x, 4x$ that cannot all hold. The problem is a two step rigidity cascade: an arbitrary colouring is unconstrained, its recolouring is mildly constrained, and the recolouring of that is over constrained.

The discernment mechanism is a rule about quantifiers. When a problem defines a set by "the values that are realised", the useful hypothesis is always non membership, because non membership is universally quantified and gives you information at every point, whereas membership hands you a single witness chosen by an adversary. Train this by making it mechanical: before doing anything else, write both the definition and its negation in full quantifier form, and look at which of the two you would rather have as a hypothesis. Nine times out of ten it is the negation, and the proof will be by contradiction.

The second mechanism is smaller but reusable: when a pigeonhole produces an "or" between two quantities s and $d - s$ that you get to choose, choose the symmetric point where the two coincide. Symmetrisation to kill a disjunction is a standard reflex, and it is why the solution never has to consider four cases instead of two.

What the examiners nudged toward is visible in two places. They specified exactly two colours, which is what makes doubling work, and they asked for a finite number of steps rather than for the limit behaviour, which signals that the true answer is an explicit small integer. A problem that says "finite" almost always has answer 1, 2 or 3, and the write up should name the number.

Revolving concepts

Difference sets and distance sets. If A_{red} and A_{blue} partition $\mathbb{R}^+$, then $D = ((A_{\text{red}} - A_{\text{red}}) \cup (A_{\text{blue}} - A_{\text{blue}})) \cap \mathbb{R}^+$. Difference sets are the natural home of this problem. The classical theorem in the area is the Steinhaus difference theorem: if $A \subseteq \mathbb{R}$ has positive Lebesgue measure then $A - A$ contains an open interval around 0. It cannot be used here because the colouring is arbitrary and its classes need not be measurable, which is a knowledge gap worth naming rather than hiding. See Book 1, field: Real analysis, topic: difference sets and Steinhaus.

Distance graphs and proper colourings. For fixed $d > 0$, let G_d be the graph on $\mathbb{R}^+$ with $t \sim t + d$. Each connected component is a path, so G_d is bipartite and has proper 2 colourings; a number d is blue for χ exactly when χ is a proper colouring of G_d. Generalising to the graph with edges at distances in a set E, the chromatic number of the line with a forbidden distance set is a large classical topic (the Hadwiger and Nelson problem is its planar cousin). See Book 1, field: Discrete structures and graphs, topic: distance graphs.

Alternation as a recursion, and its generalisation. The condition "$\chi(t + d) \neq \chi(t)$ for all t" is the recursion $u_{k+1} = u_k + 1$ over $\mathbb{F}_2$ along each coset $t + d\mathbb{Z}$, with solution $u_k = u_0 + k$ and hence period 2. The general statement is: if a colouring by m colours satisfies $\chi(t + d) = \sigma(\chi(t))$ for a fixed permutation σ of the colours, then $\chi(t + kd) = \sigma^k(\chi(t))$, and χ is periodic with period $\text{ord}(\sigma) \cdot d$. With $m = 2$ the only fixed point free permutation is the transposition, of order 2, which is why $2d$ is forced red. With $m = 3$ the permutation can be a 3 cycle, the period is $3d$, and the doubling lemma is false: colour t by $\lfloor t \rfloor \bmod 3$ and both 1 and 2 fail to be realised as monochromatic distances. See Book 1, field: Combinatorics, topic: colourings and periodicity.

Iterated maps on colourings and fixed points. The recolouring Φ acts on the set of all 2 colourings. Our theorem says Φ^2 is the constant map onto the all red colouring. Consequently the all red colouring is the unique fixed point of Φ, and there are no periodic orbits of any length: if $\Phi(\chi) = \chi$ then $\chi = \Phi^2(\chi)$, which is all red. See Book 1, field: Logic and set theory, topic: iterated maps and fixed points.

Quantifier negation. $d \notin \{d : \exists t,\ \chi(t) = \chi(t + d)\}$ means $\forall t,\ \chi(t) \neq \chi(t + d)$. Elementary, and the single most valuable move in the problem. See Book 1, field: Logic and set theory, topic: quantifiers.

Circuit Bank

- **WHEN** a set is defined as "the values that are realised" and you must prove it is everything **DO** assume an element is missing and write the negation as a for all statement **BECAUSE** membership gives you one adversarial witness, non membership gives you information at every point, so the complement is always the stronger hypothesis
- **WHEN** a two colouring satisfies $\chi(t) \neq \chi(t + d)$ for all t **DO** write $\chi(t + 2d) = \chi(t)$ at once **BECAUSE** with exactly two colours "different" composed with "different" is "same", so alternation is periodicity of period $2d$ and monochromatic pairs at distance $2d$ appear for free
- **WHEN** a pigeonhole gives you an "or" between two quantities s and $d - s$ with s at your

disposal **DO** choose the symmetric value $s = d/2$ **BECAUSE** the midpoint is the fixed point of $s \mapsto d - s$, so the disjunction collapses and no case analysis survives

- **WHEN** a process is iterated and the question says "after a finite number of steps" **DO** find the unique fixed point, prove an explicit bound, and produce an example showing the bound is sharp **BECAUSE** a finiteness question of this shape almost always has a small explicit answer, and the sharpness example is what turns a correct proof into a complete one

Backtesting

1. First useful cue: D is defined by an existential quantifier and the target is "everything is in D", so the working hypothesis must be that some d is not, written out in full as a for all statement.
2. Method the expression suggested: convert blue into alternation, then extract two rules, one that pushes upward (doubling, from two colours) and one that pushes downward (halving, from the three point pigeonhole at the midpoint).
3. Where you would hesitate, and the thought to reinforce: at the choice of the window $x, 2x, 3x, 4x$. Reinforce this: you are trying to prove that x itself is red, so you need two same coloured points differing by exactly x; the halves $x/2$ and $3x/2$ are the cheapest such pair, and they come from the odd multiples x and $3x$, so the window must reach as far as $4x$ to close the case split.
4. The trap the question sets: the phrase "will we always" invites a counterexample hunt, and the floor parity colouring rewards that hunt with a false positive at step one. Recognise that a one step obstruction is not an obstruction.
5. What makes you recognise it faster next time: any problem in which the objects being coloured and the objects being classified live in the same set is self referential by design, and the solution will use an arithmetic identity connecting a pair of points to the number they define (here $3x/2 - x/2 = x$).
6. The reusable decision rule: negate the defining quantifier, exploit that two colours make alternation an involution, and symmetrise to kill disjunctions.

Mirror drills

1. Show that there is a two colouring of $\mathbb{R}^+$ with no two points of the same colour at distance 1, and prove that any such colouring satisfies $\chi(t+2) = \chi(t)$ for all t. *Answer:* colour t by the parity of $\lfloor t \rfloor$; the alternation condition composed with itself gives period 2.
2. Show that the Doubling Lemma fails for three colours, and identify the exact line of the proof that breaks. *Answer:* colour t by $\lfloor t \rfloor$ mod 3; neither 1 nor 2 is realised as a monochromatic distance, so a blue number and its double coexist. The broken line is "there are only two colours, so $\chi(t) = \chi(t+2d)$": with three colours the alternation can be a 3 cycle of period 3.
3. Prove that the all red colouring is the only colouring fixed by the recolouring map Φ. *Answer:* if $\Phi(\chi) = \chi$ then $\chi = \Phi^2(\chi)$, and Φ^2 is constantly all red by the theorem.

4.10 B4. Cyclic sequences whose triples are progressions

Find all integers n with $n \geq 4$ for which there exists a sequence of distinct real numbers $x_1, \ldots, x_n$ such that each of the sets

$$\{x_1, x_2, x_3\}, \{x_2, x_3, x_4\}, \ldots,$$
$$\{x_{n-2}, x_{n-1}, x_n\}, \{x_{n-1}, x_n, x_1\}, \text{ and } \{x_n, x_1, x_2\}$$

forms a 3-term arithmetic progression when arranged in increasing order.

Read it out loud

A cyclic sequence of pairwise distinct reals in which every window of three consecutive terms, read as an unordered set, is an arithmetic progression. The fields wired in are elementary number theory (a 2-adic scale and a reduction mod 3), the combinatorics of cyclic overlapping windows, and an explicit construction problem. As always with "find all n", the work splits into an obstruction and a construction, and the answer will be a congruence class with the small cases inspected by hand.

The key structural feature is the overlap. Consecutive windows share two of their three elements, so their common differences cannot be unrelated. In a 3-term arithmetic progression with common difference d, the distance between any two members is d or $2d$, and nothing else. Two consecutive windows must therefore agree about the gap $|x_{m+1} - x_{m+2}|$, which forces the ratio d_{m+1}/d_m into $\{1/2, 1, 2\}$. That single line is the engine: it says all the common differences sit on one multiplicative lattice $2^{\mathbb{Z}} d_1$, which is exactly the situation in which you normalise.

Within thirty seconds you should have written three things: that a set $\{a, b, c\}$ is an arithmetic progression exactly when one of the three is the average of the other two (equivalently, $a + b + c$ is three times the middle term); that consecutive common differences are related by a factor $1/2$, 1 or 2; and that scaling and translating the whole sequence changes nothing, so you may put the smallest common difference at 1 and start counting.

The answer is: exactly the multiples of 3 that are at least 9.

Approaches, ranked worst to best

1. **Case analysis on which term is the middle.** *Cue:* the arithmetic progression condition is a linear equation once you know the middle term. *Circuit:* write $x_m + x_{m+2} = 2x_{m+1}$ for each choice and solve the linear system. (zombie route: there are three choices of middle term in each of n windows, so 3^n linear systems; even for $n = 6$ that is 729 systems, and the exponential structure hides the fact that the choices are heavily constrained by the overlaps)

2. **Computer or hand search.** *Cue:* "find all integers n". *Circuit:* enumerate small cases and guess the pattern. (reconnaissance only: it tells you $n = 9$ works and $n = 6$ does not, which is most of the answer and none of the proof, and it will not produce the general construction)

3. **Transfer matrix on window patterns.** *Cue:* each window is labelled by which of its three positions holds the middle term, and consecutive labels are constrained. *Circuit:* encode admissible label words and count closed walks. (workable and genuinely close to a solution: the ratio law is exactly the transition rule of this automaton, and the cyclic closure condition is a closed walk; but the bookkeeping is heavy and you still need an arithmetic invariant to rule out $3 \nmid n$ and a construction for the survivors)

4. **Multiplicative closure of the ratios.** *Cue:* $d_{m+1}/d_m \in \{1/2, 1, 2\}$ and the cycle returns to its start. *Circuit:* take logarithms and note the exponents sum to zero around the cycle. (true, useful, and worth stating as a remark, but on its own it gives no congruence condition on n; it constrains the pattern of doublings, not the length)

5. **Normalise, then reduce modulo 3.** *Cue:* all common differences are powers of 2, hence units modulo 3. *Circuit:* scale the smallest difference to 1, shift to integers, and observe each window is a complete residue system mod 3. (ideal: three lines give $3 \mid n$, a short forced chase kills $n = 6$, and an explicit concatenation of three progressions covers every remaining case)

The ideal solution

The answer is: the multiples of 3 that are at least 9, that is $n \in \{9, 12, 15, \dots\}$. Throughout, "distinct" means pairwise distinct, indices are read modulo n, and T_m denotes the window $\{x_m, x_{m+1}, x_{m+2}\}$. Since the x_i are pairwise distinct, each T_m has three distinct elements, so it is an arithmetic progression with a common difference $d_m > 0$: sorted, $T_m = \{t_m, t_m + d_m, t_m + 2d_m\}$.

Lemma 4.10.1 (Ratio law)**.** *For every m, $d_{m+1} \in \{\frac{1}{2}d_m,\ d_m,\ 2d_m\}$.*

Proof. The distance between two distinct members of a 3-term progression with common difference d is either d or $2d$. The elements x_{m+1} and x_{m+2} lie in both T_m and T_{m+1}, so

$$|x_{m+1} - x_{m+2}| \in \{d_m, 2d_m\} \cap \{d_{m+1}, 2d_{m+1}\},$$

and the four possible matches give $d_{m+1} = d_m$, $d_{m+1} = 2d_m$, $d_{m+1} = \frac{1}{2}d_m$ or $d_{m+1} = d_m$ again. □

Lemma 4.10.2 (Normalisation)**.** *If a sequence exists for a given n, then one exists in which every d_m is a power of 2 with $\min_m d_m = 1$, every x_i is an integer, and the minimum is attained at $m = 1$.*

Proof. The hypothesis is invariant under $x_i \mapsto \lambda x_i + c$ for $\lambda \neq 0$, under cyclic rotation of the indices, and under reversal of the sequence, since all of these carry the family of cyclic windows to itself. By the ratio law every d_m equals $2^{k_m} d_1$ for some integer k_m, so the d_m take finitely many values on one multiplicative lattice and a smallest one exists; rotate so that it occurs at $m = 1$ and scale so that it equals 1. Then every d_m is a power of 2, in particular a positive integer. Consecutive terms lie in a common window, so $x_{m+1} - x_m \in \{\pm d_m, \pm 2d_m\} \subset \mathbb{Z}$, whence every x_i differs from x_1 by an integer; translate by $-x_1$. □

Proposition 4.10.3. *If such a sequence exists then $3 \mid n$.*

Proof. Normalise as above. Each d_m is a power of 2 and is therefore not divisible by 3, so in the progression $t_m, t_m + d_m, t_m + 2d_m$ the three residues modulo 3 are pairwise distinct: each window T_m is a complete residue system modulo 3. Now T_m and T_{m+1} share x_{m+1} and x_{m+2}, which occupy two of the three residue classes, so x_{m+3} and x_m must both occupy the remaining one:

$$x_{m+3} \equiv x_m \pmod 3 \qquad \text{for all } m.$$

(The same conclusion follows from the fact that the sum of a 3-term progression is three times its middle term, so $x_m + x_{m+1} + x_{m+2} \equiv 0 \pmod 3$ for every m, and subtracting consecutive instances gives $x_{m+3} \equiv x_m$.) Thus the map $m \mapsto x_m \bmod 3$ on $\mathbb{Z}/n$ is invariant under the shift by 3. If $3 \nmid n$ then 3 is a generator of $\mathbb{Z}/n$, so that map is constant, contradicting the fact that x_1, x_2, x_3 lie in three different residue classes. Hence $3 \mid n$. □

Proposition 4.10.4. *There is no such sequence with $n = 6$.*

Proof. Normalise as above, so $d_1 = 1 = \min_m d_m$, every d_m is a power of 2, the x_i are integers, and $T_1 = \{x_1, x_2, x_3\}$ is a set of three consecutive integers; translating, $T_1 = \{0, 1, 2\}$. The reversal $x_i \mapsto x_{4-i}$ (indices mod 6) preserves the hypothesis and exchanges x_1 with x_3, and the reflection $x \mapsto 2 - x$ preserves the hypothesis and fixes T_1. Under the group these generate, the six orderings of $\{0, 1, 2\}$ fall into the two classes represented by $(x_1, x_2, x_3) = (0, 1, 2)$ and $(x_1, x_2, x_3) = (0, 2, 1)$.

In both cases $\{x_2, x_3\} = \{1, 2\}$, a pair at distance 1. Since every $d_m \geq 1$, a gap of 1 inside T_2 must equal d_2 (it cannot equal $2d_2 \geq 2$), so $d_2 = 1$ and T_2 is a set of three consecutive integers containing 1 and 2 adjacently: either $\{0, 1, 2\}$, forcing $x_4 = 0 = x_1$, or $\{1, 2, 3\}$. Distinctness leaves $x_4 = 3$.

Case A: $(x_1, x_2, x_3) = (0, 1, 2)$. Then $x_3 = 2$ and $x_4 = 3$ are at distance 1, so as above $d_3 = 1$ and $T_3 \in \{\{1, 2, 3\}, \{2, 3, 4\}\}$, giving $x_5 \in \{1, 4\}$; but $1 = x_2$, so $x_5 = 4$. Repeating with $\{x_4, x_5\} = \{3, 4\}$ gives $d_4 = 1$ and $x_6 \in \{2, 5\}$; but $2 = x_3$, so $x_6 = 5$. The window $\{x_5, x_6, x_1\} = \{0, 4, 5\}$ has gaps 4 and 1, so it is not an arithmetic progression.

Case B: $(x_1, x_2, x_3) = (0, 2, 1)$. Then $x_3 = 1$ and $x_4 = 3$ are at distance 2, so $d_3 \in \{1, 2\}$. If $d_3 = 1$ then 1 and 3 are the two endpoints of T_3 and $x_5 = 2 = x_2$, excluded. So $d_3 = 2$ and $T_3 \in \{\{-1, 1, 3\}, \{1, 3, 5\}\}$, giving $x_5 \in \{-1, 5\}$.

If $x_5 = -1$, then x_4 and x_5 are at distance 4, so $d_4 \in \{2, 4\}$; $d_4 = 2$ makes -1 and 3 the endpoints and $x_6 = 1 = x_3$, excluded, so $d_4 = 4$ and $x_6 \in \{-5, 7\}$. The window $\{x_5, x_6, x_1\}$ is then $\{-5, -1, 0\}$ with gaps 4 and 1, or $\{-1, 0, 7\}$ with gaps 1 and 7; neither is an arithmetic progression.

If $x_5 = 5$, then x_4 and x_5 are at distance 2, so $d_4 \in \{1, 2\}$, giving $x_6 = 4$ (from $d_4 = 1$) or $x_6 \in \{1, 7\}$ (from $d_4 = 2$), of which $1 = x_3$ is excluded. The window $\{x_5, x_6, x_1\}$ is then $\{0, 4, 5\}$ with gaps 4 and 1, or $\{0, 5, 7\}$ with gaps 5 and 2; neither is an arithmetic progression.

Every branch fails, so no sequence exists for $n = 6$. □

Proposition 4.10.5. *For every integer $m \geq 2$ there is such a sequence with $n = 3m + 3$.*

Proof. Concatenate the three progressions

$$(1, 3, 5, \ldots, 4m - 1), \quad (4m - 2), \quad (4m, 4m - 4, \ldots, 4, 0), \quad (2),$$

that is, take the $2m$ odd numbers from 1 to $4m - 1$ in increasing order, then $4m - 2$, then the $m + 1$ multiples of 4 from $4m$ down to 0 in decreasing order, then 2. The length is $2m + 1 + (m + 1) + 1 = 3m + 3$.

The terms are distinct: the first block consists of odd numbers, the third block of multiples of 4, and the two remaining terms $4m - 2$ and 2 are congruent to 2 modulo 4 and are distinct because $m \geq 2$.

Every cyclic window is an arithmetic progression. Windows inside the first block are $\{4i - 3, 4i - 1, 4i + 1\}$, of common difference 2. Windows inside the third block are $\{4j - 4, 4j, 4j + 4\}$, of common difference 4. The seven remaining windows, in order, are

$$\{4m - 3, 4m - 1, 4m - 2\}, \quad \{4m - 1, 4m - 2, 4m\}, \quad \{4m - 2, 4m, 4m - 4\},$$
$$\{4m, 4m - 4, 4m - 8\}, \quad \{4, 0, 2\}, \quad \{0, 2, 1\}, \quad \{2, 1, 3\},$$

with common differences $1, 1, 2, 4, 2, 1, 1$ respectively (the fourth is already of the interior type when $m \geq 2$). All are arithmetic progressions. □

Combining, the values of $n \geq 4$ for which a sequence exists are

$$\boxed{n \equiv 0 \pmod 3 \text{ with } n \geq 9}.$$

For orientation, the case $m = 2$ reads $1, 3, 5, 7, 6, 8, 4, 0, 2$.

Layer 1: WHAT

Block 1: read the condition as a statement about unordered sets, so each window has a well defined positive common difference d_m.

Block 2: consecutive windows overlap in two terms, and in a progression every internal gap is d or $2d$; this forces $d_{m+1}/d_m \in \{1/2, 1, 2\}$.

Block 3: therefore all d_m lie on the lattice $2^{\mathbb{Z}} d_1$. Scale the smallest to 1 and rotate it to position 1; every difference becomes a power of 2 and every term becomes an integer after a shift.

Block 4: powers of 2 are units modulo 3, so each window occupies all three residue classes; hence $x_{m+3} \equiv x_m \pmod 3$, and on a cycle of length n this forces $3 \mid n$ unless the residues are constant, which they are not.

Block 5: for $n = 6$ the normalisation pins $\{x_1, x_2, x_3\} = \{0, 1, 2\}$, the symmetries cut six orderings to two, and the minimality of d_1 forces every subsequent term; five branches survive to x_6 and all five fail the closing window.

Block 6: for $n = 3m + 3$ with $m \geq 2$, concatenate an increasing progression of odds, a single term, a decreasing progression of multiples of 4, and one more term; check the seven junction windows and the distinctness by residues modulo 4.

The nominal route fixes attention on the terms x_i, of which there are n unknowns, and on the choice of middle term in each window, of which there are 3^n patterns. The bifurcation point is Block 2: look at the differences, not the terms. The differences are a single positive number together with a walk of exponents in $\{-1, 0, 1\}$, which is one unknown and a bounded walk. That is the reduction that makes everything else possible, and it is available only because the windows overlap in two places rather than one.

Layer 2: HOW

Block 1. **Cue.** "forms a 3-term arithmetic progression when arranged in increasing order", and "distinct real numbers". **Why natural.** Sorting is what makes the common difference well defined and positive; distinctness is what stops d_m from being 0. Naming d_m turns a geometric condition on a set into a numerical parameter you can chase around the cycle. **Link to the next block.** You now have n parameters $d_1, \ldots, d_n$ attached to overlapping windows, so the next question is how consecutive ones interact.

Block 2. **Cue.** Consecutive windows share two elements. **Why natural.** The only distances available inside a 3-term progression of difference d are d and $2d$. A shared pair therefore has to be describable by both windows, which is a two by two matching and gives a ratio in $\{1/2, 1, 2\}$. Whenever consecutive constraints overlap in all but one element, the correct first move is always to write the compatibility relation between their local parameters. **Link to the next block.** The differences live on a multiplicative lattice, which is the standard setup for a normalisation.

Block 3. **Cue.** A finite set of positive reals closed under ratios that are powers of 2, plus a problem invariant under scaling and translation. **Why natural.** Scaling is free, so put the smallest difference at 1; then every difference is a positive integer power of 2. Consecutive terms differ by $\pm d_m$ or $\pm 2d_m$, all integers, so after one translation the whole sequence is integral. Normalising is not cosmetic: it is what makes a congruence argument legal, since congruences require integers. **Link to the next block.** Integers plus differences that are powers of 2 is a request for a modulus in which 2 is a unit.

Block 4. **Cue.** Every common difference is a power of 2, so no d_m is divisible by 3. **Why natural.** In $\{t, t + d, t + 2d\}$ with $\gcd(d, 3) = 1$, the three residues mod 3 are distinct, so a window is a complete residue system. Two consecutive windows share two elements, so the third elements agree modulo 3, and the residue pattern is 3 periodic. On $\mathbb{Z}/n$ a shift by 3 generates everything unless $3 \mid n$, and a constant residue pattern is impossible. The choice of modulus is forced: you want the smallest modulus in which all possible differences are invertible and in which a 3-term progression is spread out, and 3 is it. **Link to the next block.** Only the boundary cases $n = 6$ and the construction remain.

Block 5. **Cue.** $n = 6$ is the one multiple of 3 in range that the construction will not reach, and the normalisation has already pinned the first window. **Why natural.** With $d_1 = 1$ minimal and $T_1 = \{0, 1, 2\}$, every later step is forced: a gap of 1 between two known consecutive terms cannot

be $2d$, so $d = 1$ and there are only two candidate windows, one of which repeats an earlier term. Distinctness is doing the pruning, which is why the chase terminates instead of branching. Reversal and the reflection $x \mapsto 2 - x$ cut the six starting orders to two before the chase begins, which is the difference between two cases and six. **Link to the next block.** The obstruction is complete; now produce examples.

Block 6. Cue. A construction is needed for every multiple of 3 from 9 upwards, so it must be a family with a free parameter. **Why natural.** Long stretches of a single progression give interior windows for free, so the design problem is only about the junctions. You need to leave one progression and enter another with two junction windows that are themselves progressions, and you need the cycle to close through two extra terms. Choosing the blocks to be odd numbers and multiples of 4, with the two connectors congruent to 2 modulo 4, makes distinctness a residue check rather than an inequality chase.

Layer 3: WHY

Two invariants run this problem, one multiplicative and one additive, and they are linked by the normalisation.

The multiplicative invariant is the ratio law. Writing $d_{m+1} = 2^{\varepsilon_m} d_m$ with $\varepsilon_m \in \{-1, 0, 1\}$ and going once around the cycle gives $\sum_{m=1}^{n} \varepsilon_m = 0$: the number of doublings equals the number of halvings. This is the general shape of every cyclic problem with local multiplicative constraints. Take logarithms, and a local constraint becomes a bounded walk that must return to its starting point.

The additive invariant is the residue pattern modulo 3. It is available only because the ratios are powers of 2, so that 2 is a unit in the chosen modulus and a progression cannot collapse into fewer than three residue classes. The general principle: to convert a statement about gaps into a statement about labels, reduce modulo a q in which every possible gap is invertible; then arithmetic progressions become rainbow patterns and periodicity arguments become available.

The discernment mechanism is a question you should ask of any cyclic or chain problem: what is the local compatibility relation between consecutive constraints, and what does it force after one full lap? Here the lap gives two things, the exponent sum zero and the residue period 3, and the second is the one that constrains n. Training this means always converting a global existence question into a one step recursion plus a closure condition, before attempting any construction.

What the examiners nudged toward is visible in the phrase "when arranged in increasing order". Had the windows been progressions in the given order, the sequence would have constant difference d and the cycle would force $nd = 0$, killing everything at once; the reordering is exactly what creates the three way choice, hence the ratio law, hence the whole problem. The lower bound $n \geq 4$ is also a nudge: it quietly removes $n = 3$, where the three windows are all the same set, so that the only interesting small case left for you to inspect is $n = 6$.

Revolving concepts

Three term progressions. A set $\{a, b, c\}$ of distinct reals is an arithmetic progression exactly when one element is the mean of the other two, equivalently when $a + b + c$ is three times one of them. Consequences used here: the internal distances are d and $2d$ only; the sum is three times the middle term, which is why sums of consecutive windows differ by $x_{m+3} - x_m$ and give the mod 3 periodicity in one line. See Book 1, field: Sequences and recurrences, topic: arithmetic progressions.

Overlapping window recursions and their generalisation. A constraint imposed on every window of length k in a cyclic sequence becomes a one step recursion on the local parameters, together with a closure condition after n steps. Here the recursion is $d_{m+1} = 2^{\varepsilon_m} d_m$ with $\varepsilon_m \in \{-1, 0, 1\}$, whose general solution is $d_m = 2^{\varepsilon_1 + \cdots + \varepsilon_{m-1}} d_1$, and the closure condition is $\sum_{m=1}^{n} \varepsilon_m = 0$.

The same pattern governs every cyclic problem with local multiplicative constraints: take logarithms, obtain a bounded walk, and impose that it returns to its start. See Book 1, field: Sequences and recurrences, topic: cyclic recursions and closure.

Normalisation by the symmetry group. The hypothesis is invariant under the affine maps $x \mapsto \lambda x + c$ with $\lambda \neq 0$, under cyclic rotation, and under reversal. Spending this group to place the extremal object (the smallest common difference) at a standard position is the standard extremal normalisation, and it is what reduces the $n = 6$ analysis from six starting orders to two. See Book 1, field: Combinatorics, topic: normalisation and extremal choice.

Reduction modulo a unit. If every difference appearing in a configuration is invertible modulo q, then progressions occupy distinct residues mod q, and metric statements become colouring statements. Here $q = 3$ and the differences are powers of 2. The general slogan: choose the modulus so that the step sizes become units. See Book 1, field: Number theory, topic: choosing a modulus.

Cyclic periodicity. A function on $\mathbb{Z}/n$ invariant under the shift by p is constant on the cosets of the subgroup generated by p, which has index $\gcd(p, n)$. So p periodicity plus non constancy forces $\gcd(p, n) > 1$, and here $p = 3$ gives $3 \mid n$. See Book 1, field: Number theory, topic: cyclic groups and periods.

Circuit Bank

- **WHEN** consecutive constraints overlap in all but one element **DO** write the compatibility relation between their local parameters immediately **BECAUSE** overlapping windows convert a global search over all terms into a one step recursion on a single parameter, which is the difference between 3^n cases and one lemma
- **WHEN** local parameters are related by bounded multiplicative factors and the problem is scale invariant **DO** take the smallest, scale it to 1, and check that everything becomes integral **BECAUSE** a multiplicative lattice with a minimum is exactly the setup for a reduction to integers, and congruence arguments are illegal until you have integers
- **WHEN** all the step sizes in a configuration are units modulo some small q **DO** reduce modulo q and look at which residues each configuration occupies **BECAUSE** a progression whose difference is invertible occupies distinct residues, so a metric condition becomes a colouring condition and periodicity arguments become available
- **WHEN** a cyclic object forces a pattern of period p **DO** conclude $\gcd(p, n) > 1$ or the pattern is constant **BECAUSE** the shift by p on $\mathbb{Z}/n$ generates a subgroup of index $\gcd(p, n)$, so a nonconstant p periodic pattern cannot exist when $\gcd(p, n) = 1$
- **WHEN** the answer is a congruence class with small exceptions **DO** handle the smallest case by a forced chase from the normalised extremal position, and build the general case as blocks with only junctions to check **BECAUSE** minimality plus distinctness prunes the chase to a handful of branches, and interior windows of a long block are free

Backtesting

1. First useful cue: consecutive windows share two elements, and in a 3-term progression only the gaps d and $2d$ occur; that pairing gives the ratio law before any algebra.
2. Method the expression suggested: pass from the terms to the common differences, normalise the smallest to 1, become integral, and then reduce modulo 3.
3. Where you would hesitate, and the thought to reinforce: at the choice of modulus. Reinforce this: the modulus is not guessed, it is determined by the requirement that every possible difference be a unit and that a progression have three distinct residues. Powers of 2 are units

modulo every odd number, and 3 is the smallest odd modulus in which a progression is a complete residue system.

4. The trap the question sets: assuming the answer is "all multiples of 3" and never testing $n = 6$; the construction needs two connector terms with the same residue mod 4, and at $m = 1$ they collide, which is exactly why 6 fails.
5. What makes you recognise it faster next time: cyclic sequences with a local condition on every window are always a one step recursion plus a closure condition; if the local condition is multiplicative, take logarithms, and if it is additive, sum around the cycle.
6. The reusable decision rule: differences before terms, normalise before congruences, and always inspect the smallest member of the surviving congruence class by hand.

Mirror drills

1. Show that in any such sequence, the number of indices m with $d_{m+1} = 2d_m$ equals the number with $d_{m+1} = \frac{1}{2}d_m$. *Answer:* write $d_{m+1} = 2^{\varepsilon_m} d_m$ and sum ε_m around the cycle; the sum telescopes to $\log_2(d_1/d_1) = 0$.
2. For which $n \geq 3$ is there a cyclic sequence of distinct reals with x_m, x_{m+1}, x_{m+2} an arithmetic progression in that order for every m? *Answer:* none. The condition says $x_{m+1} - x_m$ is a constant d, and summing around the cycle gives $nd = 0$, so $d = 0$ and the terms coincide. This is exactly what the phrase "when arranged in increasing order" is there to prevent.
3. Verify that $1, 3, 5, 7, 6, 8, 4, 0, 2$ works and identify the three blocks and the junction windows. *Answer:* the blocks are $(1, 3, 5, 7)$ of difference 2, $(8, 4, 0)$ of difference 4, and the connectors 6 and 2; the junction windows are $\{5, 7, 6\}, \{7, 6, 8\}, \{6, 8, 4\}, \{4, 0, 2\}, \{0, 2, 1\}, \{2, 1, 3\}$, with differences $1, 1, 2, 2, 1, 1$.

4.11 B5. When zero is the most likely weighted sum

For $0 \leq p \leq 1/2$, let $X_1, X_2, \ldots$ be independent random variables such that

$$X_i = \begin{cases} 1 & \text{with probability } p, \\ -1 & \text{with probability } p, \\ 0 & \text{with probability } 1-2p, \end{cases}$$

for all $i \geq 1$. Given a positive integer n and integers $b, a_1, \ldots, a_n$, let $P(b, a_1, \ldots, a_n)$ denote the probability that $a_1X_1 + \cdots + a_nX_n = b$. For which values of p is it the case that

$$P(0, a_1, \ldots, a_n) \geq P(b, a_1, \ldots, a_n)$$

for all positive integers n and all integers $b, a_1, \ldots, a_n$?

Read it out loud

A lazy symmetric three point random walk step, rescaled by arbitrary integer weights and summed, with the question: for which p is the origin always the most likely outcome, whatever the weights? The fields wired in are probability (independence and distributions of integer valued sums), generating functions (a probability of an exact integer value is a coefficient), and harmonic analysis on the circle (the coefficient is a Fourier coefficient, and "largest at 0" is a positivity statement).

What is really being tested is whether you can name the right closed class. The property "the distribution has its maximum at 0" is a statement about one coefficient among many, and coefficientwise statements do not survive convolution. So the reflex must be: transform. Write the distribution of $a_1X_1 + \cdots + a_nX_n$ as a product, because independence is multiplicative after transforming, and then ask what property of a single factor is both multiplicative and strong enough to force the maximum to sit at 0.

Within thirty seconds you should have written

$$E\left[x^S\right] = \prod_{k=1}^{n} f(x^{a_k}), \qquad f(x) = px + px^{-1} + (1-2p),$$

and then set $x = e^{i\theta}$ to get $f(e^{i\theta}) = 1 - 2p + 2p\cos\theta$, a real function whose minimum over θ is $1 - 4p$. The threshold in the answer is already visible: $p = 1/4$ is exactly where a single step stops having a nonnegative transform, equivalently where the palindromic quadratic $pt^2 + (1-2p)t + p$ stops having real roots, its discriminant being $(1-2p)^2 - 4p^2 = 1 - 4p$.

The answer is $0 \leq p \leq 1/4$.

Approaches, ranked worst to best

1. **Injection between representations.** *Cue:* two probabilities are being compared, and each is a sum over solutions of a linear equation. *Circuit:* build an injection from the solutions of $\sum a_k X_k = b$ into the solutions of $\sum a_k X_k = 0$. (zombie route: the terms carry unequal weights, since a solution with j nonzero coordinates has probability $p^j(1-2p)^{n-j}$, so an injection proves nothing unless it does not decrease the number of zero coordinates, and no such injection exists in general; the counterexample family for $p > 1/4$ is precisely a case where the target has more solutions than the source)

2. **Induction on n with a unimodality hypothesis.** *Cue:* sums of independent symmetric variables. *Circuit:* prove the distribution is symmetric and unimodal, hence maximal at 0. (fails at the first step: the weights a_k put the summands on different lattices, so unimodality is not available, and the class of distributions whose maximum sits at 0 is not visibly closed under convolution, so the induction has no invariant class to live in)

3. **Threshold hunting by examples.** *Cue:* "for which values of p". *Circuit:* test small configurations until the inequality breaks. (necessary reconnaissance, and it does deliver the exact threshold if you pick the right family, but it proves only one of the two halves)
4. **Laurent polynomial factorisation.** *Cue:* $f(x) = px + px^{-1} + (1-2p)$ is palindromic. *Circuit:* factor $f(x) = \frac{p}{\alpha}(x+\alpha)(x^{-1}+\alpha)$ and write the whole product as $g(x)g(x^{-1})$, then compare coefficients by Cauchy and Schwarz. (correct, fully elementary, and it exposes the discriminant $1-4p$ as the source of the threshold; it ranks just below the transform route only because it needs a separate word for $p=0$ and a normalisation from Laurent polynomials to genuine polynomials)
5. **Characteristic functions.** *Cue:* a probability of an exact integer value is a Fourier coefficient, and independence is multiplication. *Circuit:* prove the transform of one step is nonnegative and note that nonnegativity is multiplicative. (ideal: three standard facts, no edge cases, and the threshold appears as the minimum of $1-2p+2p\cos\theta$)

The ideal solution

The answer is

$$\boxed{0 \le p \le \tfrac{1}{4}}.$$

Write $S = a_1X_1 + \cdots + a_nX_n$, an integer valued random variable taking finitely many values.

Part 1: every p with $1/4 < p \le 1/2$ fails.

First dispose of $p = 1/2$: take $n = 1$, $a_1 = 1$, $b = 1$. Then $P(0,1) = 1-2p = 0 < 1/2 = P(1,1)$.

Now let $1/4 < p < 1/2$ and take $a_k = 2^{k-1}$ for $k = 1, \dots, n$, with $b = 1$.

The only $(X_1, \dots, X_n) \in \{0, \pm 1\}^n$ with $\sum_k 2^{k-1}X_k = 0$ is the zero vector. Indeed, if some coordinate is nonzero, let j be the largest index with $X_j \neq 0$; then $\left|\sum_{k<j} 2^{k-1}X_k\right| \le 2^{j-1} - 1$, so the total has absolute value at least $2^{j-1} - (2^{j-1}-1) = 1$. Hence

$$P(0, a_1, \dots, a_n) = (1-2p)^n.$$

Next, the solutions of $\sum_k 2^{k-1}X_k = 1$ are exactly the n vectors

$$(\underbrace{-1, \dots, -1}_{j-1}, 1, 0, \dots, 0), \qquad j = 1, \dots, n,$$

since $2^{j-1} - (2^{j-2} + \cdots + 1) = 1$. To see there are no others, let j again be the largest index with $X_j \neq 0$. If $X_j = -1$ the sum is at most $-2^{j-1} + (2^{j-1}-1) = -1 < 1$, so $X_j = 1$ and the remaining coordinates must sum to $1 - 2^{j-1} = -(2^{j-1}-1)$, the least value they can attain, which happens only when $X_k = -1$ for every $k < j$. The vector indexed by j has exactly j nonzero coordinates, so

$$P(1, a_1, \dots, a_n) = \sum_{j=1}^{n} p^j (1-2p)^{n-j}.$$

Dividing, and writing $r = \dfrac{p}{1-2p} > 0$ (legitimate since $p < 1/2$),

$$\frac{P(1, a_1, \dots, a_n)}{P(0, a_1, \dots, a_n)} = \sum_{j=1}^{n} r^j.$$

Now $r > 1/2$ if and only if $2p > 1-2p$, that is $p > 1/4$. If $r \ge 1$ the partial sums are at least n and exceed 1 as soon as $n \ge 2$; if $1/2 < r < 1$ the partial sums increase to $r/(1-r) > 1$, so they exceed 1 for all large n. Either way there is an n with $P(1, a_1, \dots, a_n) > P(0, a_1, \dots, a_n)$, so p fails.

Part 2: every p with $0 \le p \le 1/4$ works.

For an integer valued random variable X taking finitely many values, define its characteristic function

$$\varphi_X(\theta) = E\left[e^{iX\theta}\right] = \sum_{\ell\in\mathbb{Z}} \Pr(X=\ell)\, e^{i\ell\theta},$$

a finite trigonometric sum. We use three facts, each one line.

Inversion. For every integer b,

$$\frac{1}{2\pi}\int_0^{2\pi} e^{-ib\theta}\varphi_X(\theta)\,d\theta = \sum_{\ell}\Pr(X=\ell)\cdot\frac{1}{2\pi}\int_0^{2\pi} e^{i(\ell-b)\theta}\,d\theta = \Pr(X=b),$$

because the inner integral is 1 when $\ell = b$ and 0 otherwise.

Independence. If X and Y are independent then $\varphi_{X+Y} = \varphi_X\varphi_Y$, since $E[e^{i(X+Y)\theta}] = E[e^{iX\theta}]E[e^{iY\theta}]$.

Scaling. For an integer a, $\varphi_{aX}(\theta) = E[e^{iaX\theta}] = \varphi_X(a\theta)$.

For our steps,

$$\varphi_{X_k}(\theta) = (1-2p) + pe^{i\theta} + pe^{-i\theta} = 1 - 2p + 2p\cos\theta \geq 1 - 4p \geq 0$$

for all θ, using $p \leq 1/4$. Hence, by independence and scaling,

$$\varphi_S(\theta) = \prod_{k=1}^{n}\varphi_{X_k}(a_k\theta) = \prod_{k=1}^{n}\big(1 - 2p + 2p\cos(a_k\theta)\big) \geq 0.$$

Finally, for any integer b, inversion and $|e^{-ib\theta}| = 1$ give

$$P(b,a_1,\ldots,a_n) = \frac{1}{2\pi}\int_0^{2\pi} e^{-ib\theta}\varphi_S(\theta)\,d\theta \leq \frac{1}{2\pi}\int_0^{2\pi}|\varphi_S(\theta)|\,d\theta = \frac{1}{2\pi}\int_0^{2\pi}\varphi_S(\theta)\,d\theta = P(0,a_1,\ldots,a_n),$$

where the last two steps use $\varphi_S \geq 0$ and inversion at $b = 0$. This holds for every n and all integers $b, a_1, \ldots, a_n$, which completes the proof.

Layer 1: WHAT

Block 1: recognise $P(b,a_1,\ldots,a_n)$ as a coefficient. Independence says the distribution of S is a convolution, and convolutions become products only after a transform, so transform first and ask questions later.

Block 2: on the unit circle the transform of one step is $1 - 2p + 2p\cos\theta$, a real function, and the transform of S is the product of such factors at the arguments $a_k\theta$.

Block 3: identify the correct multiplicative property. "The coefficient at 0 is the largest" is not multiplicative; "the function is nonnegative" is, and it implies the former, because the coefficient at 0 is the average of the function and every other coefficient is bounded by the average of the modulus.

Block 4: the single step transform has minimum $1 - 4p$ at $\theta = \pi$, so nonnegativity holds exactly when $p \leq 1/4$. Sufficiency is finished.

Block 5: for necessity, design the weights so that 0 is starved: powers of 2 make 0 uniquely representable while $b = 1$ has a chain of n representations whose probabilities form a geometric sequence with ratio $r = p/(1-2p)$.

Block 6: the ratio of the two probabilities is $\sum_{j=1}^{n} r^j$, which can exceed 1 exactly when $r > 1/2$, that is when $p > 1/4$. The two halves meet at the same number by two different looking computations, and Layer 3 explains why they must.

The nominal route reads the problem as a comparison of two counts and starts building injections between solution sets. The bifurcation point is Block 1: the decision to stop looking at individual outcomes and to encode the whole distribution in one function. Everything after that is forced, because there is exactly one property of a single factor that both multiplies and controls coefficients.

Layer 2: HOW

Block 1. Cue. Independent summands, integer values, and a probability of an exact value. **Why natural.** Independence is a multiplicative hypothesis, but only after you leave the space of distributions and enter the space of transforms. A probability of an exact integer value is a coefficient, and coefficients of products are convolutions, so the dictionary runs in the direction you need. Writing $E[x^S] = \prod f(x^{a_k})$ costs one line and converts the entire hypothesis into a formula. **Link to the next block.** You now need to decide where to evaluate x.

Block 2. Cue. The Laurent polynomial $f(x) = px + px^{-1} + (1-2p)$ is palindromic, that is invariant under $x \mapsto x^{-1}$. **Why natural.** Palindromic means real on the unit circle, since $x^{-1} = \bar{x}$ there. That is the cue to set $x = e^{i\theta}$: the object becomes a real valued function of a real variable, and real valued functions have signs, and signs are things you can use. Off the circle the product is a complex mess with no order structure. **Link to the next block.** On the circle the coefficient extraction becomes an integral.

Block 3. Cue. You must prove one coefficient dominates all the others, uniformly over n and over the weights. **Why natural.** Uniform statements over an unbounded family need a property closed under the operation that builds the family, and the operation here is multiplication of transforms. So ask which properties are multiplicative. "Nonnegative on the circle" is multiplicative and immediately gives coefficient domination through the triangle inequality for integrals, since the zeroth coefficient is the mean of the function and every other coefficient is at most the mean of its modulus. That is the whole engine, and it is the standard notion of a positive definite sequence. **Link to the next block.** It remains to check nonnegativity for a single factor.

Block 4. Cue. $1 - 2p + 2p\cos\theta$ with $\cos\theta$ ranging over $[-1, 1]$. **Why natural.** The minimum is at $\theta = \pi$, where the two symmetric atoms at ± 1 interfere destructively with each other and constructively against the atom at 0. The value $1 - 4p$ is a discriminant in disguise, and the condition $p \le 1/4$ is exactly the condition under which the step distribution is a self convolution of a signed measure, that is, a square. **Link to the next block.** Sufficiency is complete; the threshold now has to be shown sharp.

Block 5. Cue. To break "the mode is at 0", starve the origin. **Why natural.** $P(0)$ is a sum over all representations of 0, so make that sum a single term. Weights $1, 2, 4, \ldots, 2^{n-1}$ do it, because binary expansions with digits $0, \pm 1$ represent 0 only trivially. Meanwhile $b = 1$ picks up the whole chain $1, -1+2, -1-2+4$, and so on: the borrow chain of binary arithmetic. Choosing the weights so that one target has a unique representation and a neighbouring target has a geometric family is the standard design for this kind of counterexample. **Link to the next block.** The two probabilities are now a single term against a geometric sum.

Block 6. Cue. A geometric series with ratio $r = p/(1-2p)$ compared to 1. **Why natural.** $\sum_{j \ge 1} r^j > 1$ exactly when $r > 1/2$, and $r > 1/2$ is $2p > 1 - 2p$, that is $p > 1/4$. No case analysis on p is needed and no asymptotics beyond the elementary geometric series, provided you divide by $P(0)$ first instead of expanding both sides.

Layer 3: WHY

The mathematical truth underneath is the theory of positive definite sequences. A sequence $(c_b)_{b \in \mathbb{Z}}$ is the Fourier coefficient sequence of a nonnegative function on the circle exactly when it is positive definite, and every positive definite sequence satisfies $|c_b| \le c_0$. Our problem asks for the values of p making the step distribution positive definite, because positive definiteness is preserved by

the two operations the problem applies: independent sums (products of transforms) and integer rescaling $X \mapsto aX$ (which replaces θ by $a\theta$). The property actually asked about, "the maximum is at 0", is a consequence of positive definiteness but is not itself closed under these operations, which is why every attempt to induct directly on n stalls. This is the general lesson: when a property must survive an operation, strengthen it to the property the transform makes multiplicative.

The two routes to sufficiency are the same proof in two alphabets. Since $p \le 1/4$, the palindromic quadratic $pt^2 + (1-2p)t + p$ has real roots α and $1/\alpha$ with $\alpha > 0$, so for $p > 0$

$$f(x) = \frac{p}{\alpha}\,(x+\alpha)(x^{-1}+\alpha), \qquad \prod_k f(x^{a_k}) = g(x)\,g(x^{-1}), \quad g(x) = \Big(\frac{p}{\alpha}\Big)^{n/2} \prod_k (x^{a_k}+\alpha),$$

after multiplying g by a power of x to clear negative exponents, which does not change $g(x)g(x^{-1})$. Writing $g(x) = \sum_j c_j x^j$, the coefficient of x^0 in $g(x)g(x^{-1})$ is $\sum_j c_j^2$ and the coefficient of x^b is $\sum_j c_j c_{j+b}$, and $\sum_j c_j c_{j+b} \le \sum_j c_j^2$ by Cauchy and Schwarz. Setting $x = e^{i\theta}$ turns $g(x)g(x^{-1})$ into $|g(e^{i\theta})|^2$, so the factorisation and the nonnegativity of the transform are literally the same statement; the general fact behind it is the Fejer and Riesz theorem, that every nonnegative trigonometric polynomial is $|g(e^{i\theta})|^2$ for some polynomial g. That is also why the threshold appears twice, once as a discriminant $1-4p$ and once as a geometric ratio $r \le 1/2$: both are the statement that the quadratic factors over the reals.

The discernment mechanism is short. When a problem quantifies over an unbounded family built by one operation, find the transform under which the operation becomes multiplication, then find the multiplicative property that implies what you want. To train it, keep a list of the transforms and the operations they linearise: generating functions for convolution of sequences, characteristic functions for sums of independent variables, logarithms for products, determinants for composition of maps.

What the examiners nudged toward is the number $1/2$ in the range $0 \le p \le 1/2$, which is there only to make $1-2p$ a probability, and the phrase "for all positive integers n", which tells you the answer is a uniform statement and hence that the counterexample must be a family growing with n, not a single configuration.

Revolving concepts

Characteristic functions of integer valued variables. $\varphi_X(\theta) = E[e^{iX\theta}]$ is a finite trigonometric sum; inversion recovers $\Pr(X = b)$ as the bth Fourier coefficient; independence gives $\varphi_{X+Y} = \varphi_X \varphi_Y$; and $\varphi_{aX}(\theta) = \varphi_X(a\theta)$. All four are one line proofs from the definition. See Book 1, field: Probability, topic: characteristic functions.

Positive definiteness. A sequence is positive definite exactly when it is the Fourier coefficient sequence of a nonnegative function (the Herglotz theorem), and then $|c_b| \le c_0$. The class of integer valued random variables with $\varphi \ge 0$ is closed under independent sums and integer scalings, which is what makes it the right invariant class here. See Book 1, field: Probability, topic: positive definite sequences.

Palindromic Laurent polynomials and Fejer and Riesz. A Laurent polynomial invariant under $x \mapsto x^{-1}$ is real on the unit circle; it is nonnegative there exactly when it equals $g(x)g(x^{-1})$ for a polynomial g. For the quadratic $px + px^{-1} + (1-2p)$ this is the condition that $pt^2 + (1-2p)t + p$ has real roots, that is $1 - 4p \ge 0$. See Book 1, field: Polynomials, topic: reciprocal polynomials.

Signed binary representations. With digits in $\{0, \pm 1\}$ and weights 2^{k-1}, the number 0 has only the trivial representation, and 1 has exactly the n representations given by the borrow chain $2^{j-1} - 2^{j-2} - \cdots - 1 = 1$. The general fact: weights that grow at least as fast as the partial sums of their predecessors make representations essentially unique, which is the standard way to design a target with a prescribed number of preimages. See Book 1, field: Number theory, topic: digit systems.

The recursion behind the geometric sum, generalised. Let $Q_n = P(1; 1, 2, \ldots, 2^{n-1}) = \sum_{j=1}^{n} p^j (1-2p)^{n-j}$. Splitting on whether the last weight is used gives the first order linear recursion

$$Q_n = (1-2p)\, Q_{n-1} + p^n, \qquad Q_0 = 0.$$

The general solution of $u_n = \alpha u_{n-1} + \beta^n$ with $u_0 = 0$ is $u_n = \beta\, \dfrac{\beta^n - \alpha^n}{\beta - \alpha}$ when $\alpha \neq \beta$, and $u_n = n\beta^n$ when $\alpha = \beta$. Here $\alpha = 1-2p$ and $\beta = p$ give $Q_n = p\dfrac{(1-2p)^n - p^n}{1-3p}$, and the degenerate case $\alpha = \beta$ is exactly $p = 1/3$. Dividing by $(1-2p)^n$ first, as in the ideal solution, replaces all of this by a geometric series and removes the degenerate case entirely. See Book 1, field: Sequences and recurrences, topic: first order linear recursions with geometric forcing.

Circuit Bank

- **WHEN** a probability that a sum of independent integer valued variables equals an exact value **DO** write it as a coefficient of a Laurent polynomial, or as a Fourier coefficient of a product **BECAUSE** independence becomes multiplication only after transforming, and exact value conditions become coefficient extractions
- **WHEN** you must show the coefficient at 0 dominates every other coefficient **DO** prove the generating function is nonnegative on the unit circle **BECAUSE** the zeroth coefficient is the mean of the function and every other coefficient is bounded by the mean of its modulus, so nonnegativity is exactly the right strengthening
- **WHEN** a property must survive an operation applied unboundedly often **DO** strengthen it to a property that the relevant transform makes multiplicative **BECAUSE** only multiplicative classes are closed under products, and a class that is not closed gives an induction with nothing to induct on
- **WHEN** you must break a claim that the mode sits at 0 **DO** choose weights making 0 uniquely representable while a neighbouring value collects a geometric family of representations **BECAUSE** the ratio of the two probabilities then becomes a geometric series, and the threshold is where its sum crosses 1
- **WHEN** a threshold of the form $1/4$ or $1-4p$ appears **DO** look for the discriminant of a palindromic quadratic **BECAUSE** thresholds in positivity problems are almost always the point where a factorisation stops being real

Backtesting

1. First useful cue: independence plus an exact integer target, which is the standing invitation to write the probability as a coefficient and then evaluate on the unit circle.
2. Method the expression suggested: transform, note that the single step transform is $1-2p+2p\cos\theta$, and read the threshold off its minimum.
3. Where you would hesitate, and the thought to reinforce: at the step "nonnegativity of the transform implies the maximum is at 0". Reinforce this: the zeroth Fourier coefficient is the average of the function, and averaging a nonnegative function against a unimodular factor can only shrink it. One line, no theory quoted.
4. The trap the question sets: believing the inequality can be proved combinatorially by comparing solution counts. The counts genuinely go the wrong way for $p > 1/4$, so any purely combinatorial argument must be false; the weights matter, not the counts.

5. What makes you recognise it faster next time: any question of the form "is the distribution of a weighted sum maximal at 0" is a positive definiteness question, and the answer is always governed by the sign of the single step transform.
6. The reusable decision rule: transform first, strengthen to the multiplicative property, and design counterexamples by starving the target you want to be small.

Mirror drills

1. Compute the characteristic function of one step and find exactly the p for which it is nonnegative for all θ. *Answer:* $\varphi(\theta) = 1 - 2p + 2p\cos\theta$, with minimum $1 - 4p$ at $\theta = \pi$; nonnegative for all θ exactly when $p \leq 1/4$.
2. With $p = 1/3$, so that each X_i is uniform on $\{-1, 0, 1\}$, compare $\Pr(X_1 + 2X_2 = 0)$ and $\Pr(X_1 + 2X_2 = 1)$. *Answer:* $1/9$ against $2/9$; the representations of 1 are $(1, 0)$ and $(-1, 1)$, while 0 has only $(0, 0)$.
3. Show that if X and Y are independent integer valued variables with $\varphi_X \geq 0$ and $\varphi_Y \geq 0$, then $\varphi_{X+Y} \geq 0$ and $\varphi_{aX} \geq 0$ for every integer a. *Answer:* $\varphi_{X+Y} = \varphi_X \varphi_Y$, a product of nonnegative functions, and $\varphi_{aX}(\theta) = \varphi_X(a\theta)$, a reparametrisation. This is precisely the closure that the naive property "maximum at 0" lacks.

4.12 B6. A continuous functional equation on the positive reals

Find all continuous functions $f : \mathbb{R}^+ \to \mathbb{R}^+$ such that

$$f(xf(y)) + f(yf(x)) = 1 + f(x+y)$$

for all $x, y > 0$. Here $\mathbb{R}^+$ denotes the set of positive real numbers, excluding 0.

Read it out loud

A symmetric functional equation in which the left side feeds products $xf(y)$ into f and the right side feeds a sum $x+y$ into f, with an additive constant 1 sitting between them. The fields wired in are functional equations, but the tools that actually do the work are all real analysis: limits superior and inferior, the intermediate value theorem applied to the image of an interval, compactness on closed bounded intervals, and the iteration of an affine contraction. No algebraic identity will finish this problem. It is an analysis problem wearing a functional equation costume.

Three structural features are worth naming before you compute anything. First, the equation is symmetric under swapping x and y, so the diagonal $y = x$ is special: it collapses the two left hand terms into one and produces

$$2f(xf(x)) = 1 + f(2x),$$

which is the single most used line of the whole solution. It says that the value of f along the curve $h(x) := xf(x)$ is controlled by the value of f at $2x$. The unknown of this problem is not f; it is h.

Second, the equation has a scaling symmetry: if f is a solution then so is $x \mapsto f(cx)$ for every $c > 0$, because writing the original equation at the pair (cx, cy) gives exactly the equation for the new function. So solutions come in one parameter families, the answer will contain a free positive constant, and any proof of uniqueness must spend that symmetry on a normalisation at some point.

Third, the mismatch between products on the left and a sum on the right is the real content. For $f(xf(y))$ and $f(x+y)$ to be comparable when x is large, you need $xf(y)$ and $x+y$ to be comparable, that is you need f to behave like 1 near 0 and like $1/x$ near infinity. That is the shape of the answer before you have proved anything: $f(x) = \dfrac{1}{1+cx}$ with $c \geq 0$, and $xf(x) \to 1/c$.

Within thirty seconds you should have written the diagonal identity, named $h(x) = xf(x)$, and verified the family $1/(1+cx)$. Those three lines are worth real marks on their own, and they are the skeleton of everything that follows.

Approaches, ranked worst to best

1. **Substitution hunting.** *Cue:* it is a functional equation, so try $x = y$, $x = 1$, $y = 1$, $f(1) = t$. *Circuit:* plug in special values until something cancels. (zombie route: the domain is $\mathbb{R}^+$ with no distinguished point and no value of f given, so nothing cancels; the scaling symmetry guarantees that no substitution can ever pin a value, because there is no canonical point to pin it at)

2. **Assume differentiability and differentiate.** *Cue:* the equation looks like it wants a derivative. *Circuit:* differentiate in x at fixed y and solve the resulting differential equation. (illegal and unrecoverable: only continuity is given, and continuous solutions of functional equations can behave very badly; a grader will delete the entire solution at the first unproved differentiation)

3. **Guess the family and claim rigidity.** *Cue:* the shape $1/(1+cx)$ is forced by the product versus sum mismatch. *Circuit:* verify the family and assert uniqueness. (worth two or three marks and no more: the verification is three lines and the uniqueness is the entire problem)

4. **Monotonicity first.** *Cue:* the equation compares $f(xf(y))$ with $f(x+y)$, so if f were injective you could cancel. *Circuit:* prove f is strictly decreasing, hence injective, then compare arguments. (a genuine and useful tool, but it is available only after you know $f < 1$ everywhere, which needs the asymptotics at both ends; used as an opening move it stalls, used at the end it gives a clean alternative finish)

5. **Pin the two boundary behaviours, then propagate inwards.** *Cue:* a functional equation on an open half line with only continuity has no interior structure to exploit, so the information must come from the ends. *Circuit:* prove $f(0^+) = 1$; split off the case $f \geq 1$; prove $f(\infty) = 0$ and $xf(x) \to 1$; normalise the scale; take limits inside the equation. (ideal: every step is a limit taken inside the equation, and the whole proof is the study of the single function $h(x) = xf(x)$)

The ideal solution

The solutions are exactly

$$\boxed{f(x) = \frac{1}{1+cx} \quad \text{for a constant } c \geq 0,}$$

the case $c = 0$ being the constant function 1. Throughout, $E(x,y)$ denotes the given equation and $h(x) = xf(x)$.

Step 0: these functions work. With $f(x) = 1/(1+cx)$ we have $xf(y) = x/(1+cy)$, so

$$f(xf(y)) = \frac{1}{1+\frac{cx}{1+cy}} = \frac{1+cy}{1+cx+cy}, \qquad f(yf(x)) = \frac{1+cx}{1+cx+cy},$$

and the sum is $\dfrac{2+cx+cy}{1+cx+cy} = 1 + \dfrac{1}{1+c(x+y)} = 1 + f(x+y)$.

Also record the scaling symmetry: if f solves E and $c > 0$, then $g(x) = f(cx)$ solves E, since $E(cx, cy)$ reads $f(cx\, f(cy)) + f(cy\, f(cx)) = 1 + f(c(x+y))$, which is $g(xg(y)) + g(yg(x)) = 1 + g(x+y)$.

Now let f be any continuous solution.

Step 1: $\lim_{x\to 0^+} f(x) = 1$**.**

First, f is bounded near 0. For $0 < x < 1$, $E(x,1)$ and $f(f(x)) > 0$ give $f(xf(1)) < 1 + f(x+1) \leq 1 + \max_{[1,2]} f$, the maximum existing by continuity on a compact interval. As x ranges over $(0,1)$, $xf(1)$ ranges over $(0, f(1))$, so f is bounded on $(0, f(1))$. Consequently $h(x) = xf(x) \to 0$ as $x \to 0^+$.

Write $L_+ = \limsup_{t\to 0^+} f(t)$ and $L_- = \liminf_{t\to 0^+} f(t)$; both are finite by the previous paragraph, and $L_- \geq 0$.

Lemma 4.12.1. $\limsup_{x\to 0^+} f(h(x)) = L_+$ *and* $\liminf_{x\to 0^+} f(h(x)) = L_-$.

Proof. Since $h(x) \to 0^+$ as $x \to 0^+$, the inequalities $\limsup_{x\to 0^+} f(h(x)) \leq L_+$ and $\liminf_{x\to 0^+} f(h(x)) \geq L_-$ are immediate. For the reverse inequalities, note that h is continuous and positive on $(0,\infty)$ with $h(x) \to 0$ as $x \to 0^+$, so for every $\delta > 0$ the image $h((0,\delta))$ contains the interval $(0, h(\delta/2))$: given t in that interval, choose $x_1 \in (0, \delta/2)$ with $h(x_1) < t$, and apply the intermediate value theorem to h on $[x_1, \delta/2]$. Now fix $\eta > 0$ and $\delta > 0$. By definition of L_+ there are points t arbitrarily close to 0 with $f(t) > L_+ - \eta$; choose such a t with $t < h(\delta/2)$ and write $t = h(x)$ with $x \in (0,\delta)$. Hence $\sup_{0<x<\delta} f(h(x)) > L_+ - \eta$ for every δ and η, giving $\limsup_{x\to 0^+} f(h(x)) \geq L_+$. The liminf statement is identical with the inequalities reversed. □

Now take $y = x$ in E:

$$2f(h(x)) = 1 + f(2x) \qquad \text{for all } x > 0. \tag{D}$$

Taking lim sup as $x \to 0^+$ in (D) gives $2L_+ = 1 + L_+$, so $L_+ = 1$; taking lim inf gives $2L_- = 1 + L_-$, so $L_- = 1$. Hence $f(x) \to 1$ as $x \to 0^+$.

Step 2: if $f(x) \geq 1$ for all $x > 0$, then $f \equiv 1$.

Suppose $f \geq 1$ everywhere and, for contradiction, that $\lambda := f(y) > 1$ for some $y > 0$. Since $f(yf(x)) \geq 1$, the equation $E(x, y)$ gives

$$f(\lambda x) \leq f(x + y) \qquad \text{for all } x > 0,$$

that is, writing $u = \lambda x$ and $T(u) = u/\lambda + y$,

$$f(u) \leq f(T(u)) \qquad \text{for all } u > 0.$$

The affine map T has slope $1/\lambda \in (0, 1)$ and fixed point $c_0 = \lambda y/(\lambda - 1) > 0$, and $T^k(u) - c_0 = (u - c_0)\lambda^{-k} \to 0$. Iterating the inequality and using continuity of f at c_0,

$$f(u) \leq f(T^k(u)) \xrightarrow[k\to\infty]{} f(c_0),$$

so $M := \sup_{x>0} f(x) \leq f(c_0) < \infty$: the function is bounded.

Next, $f \geq 1$ gives $h(x) = xf(x) \geq x \to \infty$, while $h(x) \to 0$ as $x \to 0^+$ by Step 1. Since h is continuous on the interval $(0, \infty)$, the intermediate value theorem shows h takes every positive value. So given $t > 0$, choose x with $h(x) = t$; then (D) gives

$$f(t) = \frac{1 + f(2x)}{2} \leq \frac{1 + M}{2}.$$

Taking the supremum over t yields $M \leq (1 + M)/2$, hence $M \leq 1$, hence $f \equiv 1$, contradicting $f(y) > 1$. Therefore no such y exists and $f \equiv 1$, which is the case $c = 0$.

From now on assume $f(x_0) < 1$ for some $x_0 > 0$.

Step 3: h is bounded and $f(x) \to 0$ as $x \to \infty$.

Let $I = \inf_{x>0} f(x) < 1$, choose $\varepsilon \in \left(0, \frac{1-I}{2}\right)$, and choose $y_\varepsilon > 0$ with $f(y_\varepsilon) < I + \varepsilon$. If $h(x) = y_\varepsilon$ for some x, then (D) gives

$$1 + I \leq 1 + f(2x) = 2f(y_\varepsilon) < 2I + 2\varepsilon,$$

so $1 - I < 2\varepsilon$, contradicting the choice of ε. Hence h omits the value y_ε. Since h is continuous on the interval $(0, \infty)$ and $h(x) \to 0 < y_\varepsilon$ as $x \to 0^+$, the intermediate value theorem forces $h(x) < y_\varepsilon$ for every x. Thus $xf(x) < y_\varepsilon$ for all x, so $f(x) < y_\varepsilon/x \to 0$.

Step 4: normalisation.

By Step 1 and Step 3, f is continuous with $f(0^+) = 1$ and $f(\infty) = 0$, so there is $\delta > 0$ with $f > 3/4$ on $(0, \delta)$ and $R > \delta$ with $f < 1/4$ on (R, ∞). The set $f^{-1}(1/2)$ is therefore a nonempty (intermediate value theorem) closed subset of the compact interval $[\delta, R]$, so it has a least element x_1. Since $f > 1/2$ near 0 and f omits the value $1/2$ on $(0, x_1)$, the intermediate value theorem gives $f > 1/2$ on $(0, x_1)$. Replacing f by $x \mapsto f(x_1 x)$, which is again a solution by the scaling symmetry, we may and do assume

$$f(1) = \tfrac{1}{2} \qquad \text{and} \qquad f(t) > \tfrac{1}{2} \text{ for } 0 < t < 1.$$

It now suffices to prove $f(x) = 1/(1 + x)$; undoing the normalisation then gives $f(x) = 1/(1 + cx)$ with $c = 1/x_1 > 0$.

Step 5: $\lim_{x\to\infty} h(x) = 1$.

By (D) and positivity of f, $f(h(x)) = \frac{1}{2}(1 + f(2x)) > \frac{1}{2} = f(1)$, so $h(x) \neq 1$ for every x. As h is continuous with $h(x) \to 0$ as $x \to 0^+$, the intermediate value theorem gives $h(x) < 1$ for all x.

Suppose $h(x) \not\to 1$. Then there are $\delta \in (0, 1)$ and $x_n \to \infty$ with $h(x_n) \leq 1 - \delta$. Choose $\delta'' \in (0, 1 - \delta)$ with $f > 3/4$ on $(0, \delta'']$; on the compact interval $[\delta'', 1 - \delta]$ the continuous function f attains a minimum, which exceeds $1/2$ because $f > 1/2$ on $(0, 1)$. Hence

$$\mu := \inf\{f(t) : 0 < t \leq 1 - \delta\} > \tfrac{1}{2},$$

and so $f(h(x_n)) \geq \mu > 1/2$ for all n. But $f(2x_n) \to 0$ by Step 3, so (D) gives $f(h(x_n)) \to \frac{1}{2}$, a contradiction. Therefore $h(x) \to 1$ as $x \to \infty$.

Step 6: the reflection identity $f(y) + f(1/y) = 1$ for all $y > 0$.

Fix $y > 0$ and replace y by xy in E:

$$f(xf(xy)) + f(xyf(x)) = 1 + f(x(1+y)).$$

Let $x \to \infty$. Then $xy \to \infty$, so $xf(xy) = \frac{1}{y}\, h(xy) \to \frac{1}{y}$ and $xyf(x) = y\, h(x) \to y$, while $x(1+y) \to \infty$ gives $f(x(1+y)) \to 0$. Since f is continuous at the positive numbers $1/y$ and y, the three limits give

$$f(1/y) + f(y) = 1.$$

Step 7: conclusion.

Apply Step 6 to the positive number $yf(x)$: $f(yf(x)) = 1 - f\left(\frac{1}{yf(x)}\right)$. Substituting into $E(x,y)$ and cancelling the 1,

$$f(xf(y)) = f(x+y) + f\left(\frac{1}{yf(x)}\right).$$

Fix y, multiply through by $xf(y)$, and let $x \to \infty$, examining each term.

The left side is $vf(v) = h(v)$ with $v = xf(y) \to \infty$, so it tends to 1 by Step 5.

The first term on the right is

$$xf(y)f(x+y) = f(y) \cdot \frac{x}{x+y} \cdot h(x+y) \longrightarrow f(y) \cdot 1 \cdot 1 = f(y).$$

For the second term, put $u = \dfrac{1}{yf(x)}$, which tends to ∞ because $f(x) \to 0$. Then $f(u) = h(u)/u = h(u)\, yf(x)$, so

$$xf(y)\, f(u) = f(y)\, y\, h(u)\, \big(xf(x)\big) = f(y)\, y\, h(u)\, h(x) \longrightarrow f(y)\, y.$$

Therefore $1 = f(y) + yf(y)$, that is $f(y) = \dfrac{1}{1+y}$ for every $y > 0$, as required. Undoing the normalisation of Step 4 completes the classification.

Layer 1: WHAT

Block 1: verify the family, and record the scaling symmetry $f \mapsto f(c\,\cdot)$, which tells you the answer is a one parameter family and that a normalisation will be needed.

Block 2: put $y = x$. The diagonal identity $2f(xf(x)) = 1 + f(2x)$ names the true unknown $h(x) = xf(x)$ and is used four separate times.

Block 3: bound f near 0 straight from the equation, deduce $h \to 0$ at 0^+, and then run the diagonal identity through lim sup and lim inf to get $f(0^+) = 1$. The only technical point is that h covers a punctured neighbourhood of 0, so limits along h see the same limsup as limits along the identity.

Block 4: dispose of the case $f \geq 1$. The equation gives $f(\lambda x) \leq f(x+y)$, an affine contraction inequality; iterating to its fixed point bounds f, and the diagonal identity then squeezes sup f to 1.

Block 5: in the remaining case, the diagonal identity shows h cannot hit a value where f is nearly minimal, so h is bounded and $f(x) \to 0$ at infinity.

Block 6: spend the scaling symmetry: put the least solution of $f(t) = 1/2$ at $t = 1$.

Block 7: sharpen the bound on h to a limit: h omits 1, hence $h < 1$, and $f(h(x)) \to 1/2$ forces $h \to 1$.

Block 8: substitute $y \mapsto xy$ and let $x \to \infty$; the three terms converge to $f(1/y)$, $f(y)$ and 0, giving the reflection identity.

Block 9: feed the reflection identity back into E, multiply by $xf(y)$ so that every term converges, and let $x \to \infty$ to get $f(y)(1+y) = 1$.

The nominal route treats this as a substitution puzzle and spends the exam hunting for values of x and y that make two arguments coincide. The bifurcation point is Block 2, at the decision of what the unknown is. Once you write $h(x) = xf(x)$ and read the diagonal identity as a statement about h, every later step is a question about a single continuous function on an interval: what is its limit at each end, and which values does it omit. Those are questions the intermediate value theorem answers.

Layer 2: HOW

Block 1. **Cue.** The equation is unchanged when x and y are swapped, and it is unchanged under $x \mapsto cx$ in the sense that $f(c\,\cdot)$ is again a solution. **Why natural.** Symmetries are free information. The swap symmetry tells you the diagonal is the degenerate direction and therefore the cheapest substitution. The scaling symmetry tells you in advance that the answer contains a free parameter, so any attempt to compute a specific value such as $f(1)$ is doomed until you normalise. **Link to the next block.** Take the diagonal.

Block 2. **Cue.** $y = x$ makes the two left hand terms identical. **Why natural.** It converts a two variable equation into a one variable identity, and the argument that appears, $xf(x)$, is exactly the product versus sum hybrid that the whole equation is about. Naming it h is not decoration: everything you can prove is a statement about the limits and the image of h. **Link to the next block.** You need boundary information about f before the identity can be exploited.

Block 3. **Cue.** The term $f(xf(y))$ with y fixed and $x \to 0^+$ sends its argument to 0^+, and the right side stays bounded by continuity at y. **Why natural.** That is a free upper bound for f near 0, and boundedness near 0 is what makes $h(x) \to 0$. With $h \to 0$ at 0^+, the diagonal identity relates the behaviour of f near 0 to itself, and a self referential relation between lim sup and lim sup is an equation: $2L_+ = 1 + L_+$. The one honest technicality is that lim sup along the curve h equals lim sup along the identity, and that needs h to cover a punctured neighbourhood of 0, which is the intermediate value theorem. **Link to the next block.** The value 1 at the left end is now known unconditionally.

Block 4. **Cue.** The right side of E contains $f(x+y)$ and the left contains $f(xf(y))$; if $f \geq 1$, the other left hand term is at least 1 and can be discarded. **Why natural.** Discarding a term turns an equation into an inequality, and the inequality $f(\lambda x) \leq f(x+y)$ compares a multiplicative shift with an additive one. Multiplication beats addition, so iterating drives the argument to the fixed point of $u \mapsto u/\lambda + y$, and continuity converts the infinite chain into a single bound $f \leq f(c_0)$. This is the standard way to prove boundedness from a one sided functional inequality. **Link to the next block.** With f bounded, the diagonal identity plus surjectivity of h pins the supremum.

Block 5. **Cue.** The diagonal identity says $f(h(x)) = \frac{1}{2}(1 + f(2x)) \geq \frac{1}{2}(1 + \inf f)$, so f can never be close to its infimum at a point of the image of h. **Why natural.** Values near the infimum are therefore omitted by h, and an omitted value plus continuity on an interval plus values below it forces h to stay below it. That is a boundedness statement about $xf(x)$, which is exactly a decay statement about f. Note how little was used: only that $\inf f < 1$. **Link to the next block.** You now have both boundary behaviours, 1 at 0^+ and 0 at ∞.

Block 6. **Cue.** A one parameter family of solutions and a proof that must end with a specific formula. **Why natural.** Normalise, using the least point where $f = 1/2$, because $1/2$ is the value

the diagonal identity refers to: (D) says $f(h(x)) > 1/2$ always. Choosing the least such point is what makes the interval $(0, 1)$ a region where $f > 1/2$, which is the fact used in Step 5. **Link to the next block.** The normalisation is chosen to serve the next step, not for aesthetics.

Block 7. Cue. $f(h(x)) > f(1)$ for every x. **Why natural.** So h omits the value 1, hence $h < 1$ everywhere by the same omission argument as before. Then $f(h(x)) \to 1/2$ as $x \to \infty$, and since f is bounded away from $1/2$ on any interval $(0, 1 - \delta]$, the point $h(x)$ must approach 1. This upgrades a bound into a limit, which is what the final computation needs. **Link to the next block.** You now know the exact asymptotic $f(x) \sim 1/x$.

Block 8. Cue. You have an asymptotic at infinity and an equation with two free variables. **Why natural.** Substituting $y \mapsto xy$ makes both left hand arguments converge to finite positive limits as $x \to \infty$, namely $1/y$ and y, while the right hand argument runs to infinity where f vanishes. That is the only substitution for which all three terms have limits, and it produces the reflection identity for free. **Link to the next block.** The reflection identity lets you replace an awkward term by a computable one.

Block 9. Cue. Every term of the resulting identity behaves like $1/(\text{argument})$ for large x, so multiplying by the right factor makes each term converge. **Why natural.** The only asymptotic information you have is $uf(u) \to 1$, so any term of the form $f(\text{large})$ must be multiplied by that large quantity before it can be used. Multiplying by $xf(y)$ is exactly what turns the left side into $h(xf(y)) \to 1$; the same factor happens to make both right hand terms converge, to $f(y)$ and $yf(y)$. The final equation $1 = f(y)(1 + y)$ then falls out.

Layer 3: WHY

The mathematical content is a clash between multiplication and addition. On the left the function is evaluated at products, on the right at a sum. A continuous function that reconciles the two must convert the multiplicative structure near infinity into the additive structure, and the only continuous way to do that with a bounded positive function is $f(x) \sim 1/(cx)$: then $xf(y) \approx x/(cy)$ and $f(xf(y)) \approx cy/x \cdot c$, and the additive constant 1 on the right is what forces the exact Mobius form rather than a mere asymptotic. Substituting $g = 1/f - 1$ turns the answer into $g(x) = cx$, so the equation is secretly asserting that a certain transform of f is linear, which is the Cauchy equation in disguise, and the hypothesis of continuity is doing precisely the job it does for Cauchy: excluding pathological solutions.

The organising principle for the proof is that a functional equation on an open half line with only continuity has no interior structure to exploit. All the information lives at the two ends. So the programme is forced: pin $f(0^+)$, pin $f(\infty)$, upgrade the second to the sharp asymptotic $xf(x) \to 1$, and then propagate inwards by taking limits inside the equation. Every single step of the ideal solution is an instance of that programme, and each one uses the same two instruments: the diagonal identity (D) and the fact that a continuous function on an interval which omits a value and takes a smaller one stays below it.

The discernment mechanism to train is the question *what is the true unknown?* Here it is not f but $h(x) = xf(x)$, because h is the object that appears as an argument in the diagonal identity, and because the target family is characterised by h being bounded with limit $1/c$. Whenever a functional equation feeds a composite expression into the unknown function, promote that composite to the status of the unknown and ask the three standard questions about it: what are its limits at the ends of the domain, what is its image, and which values does it omit.

Knowledge gaps, stated plainly. This problem is not approachable at all without the following installed, and none of it is on the A-level Further Mathematics syllabus except the intermediate

value theorem. First, lim sup and lim inf of a function at a point, their existence for bounded functions, and their behaviour under adding constants and under composition with a curve that covers a punctured neighbourhood. Second, the intermediate value theorem in the form "the continuous image of an interval is an interval", used three times to convert omitted values into global inequalities. Third, compactness: a continuous positive function on a closed bounded interval attains a positive minimum. Fourth, iteration of an affine contraction and convergence to its fixed point. Fifth, the discipline of taking limits inside an identity only after checking that every term converges. If any of the five is missing, the solution cannot be written, and no amount of algebraic ingenuity substitutes for them.

Revolving concepts

Functional equations with only continuity. The standard toolkit: exploit symmetry (the diagonal substitution), look for injectivity or monotonicity to cancel f, and if neither is available, work with asymptotics at the boundary of the domain. Continuity is used to move limits inside f and to upgrade pointwise information to interval information. See Book 1, field: Functional equations, topic: continuous solutions.

The Cauchy equation and its relatives. $g(x+y) = g(x) + g(y)$ with g continuous (or merely bounded on a set of positive measure, or monotone on an interval) forces $g(x) = cx$. The present answer is $1/f - 1 = cx$, so the problem is a Mobius twisted Cauchy equation. See Book 1, field: Functional equations, topic: Cauchy's equation.

Omitted values and the intermediate value theorem. If g is continuous on an interval, g never takes the value v, and g takes some value less than v, then $g < v$ everywhere. This single fact is used to prove $h < y_\varepsilon$ (Step 3) and $h < 1$ (Step 5), and its surjectivity twin is used in Step 2 and in the covering lemma of Step 1. See Book 1, field: Real analysis, topic: intermediate value theorem.

Affine contractions and their iteration, generalised. The recursion $u_{k+1} = au_k + b$ with $a \neq 1$ has the closed form

$$u_k = a^k \left(u_0 - \frac{b}{1-a} \right) + \frac{b}{1-a},$$

so when $|a| < 1$ every orbit converges to the fixed point $b/(1-a)$ geometrically. Here $a = 1/\lambda$ and $b = y$, giving the fixed point $c_0 = \lambda y/(\lambda - 1)$. The reusable pattern is: a one sided inequality $f(u) \leq f(T(u))$ with T a contraction plus continuity of f yields the global bound $f \leq f(\text{fixed point})$, by iterating and passing to the limit. The same pattern with T expanding, or with the inequality reversed, gives lower bounds instead. See Book 1, field: Sequences and recurrences, topic: affine recursions and fixed points.

The auxiliary function $h(x) = xf(x)$. For the answer $f = 1/(1+cx)$ one has $h(x) = x/(1+cx)$, which is strictly increasing from 0 to $1/c$; after the normalisation $c = 1$ this is exactly the content of Steps 5 and the bound $h < 1$. Promoting a composite argument to an unknown in its own right is the general move. See Book 1, field: Functional equations, topic: auxiliary functions.

Limits inside functional equations. If every term of an identity has a limit along a chosen path, the identity passes to the limit. The craft is choosing the path (here $y \mapsto xy$ with $x \to \infty$) and the normalising factor (here $xf(y)$) so that no term diverges. See Book 1, field: Real analysis, topic: passing to the limit.

Circuit Bank

- **WHEN** a functional equation is symmetric in its two variables **DO** substitute $y = x$ before anything else, and name whatever composite argument appears **BECAUSE** the diagonal is where the two sides collapse to a single unknown combination, and that combination is almost always the true unknown of the problem

- **WHEN** a functional equation on an open half line comes with continuity and nothing else **DO** go to the two ends of the domain and pin the limits there, then propagate inwards by taking limits inside the equation **BECAUSE** with no regularity beyond continuity there is no interior structure to exploit, so all the information lives at the boundary
- **WHEN** a continuous function on an interval is shown to omit a value v and to take some value below v **DO** conclude that it stays below v everywhere **BECAUSE** the continuous image of an interval is an interval, so a function cannot jump over a value it omits
- **WHEN** a functional equation yields a one sided inequality $f(u) \leq f(T(u))$ with T an affine contraction **DO** iterate to the fixed point and use continuity **BECAUSE** the infinite chain of inequalities collapses to the single global bound $f \leq f(\text{fixed point})$, which is how boundedness is obtained without any compactness
- **WHEN** an equation is invariant under rescaling the variable **DO** normalise before attempting uniqueness, and choose the normalisation to serve the next step **BECAUSE** the solution set is a one parameter family, so no argument can pin a value until the symmetry has been spent
- **WHEN** you want to take a limit in an identity whose terms individually vanish or diverge **DO** multiply through by the factor that makes each term converge, using the asymptotic you have already proved **BECAUSE** $uf(u) \to 1$ is usable only against a factor of size u, so the multiplier is dictated by the asymptotic, not chosen

Backtesting

1. First useful cue: the symmetry in x and y, which makes $y = x$ the cheapest substitution and produces $2f(xf(x)) = 1 + f(2x)$, the identity that carries the entire solution.
2. Method the expression suggested: study the auxiliary function $h(x) = xf(x)$, since the product versus sum mismatch means the answer must decay like $1/x$ and h is the normalised unknown.
3. Where you would hesitate, and the thought to reinforce: at the case $f \geq 1$, which looks like an irrelevant technicality and is in fact where the constant solution hides. Reinforce this: a classification must account for every solution, and the family $1/(1 + cx)$ includes $c = 0$ only because the constant 1 is genuinely a solution; the proof of the general case assumes $\inf f < 1$ at Step 3 and would be circular without the dichotomy.
4. The trap the question sets: assuming differentiability. Only continuity is given, and the entire proof is built to avoid derivatives; a solution that differentiates the equation scores nothing regardless of the answer it reaches.
5. What makes you recognise it faster next time: a functional equation that mixes $f(xf(y))$ with $f(x + y)$ is a multiplication against addition problem, and its solutions are always of Mobius or exponential type; compute the asymptotics first and the algebra afterwards.
6. The reusable decision rule: diagonal substitution, name the composite argument, pin both boundary limits, normalise the scaling symmetry, then take limits inside the equation with a multiplier chosen to make every term converge.

Mirror drills

1. Show that if f solves the equation then so does $x \mapsto f(cx)$ for every $c > 0$, and deduce that no substitution can determine $f(1)$. *Answer:* write the original equation at the pair (cx, cy); the value $f(1)$ can be moved to any value in the range of a solution by rescaling, so it is not determined by the equation alone.

2. Let g be continuous and positive on $(0,\infty)$ with $g(x)\to 0$ as $x\to 0^+$, and suppose g never takes the value 1. Prove $g(x)<1$ for all x. *Answer:* if $g(x_1)>1$ for some x_1, pick $x_0<x_1$ with $g(x_0)<1$ and apply the intermediate value theorem on $[x_0,x_1]$.

3. For $\lambda>1$ and $y>0$ let $T(u)=u/\lambda+y$. Find the fixed point c_0, show $T^k(u)\to c_0$ for every $u>0$, and deduce that a continuous f satisfying $f(u)\le f(T(u))$ for all u obeys $f\le f(c_0)$. *Answer:* $c_0=\lambda y/(\lambda-1)$ and $T^k(u)-c_0=(u-c_0)\lambda^{-k}$; iterate the inequality and use continuity at c_0.

Chapter 5

Putnam 2021

5.1 A1. Grasshopper hops of length five to the diagonal

A grasshopper starts at the origin in the coordinate plane and makes a sequence of hops. Each hop has length 5*, and after each hop the grasshopper is at a point whose coordinates are both integers; thus, there are* 12 *possible locations for the grasshopper after the first hop. What is the smallest number of hops needed for the grasshopper to reach the point* $(2021, 2021)$*?*

Read it out loud

This is a lattice walk with a finite step set and a single target, and the command term is *smallest number*. Read that phrase as a two-part contract before you touch the numbers: a lower bound that holds for every walk, and one explicit walk that attains it. Any answer that has only one half of the contract is worth at most half the marks, and the half that most candidates skip is the bound.

The fields wired in are elementary number theory (which integer vectors have length 5: the representations $25 = 0^2 + 5^2 = 3^2 + 4^2$, hence the twelve vectors $(0, \pm 5)$, $(\pm 5, 0)$, $(\pm 3, \pm 4)$, $(\pm 4, \pm 3)$), and, for the bound, the geometry of a finite step set: a potential function that no hop can change by more than a fixed amount. That second field is the one being tested. The examiners tell you the step count (twelve) to make sure you list the vectors; the real question is which measurement of progress you choose.

Within thirty seconds you should have written the twelve vectors, the target, and the observation that the target sits on the diagonal direction $(1, 1)$ while no hop of length 5 points along that diagonal (the vector $(5/\sqrt{2}, 5/\sqrt{2})$ is not a lattice point). That single observation already tells you the Euclidean bound $2021\sqrt{2}/5 \approx 571.6$ cannot be tight, and it tells you where to look instead: measure progress along the diagonal with the linear functional $x + y$, whose value each hop changes by at most $3 + 4 = 7$.

Approaches, ranked worst to best

1. **Greedy construction only.** *Cue:* the target is on the diagonal, so alternate $(3, 4)$ and $(4, 3)$. *Circuit:* aim along the target direction. (this finds a walk of 578 hops in a minute but proves nothing about minimality; without a bound you have half a solution and no way to know whether 577 is possible)

2. **Euclidean distance bound.** *Cue:* each hop has length 5. *Circuit:* distance over step length. (gives $\lceil 2021\sqrt{2}/5 \rceil = 572$; it stalls because the best hop in the diagonal direction only advances $7/\sqrt{2} < 5$ along that direction, so the bound is loose by six hops and you cannot close the gap by constructions)

3. **Parity of $x + y$.** *Cue:* every hop changes $x + y$ by $\pm 1, \pm 5$ or ± 7, all odd. *Circuit:* invariant modulo 2. (a genuine circuit, and it proves the hop count is even, but on its own it only pushes an odd bound up by one; here it is a supporting check, not the main argument)

4. **Linear functional $x + y$ plus construction.** *Cue:* the target is symmetric in x and y and no hop is diagonal. *Circuit:* potential that changes by a bounded amount per step. (each hop moves $x + y$ by at most 7, the target has $x + y = 4042 > 577 \cdot 7$, and $288(3, 4) + 288(4, 3) + (5, 0) + (0, 5)$ attains 578; both halves of the contract in four lines)

The ideal solution

The lattice points at distance 5 from a given lattice point are obtained by adding one of the twelve vectors $(0, \pm 5)$, $(\pm 5, 0)$, $(\pm 3, \pm 4)$, $(\pm 4, \pm 3)$, because $25 = a^2 + b^2$ with a, b integers forces $\{|a|, |b|\} = \{0, 5\}$ or $\{3, 4\}$.

Lower bound. Let $s = x + y$ be the sum of the grasshopper's coordinates. Initially $s = 0$, and at the target $s = 4042$. For each of the twelve hop vectors (a, b) we have $a + b \leq 7$, with equality exactly for $(3, 4)$ and $(4, 3)$. Thus after n hops, $s \leq 7n$. If $n \leq 577$ then $s \leq 7 \cdot 577 = 4039 < 4042$, so the target has not been reached. Hence at least 578 hops are needed.

Construction. Since $2021 = 288 \cdot 7 + 5$, take 288 hops of $(3, 4)$, 288 hops of $(4, 3)$, one hop of $(5, 0)$ and one hop of $(0, 5)$. The position after these 578 hops is $(288 \cdot 7 + 5,\ 288 \cdot 7 + 5) = (2021, 2021)$, and every intermediate position is a lattice point because every hop vector is a lattice vector.

Therefore the smallest number of hops is $\boxed{578}$.

Layer 1: WHAT

Block 1: list the hop set from $25 = 0^2 + 5^2 = 3^2 + 4^2$. Block 2: choose the potential $s = x + y$ and compute its maximum change per hop, 7. Block 3: divide, $4042 > 577 \cdot 7$, so at least 578. Block 4: write $2021 = 288 \cdot 7 + 5$ and assemble the walk.

Juxtapose with the nominal route. The zombie writes the same Block 1, then reaches for the only measure of progress that A-level trained into him, Euclidean distance, gets 572, and spends twenty minutes failing to build a 572-hop walk without understanding why. The bifurcation point is the choice of potential in Block 2: the zombie measures progress with the norm that the hop length is stated in; you measure progress with the linear functional aligned with the target, because a bound is only tight when the extremal hop for the potential is one you can actually use in the construction.

Layer 2: HOW

Block 1. **Cue.** "Each hop has length 5" and "coordinates are both integers" together with the planted number twelve. **Why natural.** A lattice vector of length 5 is a solution of $a^2 + b^2 = 25$; the only nonnegative solutions are $(0, 5), (5, 0), (3, 4), (4, 3)$ and the signs give $2 + 2 + 4 + 4 = 12$. Matching the examiners' count of twelve confirms you have the right set, which is the whole reason they printed it. **Link to the next block.** Now you know the step set is finite and fixed, so any linear function of position changes by a bounded amount per hop, which is precisely what a lower bound needs.

Block 2. **Cue.** "Smallest number of hops" to a target on the diagonal. **Why natural.** A step count lower bound comes from a quantity that the walk must move from 0 to some value V while each step moves it by at most M; then $n \geq V/M$. The tightest such quantity is the linear functional whose level lines are the supporting line of the hop set in the target direction. The hop set's convex hull has an edge from $(3, 4)$ to $(4, 3)$, and that edge lies on $x + y = 7$. So $x + y$ is not a guess: it is the supporting line of the hull that faces the target. **Link to the next block.** With $M = 7$ and $V = 4042$, division is the next line.

Block 3. **Cue.** $4042/7 = 577.4\ldots$. **Why natural.** If 577 hops sufficed, the sum would be at most 4039; it must be 4042. This is the complete argument and it needs no case analysis, because the bound is on a single scalar. **Link to the next block.** A bound of 578 is only worth its ink if 578 is attainable; the construction must use the extremal hops $(3, 4)$ and $(4, 3)$ almost exclusively, with slack of $578 \cdot 7 - 4042 = 4$ to absorb.

Block 4. **Cue.** The slack is 4 and the two hops $(5, 0)$, $(0, 5)$ each lose exactly 2 relative to the maximum 7. **Why natural.** $2021 = 288 \cdot 7 + 5$; the diagonal part $(2016, 2016)$ is 288 copies of $(3, 4) + (4, 3)$, and the remainder $(5, 5)$ is one axis hop in each direction. The lost slack is $2 + 2 = 4$, matching the arithmetic exactly, which is your check that nothing is wasted. **Link to the next block.** Bound equals construction; box the answer.

Layer 3: WHY

The truth underneath is weak linear programming duality. If T is the target and V the step set, then for any linear functional φ, the number of steps satisfies $n \geq \varphi(T) / \max_{v \in V} \varphi(v)$, and the best φ is a supporting functional of the convex hull of V in the direction of T. Ignoring integrality, the minimal number of steps is exactly the gauge of T with respect to that hull, and the gauge equals the maximum of $\varphi(T)$ over all φ with $\max_V \varphi \leq 1$. Here the hull is a dodecagon and the ray through $(1, 1)$ crosses the edge $x + y = 7$, so the Euclidean bound (which corresponds to a circle of radius 5 containing the hull) is strictly weaker: the circle bulges beyond the hull in the diagonal direction.

The discernment mechanism: whenever a bound is not attainable, ask which constraint of the bound is violated by every construction. The Euclidean bound assumes a hop of length 5 pointing at the target; none exists; therefore replace the norm by the functional that the actual extremal hops saturate. Train this by always writing the hop set's hull edges before choosing a potential, and by keeping parity as a second, independent check: the sum $x + y$ changes by an odd number every hop, so the hop count has the parity of 4042, namely even, and 578 is even. The examiners nudged with the diagonal target and the specific number 5 (small enough that the hull is a dodecagon with a non-axis edge facing the diagonal); a target like $(2021, 0)$ would have made the axis hop extremal and the problem trivial.

Revolving concepts

Taxicab metric. $d((x_1, y_1), (x_2, y_2)) = |x_1 - x_2| + |y_1 - y_2|$; each hop moves taxicab distance at most 7, and the target is at taxicab distance 4042. It is the norm whose unit ball is a diamond, and the diamond's edges are exactly the supporting lines $\pm x \pm y = \text{const}$. See Book 1, field: Inequalities, topic: norms and dual norms.

Supporting functionals and the gauge of a convex set. For a compact convex set K containing 0 in its interior, the gauge $\|T\|_K = \min\{t \geq 0 : T \in tK\}$ satisfies $\|T\|_K = \max\{\varphi(T) : \varphi \text{ linear}, \max_K \varphi \leq 1\}$. A step-count problem with step set V has fractional answer $\|T\|_{\text{conv}(V)}$. See Book 1, field: Inequalities, topic: convexity and duality.

Sums of two squares. $25 = 0^2 + 5^2 = 3^2 + 4^2$; in general the number of lattice points on $x^2 + y^2 = n$ is governed by the prime factorisation of n (four times the excess of divisors $\equiv 1 \pmod 4$ over divisors $\equiv 3 \pmod 4$). See Book 1, field: Number theory, topic: sums of two squares.

Parity invariants. Every hop vector has odd coordinate sum, so the parity of $x + y$ alternates; after n hops it equals the parity of n. Generalised recursion: if a quantity q_n satisfies $q_n \equiv q_{n-1} + 1 \pmod 2$, then $q_n \equiv q_0 + n$; the same one-line induction runs every invariant argument on walks. See Book 1, field: Games and invariants, topic: parity.

Circuit Bank

- **WHEN** you see "smallest number of steps" with a finite step set **DO** write the two-part contract: a scalar potential bound and an explicit construction, and refuse to box an answer until both exist **BECAUSE** because minimality is a universal statement and a construction is an existential one; a single argument never proves both
- **WHEN** you see a target direction along which no step is extremal for the Euclidean norm **DO** replace the norm by the linear functional of the hull edge facing the target **BECAUSE** because a bound is tight exactly when its extremal step is usable, and the supporting line of the hull is where that happens
- **WHEN** you see every step change some integer quantity by an odd amount **DO** record the parity of the step count as a free second constraint **BECAUSE** because parity can raise a divisional bound by one at zero cost and is a cheap check on your construction

Backtesting

1. First useful cue: the planted count of twelve hop vectors, forcing you to list them and notice that $(3,4)$ and $(4,3)$ are the diagonal-facing ones.
2. Method the expression suggested: bound a linear potential per hop, then divide; the diagonal target picks $x+y$.
3. Where you would hesitate, and the thought to reinforce: after getting 572 from Euclid and failing to construct it. Reinforce: an unattainable bound means the wrong potential, not a harder construction.
4. The trap the question sets: hop length 5 in the Euclidean norm invites a Euclidean bound; the answer lives in the taxicab norm.
5. What makes you recognise it faster next time: a target on a symmetry line of the step set plus a step set with no step on that line.
6. The reusable decision rule: choose the potential whose maximum per step is attained by a step you will actually use in the construction.

Mirror drills

1. (drill) Same hop set, target $(2021,0)$. *Answer:* the potential x changes by at most 5, so $n \geq 405$ since $404 \cdot 5 = 2020$; parity of $x+y$ forces n odd; construction $403(5,0)+(3,4)+(3,-4)$ gives 405.
2. (drill) A knight on an infinite board starts at the origin; least number of moves to $(2022,2022)$. *Answer:* $x+y$ changes by at most 3 per move and $4044 = 3 \cdot 1348$; 674 copies of $(1,2)+(2,1)$ attain 1348.
3. (drill) Steps of length $\sqrt{5}$ between lattice points, target $(0,2021)$. *Answer:* y changes by at most 2, so $n \geq 1011$; parity of $x+y$ makes n odd, consistent; $504(1,2)+506(-1,2)+(2,1)$ attains 1011.

5.2 A2. A one to the infinity limit hiding a geometric mean

For every positive real number x, let

$$g(x) = \lim_{r \to 0} \left((x+1)^{r+1} - x^{r+1} \right)^{\frac{1}{r}}.$$

Find $\lim_{x \to \infty} \dfrac{g(x)}{x}$.

Read it out loud

Two nested limits: an inner limit in r that defines a function g, then an outer limit in x of $g(x)/x$. Read the inner one structurally before you compute anything. At $r = 0$ the base is $(x+1)^1 - x^1 = 1$ and the exponent $1/r$ is unbounded; this is the 1^∞ indeterminate form, the same form as $(1 + 1/n)^n$. The field is single-variable real analysis: indeterminate forms, the definition of the derivative, and the number e. Underneath sits a second field, means of a function over an interval, which explains why the answer is what it is.

What is being tested is discipline about the order of limits. The zombie sees $x \to \infty$ and $r \to 0$, guesses that the order does not matter, expands $(x+1)^{r+1} - x^{r+1} \approx (r+1)x^r$, and gets $(r+1)^{1/r} \to e$. The number is right and the argument is worthless without a uniform estimate, because iterated limits do not commute in general. The ideal route removes the issue entirely by computing the inner limit in closed form for each fixed x.

The first useful cue is the exponent $r+1$, planted so that the base equals 1 at $r = 0$. Within thirty seconds you should have written $h(r) = (x+1)^{r+1} - x^{r+1}$, noted $h(0) = 1$, and written $\ln h(r)/r$, because a 1^∞ form is always resolved by taking logarithms, and $\ln h(r)/r$ with $\ln h(0) = 0$ is literally the difference quotient of $\ln h$ at 0.

Approaches, ranked worst to best

1. **Interchange the limits.** *Cue:* $x \to \infty$ looks like it should simplify the base to $(r+1)x^r$. *Circuit:* leading-term asymptotics. (gives $(r+1)^{1/r} \to e$ in two lines, but the interchange is unjustified; making it rigorous needs Taylor's theorem with a remainder bounded uniformly in $x \geq 1$, which is the official second solution and costs more ink than any other route)

2. **Expand in r.** *Cue:* the base is $1 + (\text{something}) \cdot r + O(r^2)$. *Circuit:* $(1 + ar + O(r^2))^{1/r} \to e^a$. (correct: $(x+1)^{r+1} = (x+1)e^{r\ln(x+1)}$ and similarly for x, so the base is $1 + r\left[(x+1)\ln(x+1) - x\ln x\right] + O(r^2)$; this is the derivative route written with more symbols, and the $O(r^2)$ bookkeeping is where a careless line loses a mark)

3. **Integral representation and squeeze.** *Cue:* u^{r+1} evaluated at $x+1$ and x is a definite integral of $(r+1)u^r$. *Circuit:* fundamental theorem of calculus, then a mean of u^r over $[x, x+1]$. (gives $x \leq \left(\int_x^{x+1} u^r\, du\right)^{1/r} \leq x+1$ and hence $e \leq g(x)/x \leq e(1+1/x)$; no closed form for g needed, but the direction of the inequality flips with the sign of r and both cases must be written)

4. **Derivative of $\ln h$ at zero.** *Cue:* $h(0) = 1$, exponent $1/r$. *Circuit:* 1^∞ resolves as $\exp((\ln h)'(0))$. (three lines to $g(x) = (x+1)^{x+1}/x^x$ and then $g(x)/x = (1+1/x)^{x+1} \to e$ is the definition of e; explicit, no cases, no interchange)

The ideal solution

Fix $x > 0$ and set $h(r) = (x+1)^{r+1} - x^{r+1}$. For $r > -1$ the function $u \mapsto u^{r+1}$ is strictly increasing on $(0, \infty)$, so $h(r) > 0$; hence for $0 < |r| < 1$ the quantity $h(r)^{1/r} = \exp(\ln h(r)/r)$ is well defined.

The function h is differentiable, with

$$h'(r) = (x+1)^{r+1}\ln(x+1) - x^{r+1}\ln x, \qquad h(0) = 1, \qquad h'(0) = (x+1)\ln(x+1) - x\ln x.$$

Since $h(0) = 1$ we have $\ln h(0) = 0$, and $\ln h$ is differentiable at 0 with $(\ln h)'(0) = h'(0)/h(0) = h'(0)$. By the definition of the derivative,

$$\lim_{r\to 0}\frac{\ln h(r)}{r} = \lim_{r\to 0}\frac{\ln h(r) - \ln h(0)}{r-0} = (x+1)\ln(x+1) - x\ln x.$$

By continuity of exp,

$$g(x) = \exp\big((x+1)\ln(x+1) - x\ln x\big) = \frac{(x+1)^{x+1}}{x^x}.$$

Therefore

$$\frac{g(x)}{x} = \frac{(x+1)^{x+1}}{x^{x+1}} = \left(1+\frac{1}{x}\right)^{x+1} = \left(1+\frac{1}{x}\right)^{x}\left(1+\frac{1}{x}\right).$$

As $x\to\infty$, $\ln\big((1+1/x)^x\big) = \ln(1+t)/t$ with $t = 1/x \to 0^+$, which tends to 1 (the derivative of ln at 1), so $(1+1/x)^x \to e$, while $1+1/x \to 1$. Hence

$$\lim_{x\to\infty}\frac{g(x)}{x} = \boxed{e}.$$

Layer 1: WHAT

Block 1: freeze x, name the base $h(r)$, observe $h(0) = 1$: a 1^∞ form. Block 2: take logarithms; $\ln h(r)/r$ is the difference quotient of $\ln h$ at 0. Block 3: differentiate h at 0 and exponentiate: $g(x) = (x+1)^{x+1}/x^x$. Block 4: $g(x)/x = (1+1/x)^{x+1} \to e$.

The nominal route never freezes x. It looks at the double limit as one object, simplifies the base for large x, and reads off e from $(r+1)^{1/r}$. The bifurcation point is Block 1: the decision to treat the inner limit as a function of r alone, with x a constant. Once x is frozen, $h(0) = 1$ is visible and the derivative circuit fires; the interchange question never arises because g is computed exactly.

Layer 2: HOW

Block 1. **Cue.** The exponent $r+1$ on both terms, and the outer power $1/r$. **Why natural.** The examiners could have written $(x+1)^r - x^r$; they wrote $r+1$ so that the base is exactly 1 at $r = 0$. A base tending to 1 with an exponent tending to infinity is the 1^∞ form, and the only question about such a form is the rate at which the base leaves 1, which is a derivative. **Link to the next block.** A rate is read from the logarithm, so Block 2 takes ln.

Block 2. **Cue.** $\ln h(r)/r$ with $\ln h(0) = 0$. **Why natural.** $\ln h(r)/r = (\ln h(r) - \ln h(0))/(r-0)$ is, by definition, the difference quotient of $\ln h$ at 0. No l'Hôpital is needed: l'Hôpital applied to a $0/0$ quotient whose denominator is r is the definition of the derivative with an extra name attached. Knowing this saves you from checking the hypotheses of a theorem you do not need. **Link to the next block.** Differentiability of $\ln h$ at 0 reduces to differentiability of h, and h is a sum of exponentials in r.

Block 3. **Cue.** $h(r) = e^{(r+1)\ln(x+1)} - e^{(r+1)\ln x}$. **Why natural.** Differentiating an exponential in r brings down the logarithm of the base, so $h'(0) = (x+1)\ln(x+1) - x\ln x$, and $g(x) = \exp(h'(0)) = (x+1)^{x+1}/x^x$. Note what this is: $g(x) = e\cdot\exp\big(\int_x^{x+1}\ln u\,du\big)$, that is e times the geometric mean of u over $[x, x+1]$, because $\int_x^{x+1}\ln u\,du = (x+1)\ln(x+1) - x\ln x - 1$. That is the structural meaning of the closed form. **Link to the next block.** The outer limit is now a limit of an explicit elementary function, and dividing by x is a one-line algebraic simplification.

Block 4. Cue. $(x+1)^{x+1}/x^{x+1}$. **Why natural.** The exponents match, so the ratio is $(1+1/x)^{x+1}$, and $(1+1/x)^x \to e$ is the definition of e (or the derivative of ln at 1 if you want it from first principles). The geometric-mean reading predicts this: $g(x)$ is e times a number between x and $x+1$, so $g(x)/x$ is squeezed between e and $e(1+1/x)$. **Link to the next block.** Box e.

Layer 3: WHY

The truth beneath the route is the general rule for 1^∞: if $f(0)=1$ and f is differentiable at 0, then $f(t)^{1/t} \to e^{f'(0)}$ as $t \to 0$, because $\ln f(t)/t \to (\ln f)'(0) = f'(0)$. Every 1^∞ limit on the Putnam is this rule, sometimes with t replaced by $1/n$. The discernment mechanism is to identify the base, evaluate it at the limit point, and if it is 1, compute the derivative of its logarithm there; if it is not 1, the limit is 0 or ∞ and there is nothing to compute.

The deeper truth is the power-mean identity. By the fundamental theorem of calculus, $(x+1)^{r+1} - x^{r+1} = (r+1)\int_x^{x+1} u^r\,du$, so

$$h(r)^{1/r} = (r+1)^{1/r}\left(\int_x^{x+1} u^r\,du\right)^{1/r}.$$

The second factor is the power mean of order r of the identity function on $[x, x+1]$, and power means tend to the geometric mean as the order tends to 0; the first factor tends to e. So $g(x) = e \cdot \mathrm{GM}_{[x,x+1]}(u)$, and since any mean of values in $[x, x+1]$ lies in $[x, x+1]$, the answer e is forced before any calculation. This is how a 120 scorer reads the problem: the answer is visible from the structure, and the derivative computation is the verification you write down.

The examiners nudged with two planted details: the exponent $r+1$ (base equals 1 at $r=0$) and the division by x in the outer limit (removing the factor GM $\approx x$ so that only e survives). Train the discernment by refusing to interchange limits without a uniform estimate: the official second solution shows the price of the interchange, a Taylor remainder bounded by $(r+1)r/x$ uniformly for $x \geq 1$. Iterated limits genuinely differ in general; $\lim_{r\to 0^+}\lim_{x\to\infty} x^{-r} = 0$ while $\lim_{x\to\infty}\lim_{r\to 0^+} x^{-r} = 1$. When the inner limit has a closed form, compute it and the question disappears.

Revolving concepts

The 1^∞ form and the derivative. If $f(0)=1$ and $f'(0)$ exists then $\lim_{t\to 0} f(t)^{1/t} = e^{f'(0)}$. Equivalently, if $a_n \to 0$ and $a_n b_n \to L$ then $(1+a_n)^{b_n} \to e^L$. Generalised recursion: none, but the rule iterates: for $f(t)^{1/t^2}$ with $f(0)=1$, $f'(0)=0$, the limit is $e^{f''(0)/2}$ by the same logarithm argument one order higher. See Book 1, field: Real analysis, topic: indeterminate forms.

Power means of a function. For a probability measure μ on an interval and positive f, $M_r(f) = (\int f^r\,d\mu)^{1/r}$ for $r \neq 0$, and $M_0(f) = \exp(\int \ln f\,d\mu)$ (the geometric mean). Lemma: $M_r(f) \to M_0(f)$ as $r \to 0$, since $\int f^r\,d\mu = 1 + r\int \ln f\,d\mu + O(r^2)$ for bounded f; and M_r is nondecreasing in r. On $[x, x+1]$ with $f(u)=u$, $M_0 = e^{-1}(x+1)^{x+1}/x^x$. See Book 1, field: Inequalities, topic: power means.

The number e. $(1+1/x)^x \to e$ as $x \to \infty$ through the reals, because $x\ln(1+1/x) = \ln(1+t)/t \to 1$; moreover $(1+1/x)^x$ increases to e and $(1+1/x)^{x+1}$ decreases to e. Also $(1+r)^{1/r} \to e$ as $r \to 0$ from either side. See Book 1, field: Real analysis, topic: the exponential function.

Interchange of limits. Iterated limits agree when one of the limits is uniform in the other variable (the Moore-Osgood theorem); without uniformity they may differ. The Putnam grader expects either a uniform bound or an exact computation of the inner limit. See Book 1, field: Real analysis, topic: uniform convergence.

Circuit Bank

- **WHEN** you see $\lim_{t\to 0} f(t)^{1/t}$ and $f(0) = 1$ **DO** write $\exp\big((\ln f)'(0)\big) = \exp(f'(0))$ and differentiate **BECAUSE** because the logarithm turns the form into a difference quotient at 0, and the difference quotient of a differentiable function is its derivative by definition
- **WHEN** you see $b^{r+1} - a^{r+1}$ with the exponent shifted by one **DO** write $(r+1)\int_a^b u^r\,du$ **BECAUSE** because the shifted exponent is the antiderivative of u^r up to the factor $r+1$, and an integral of u^r over an interval is a power mean that stays between the endpoints
- **WHEN** you see two nested limits in different variables **DO** freeze the outer variable and compute the inner limit exactly **BECAUSE** because interchanging limits needs a uniform estimate you would have to prove, while an exact inner limit makes the question vanish

Backtesting

1. First useful cue: the exponent $r+1$, which makes the base equal to 1 at $r = 0$.
2. Method the expression suggested: logarithm, then the derivative of $\ln h$ at 0; the outer limit then reduces to $(1 + 1/x)^{x+1}$.
3. Where you would hesitate, and the thought to reinforce: the temptation to send $x \to \infty$ first because the base looks simpler. Reinforce: freeze the outer variable; the inner limit is elementary.
4. The trap the question sets: the correct number e is obtainable by an illegal interchange, so a wrong argument produces a right answer and a low score.
5. What makes you recognise it faster next time: any base that evaluates to 1 at the limit point with a reciprocal exponent; and any difference $b^s - a^s$ is $s\int_a^b u^{s-1}\,du$.
6. The reusable decision rule: 1^∞ means differentiate the log of the base at the limit point; never interchange limits you can compute.

Mirror drills

1. (drill) For $a, b > 0$ find $\lim_{r\to 0}\big((a^r + b^r)/2\big)^{1/r}$. *Answer:* the base is 1 at $r = 0$ with log-derivative $(\ln a + \ln b)/2$, so the limit is $\sqrt{ab}$: the power mean tends to the geometric mean.
2. (drill) Find $\lim_{r\to 0}\big(\int_0^1 (1+t)^r\,dt\big)^{1/r}$. *Answer:* $\exp\big(\int_0^1 \ln(1+t)\,dt\big) = \exp(2\ln 2 - 1) = 4/e$.
3. (drill) Find $\lim_{n\to\infty}(n!)^{1/n}/n$. *Answer:* ln of it is $\frac{1}{n}\sum_{k=1}^n \ln(k/n) \to \int_0^1 \ln t\,dt = -1$, so the limit is $1/e$; a geometric mean again.

5.3 A3. Regular tetrahedron with lattice vertices on a sphere

Determine all positive integers N for which the sphere

$$x^2 + y^2 + z^2 = N$$

has an inscribed regular tetrahedron whose vertices have integer coordinates.

Read it out loud

A sphere centred at the origin of radius $\sqrt{N}$; four lattice points on it forming a regular tetrahedron; "determine all N". The last phrase is again a two-part contract: a family of constructions and a proof that nothing outside the family works. The fields wired in are the metric geometry of the regular tetrahedron (equal edges, circumcentre at the centroid), lattice integrality (dot products of integer vectors are integers, determinants of integer matrices are integers), and the algebra that connects lengths to determinants, which is the Gram matrix. The answer will be a Diophantine condition on N, and Diophantine conditions come from integer invariants, so the question is really: which integer invariant of the configuration is pinned down by regularity?

Read the objects by their definitions. A vertex is a position vector $P_i \in \mathbb{Z}^3$ with $|P_i|^2 = N$ (the sphere is centred at the origin, so position vectors are the natural objects, another planted cue). "Regular" means all six edges are equal, and since $|P_i - P_j|^2 = 2N - 2P_i \cdot P_j$, this says exactly that all six dot products $P_i \cdot P_j$ ($i \neq j$) are equal to one integer c. So within thirty seconds you should have written: $|P_i|^2 = N$, $P_i \cdot P_j = c \in \mathbb{Z}$ for $i \neq j$. That is the whole configuration encoded in two integers, and from here the problem is linear algebra.

The examiners were nudging toward $N = 3m^2$: the cube $[-m, m]^3$ has the sphere of radius $m\sqrt{3}$ as circumsphere and its alternate vertices form a regular tetrahedron. The construction is a memory retrieval. The necessity is the test.

Approaches, ranked worst to best

1. **Coordinates and distance equations.** *Cue:* four points, six equal distances. *Circuit:* write down everything. (ten polynomial equations in twelve integer unknowns; no structure, no progress; this is zombie maths and it stalls on the first page)
2. **Volume of the tetrahedron.** *Cue:* regular tetrahedron with known circumradius. *Circuit:* memorised formulas $R = a\sqrt{6}/4$ and $V = a^3/(6\sqrt{2})$, plus $V = |\det|/6$. (correct: $a^2 = 8N/3$ and $\det(P_2 - P_1, P_3 - P_1, P_4 - P_1) = a^3/\sqrt{2}$ is an integer, so $256N^3/27$ is a perfect square; but two formulas must be recalled exactly, and a slip in either is fatal)
3. **Complete to a cube.** *Cue:* a regular tetrahedron is the alternate vertices of a cube. *Circuit:* antipodal points $-P_i$ are lattice points on the same sphere. (the official route: the eight points $\pm P_i$ form a cube of edge $2\sqrt{N/3}$ once you know the centroid is the origin; its volume $8(N/3)^{3/2}$ is an integer determinant; one geometric picture and one formula)
4. **Gram matrix.** *Cue:* integer coordinates plus equal dot products. *Circuit:* $G = MM^{\mathsf{T}}$, $\det G = (\det M)^2$, and four vectors in $\mathbb{R}^3$ have singular Gram matrix. (no geometric formulas at all: singularity of the 4×4 Gram matrix forces $c = -N/3$, and the 3×3 Gram determinant $16k^3$ must be a perfect square; the laziest route because every step is forced by a definition)

The ideal solution

Answer. Exactly the integers $N = 3m^2$ with m a positive integer.

Construction. Let $N = 3m^2$ and take

$$P_1 = (m, m, m), \quad P_2 = (m, -m, -m), \quad P_3 = (-m, m, -m), \quad P_4 = (-m, -m, m).$$

Each has $|P_i|^2 = 3m^2 = N$. The six differences are $(0, 2m, 2m)$, $(2m, 0, 2m)$, $(2m, 2m, 0)$, $(2m, -2m, 0)$, $(2m, 0, -2m)$, $(0, 2m, -2m)$ up to sign, each of squared length $8m^2$. A tetrahedron with six equal edges is regular, so these four lattice points are the vertices of a regular tetrahedron inscribed in the sphere.

Necessity. Suppose $P_1, \dots, P_4 \in \mathbb{Z}^3$ are the vertices of a regular tetrahedron inscribed in $x^2 + y^2 + z^2 = N$, with common edge length $a > 0$. Then $|P_i|^2 = N$ and, for $i \neq j$, $P_i \cdot P_j = \frac{1}{2}\big(|P_i|^2 + |P_j|^2 - |P_i - P_j|^2\big) = N - a^2/2 =: c$, which is an integer because it is a dot product of integer vectors.

Let M be the 4×3 matrix whose rows are $P_1, \dots, P_4$ and let $G = MM^{\mathsf{T}}$ be the 4×4 Gram matrix, so $G_{ij} = P_i \cdot P_j$. Then $G = (N - c)I + cJ$, where J is the all-ones matrix. Since $\operatorname{rank} G \leq \operatorname{rank} M \leq 3$, $\det G = 0$. The matrix J has eigenvalue 4 on $(1, 1, 1, 1)$ and eigenvalue 0 on the three-dimensional orthogonal complement, so G has eigenvalues $N + 3c$ (once) and $N - c$ (three times), and

$$0 = \det G = (N - c)^3(N + 3c).$$

As $N - c = a^2/2 > 0$, we get $c = -N/3$. Since c is an integer, $3 \mid N$; write $N = 3k$ with $k \geq 1$, so $c = -k$.

Now let M_3 be the 3×3 integer matrix with rows P_1, P_2, P_3 and $G_3 = M_3 M_3^{\mathsf{T}}$ its Gram matrix. Then $G_3 = (N - c)I + cJ = 4kI - kJ$ (with I, J now 3×3), whose eigenvalues are $4k - 3k = k$ (once) and $4k$ (twice), so $\det G_3 = 16k^3$. On the other hand $\det G_3 = (\det M_3)^2 = D^2$ with $D \in \mathbb{Z}$. Hence $D^2 = 16k^3$, so $4 \mid D$ and $k^3 = (D/4)^2$ is a perfect square. For every prime p, $3\, v_p(k)$ is even, hence $v_p(k)$ is even; therefore $k = m^2$ for some positive integer m, and $N = 3m^2$.

Combining both parts, the sphere $x^2 + y^2 + z^2 = N$ has an inscribed regular tetrahedron with integer vertices if and only if

$$\boxed{N = 3m^2 \text{ for some positive integer } m.}$$

Layer 1: WHAT

Block 1: encode the configuration as $|P_i|^2 = N$, $P_i \cdot P_j = c \in \mathbb{Z}$. Block 2: four vectors in $\mathbb{R}^3$ have a singular Gram matrix; $(N - c)^3(N + 3c) = 0$ gives $c = -N/3$, hence $3 \mid N$. Block 3: the 3×3 Gram determinant $16k^3$ equals an integer squared, hence k is a square. Block 4: the cube's alternate vertices give the construction.

The nominal route writes coordinates and distances (square roots, twelve unknowns) or reaches for memorised tetrahedron formulas. The bifurcation point is Block 1: the decision to describe the tetrahedron by its Gram matrix (two integers) rather than by its coordinates or its edge length. Every later step is then a definition: rank of a product, eigenvalues of $aI + bJ$, determinant of a product. The zombie route can also arrive, via the circumradius formula, but it arrives carrying formulas it cannot verify in the arena.

Layer 2: HOW

Block 1. **Cue.** "Integer coordinates", "regular", and a sphere centred at the origin. **Why natural.** Integrality lives in dot products and determinants, not in lengths: $|P_i - P_j| = a$ is irrational in general, but $P_i \cdot P_j$ is an integer. Regularity is a statement about six equal lengths, and the polarisation identity $|P_i - P_j|^2 = |P_i|^2 + |P_j|^2 - 2P_i \cdot P_j$ converts it into six equal integers. The centre at the origin makes position vectors the objects, so $|P_i|^2 = N$ is given for free. **Link to the next block.** A set of vectors with all pairwise dot products known is exactly a Gram matrix, and a Gram matrix carries two invariants you can compute: its rank and its determinant.

Block 2. **Cue.** Four vectors in three-dimensional space. **Why natural.** $G = MM^{\mathsf{T}}$ has rank at most 3, so the 4×4 determinant vanishes; and $G = (N - c)I + cJ$ has explicitly known eigenvalues because J is rank one. The factor $N + 3c$ is the eigenvalue on $(1, 1, 1, 1)$, and its vanishing says

$M^{\mathsf{T}}(1,1,1,1) = P_1 + P_2 + P_3 + P_4 = 0$: the centroid is the origin. That is the algebraic form of the geometric fact that a regular tetrahedron's circumcentre is its centroid, derived rather than recalled. **Link to the next block.** $c = -N/3$ is an integer, so $3 \mid N$; the remaining question is what constrains $k = N/3$, and the only unused integer invariant is a determinant.

Block 3. Cue. Three of the vectors are linearly independent (their Gram determinant is $16k^3 \neq 0$) and integral. **Why natural.** $\det(M_3 M_3^{\mathsf{T}}) = (\det M_3)^2$ and $\det M_3 \in \mathbb{Z}$. So the number $16k^3$ must be a perfect square, and a cube that is a square is a sixth power up to units: exponent bookkeeping prime by prime. **Link to the next block.** Necessity is complete: $N = 3m^2$. Now the construction must exist for every m, and the Block 2 fact $\sum P_i = 0$ tells you where to look: the antipodes $-P_i$ are on the sphere too, and eight points of the form $\pm P_i$ with all dot products $\pm k$ form a cube.

Block 4. Cue. $N = 3m^2 = m^2 + m^2 + m^2$. **Why natural.** The cube $[-m, m]^3$ has circumradius $m\sqrt{3}$, and its alternate vertices (those with an even number of minus signs) are pairwise at squared distance $8m^2$. Verifying six differences is faster and safer than any other check. **Link to the next block.** Both halves done; box the family.

Layer 3: WHY

Three truths. First, a configuration of vectors is determined up to isometry by its Gram matrix, so any question "which lengths are possible" is a question about which Gram matrices are realisable, and realisability of a Gram matrix over $\mathbb{Z}^3$ imposes integrality on det and rank conditions on size. Second, for $aI + bJ$ the spectrum is a (with multiplicity $n-1$) and $a + nb$ (once); every equal-dot-product configuration, that is every regular simplex, has a Gram matrix of this form, so the eigenvalue computation is a reflex. Third, an integer matrix E with $EE^{\mathsf{T}} = \lambda I$ in odd dimension n forces $\lambda^{n/2} = |\det E| \in \mathbb{Z}$, hence λ a perfect square; the cube's three edge vectors are such an E with $\lambda = 4k$. This is why the dimension matters: in the plane, $\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}$ has $EE^{\mathsf{T}} = 2I$ with 2 not a square, and indeed a square with integer vertices can be inscribed in $x^2 + y^2 = 2$.

The discernment mechanism: when the answer must be a Diophantine condition, list the integer invariants of the configuration (dot products, determinants, areas times 2, volumes times 6) and ask which one regularity pins to a formula in N. Train it by solving every lattice-geometry problem twice, once with coordinates and once with the Gram matrix, until the second becomes the reflex. The examiners nudged with "integer coordinates" (integrality), "regular" (equal dot products), and the origin-centred sphere (position vectors), and they chose the tetrahedron rather than the octahedron precisely because the tetrahedron needs the extra step $c = -N/3$ before the determinant fires.

Revolving concepts

Regular tetrahedron. Edge a, circumradius $R = a\sqrt{6}/4$, volume $a^3/(6\sqrt{2})$; circumcentre, centroid and incentre coincide; the vertex vectors from the centre satisfy $P_i \cdot P_j = -R^2/3$; it is the set of alternate vertices of a cube of edge $a/\sqrt{2}$. See Book 1, field: Geometry, topic: regular polyhedra.

Gram matrix. For vectors $v_1, \ldots, v_m \in \mathbb{R}^n$ with matrix M of rows v_i, $G = MM^{\mathsf{T}}$; G is positive semidefinite, $\operatorname{rank} G = \operatorname{rank} M \leq n$, and for $m = n$, $\det G = (\det M)^2$ is the squared volume of the parallelepiped. Generalised recursion: a regular n-simplex centred at the origin with circumradius squared N has $c = -N/n$ and the Gram determinant of n of its vertex vectors is $N^n(n+1)^{n-1}/n^n$; for $n = 3$ this is $16N^3/27 = 16k^3$. Schoenberg (1937) used exactly this to classify the n for which a regular n-simplex has vertices in $\mathbb{Z}^n$: always for $n \equiv 3 \pmod 4$, for $n \equiv 1 \pmod 4$ if and only if $n+1$ is a sum of two squares, and for even n if and only if $n+1$ is a perfect square. See Book 1, field: Matrices and determinants, topic: Gram matrices.

Spectrum of $aI + bJ$. Eigenvalues a (multiplicity $n-1$, on the sum-zero hyperplane) and $a+nb$ (on the all-ones vector); determinant $a^{n-1}(a+nb)$. See Book 1, field: Linear algebra, topic: rank-one updates.

Perfect-square bookkeeping. If k^3 is a perfect square then k is, by parity of p-adic valuations; if $D^2 = 16k^3$ then $4 \mid D$. See Book 1, field: Number theory, topic: valuations.

Circuit Bank

- **WHEN** you see lattice points with prescribed equal lengths or angles **DO** write the Gram matrix of the position vectors and record that its entries and its determinant are integers **BECAUSE** because integrality lives in dot products and determinants, while lengths are irrational; the Gram matrix is the smallest complete integer description of the configuration
- **WHEN** you see $n+1$ vectors in $\mathbb{R}^n$ with all dot products known **DO** write $\det G = 0$ and solve for the unknown dot product **BECAUSE** because the Gram matrix of dependent vectors is singular, and for equal dot products the determinant factors as $(N-c)^n(N+nc)$
- **WHEN** you see "for which N" in a lattice problem **DO** compute an integer determinant in terms of N and demand it be an integer or a perfect square **BECAUSE** because a Diophantine condition on N can only come from an integer invariant, and $(\det M)^2 = \det G$ is the invariant that regularity makes computable

Backtesting

1. First useful cue: "integer coordinates" together with "regular", signalling integer dot products that are all equal.
2. Method the expression suggested: Gram matrix $(N-c)I + cJ$; singularity in size four, squared determinant in size three.
3. Where you would hesitate, and the thought to reinforce: whether $c = -N/3$ needs the circumradius formula. Reinforce: it falls out of $\det G = 0$; derive, do not recall.
4. The trap the question sets: reaching for coordinates and distances, which produce square roots and twelve unknowns.
5. What makes you recognise it faster next time: any regular figure inscribed in an origin-centred sphere is a Gram matrix of the form $aI + bJ$.
6. The reusable decision rule: encode lattice configurations by Gram matrices; extract integrality from determinants.

Mirror drills

1. (drill) For which positive integers N does the circle $x^2 + y^2 = N$ have an inscribed square with integer vertices? *Answer:* exactly the N that are sums of two squares; if (a, b) is on the circle, so are $(-b, a), (-a, -b), (b, -a)$, and conversely any lattice point on the circle gives $N = a^2 + b^2$.
2. (drill) Show no equilateral triangle has all three vertices in $\mathbb{Z}^2$. *Answer:* with edge vectors u, v, $|u|^2 = |v|^2 = a^2$ and $u \cdot v = a^2/2$, the Gram determinant is $3a^4/4$, which must be the square of an integer; that makes $\sqrt{3}$ rational.
3. (drill) For which N does $x^2 + y^2 + z^2 = N$ have an inscribed regular octahedron with integer vertices? *Answer:* the vertices are $\pm u_1, \pm u_2, \pm u_3$ with u_i mutually orthogonal integer vectors of squared length N; the matrix E with rows u_i has $EE^{\mathsf{T}} = NI$, so $N^{3/2} = |\det E| \in \mathbb{Z}$ and N is a perfect square; conversely $(m, 0, 0), (0, m, 0), (0, 0, m)$ and their negatives work.

5.4 A4. Two divergent integrals whose difference survives

Let

$$I(R) = \iint_{x^2+y^2\le R^2} \left(\frac{1+2x^2}{1+x^4+6x^2y^2+y^4} - \frac{1+y^2}{2+x^4+y^4} \right) dx\, dy.$$

Find

$$\lim_{R\to\infty} I(R),$$

or show that this limit does not exist.

Read it out loud

Say the structure back to yourself before you touch a pen. This is a double integral over an expanding disc of a difference of two rational functions, each of which is a quadratic in x and y divided by a quartic in x and y. Both denominators are strictly positive everywhere, so for each fixed R there is nothing improper about the integral: the integrand is continuous on a compact set and $I(R)$ is an honest number. The only analysis lives in the limit.

Now the size count, which is the single most informative thing you can do in the first thirty seconds. At radius r, each numerator is of size r^2 and each denominator is of size r^4, so each integrand is of size r^{-2}, and the area element in polar coordinates is $r\,dr\,d\theta$. Each of the two pieces on its own therefore contributes $\int^R r^{-1}\,dr$, which is $\log R$: each piece diverges. The problem is engineered so that two logarithmic divergences cancel and a finite residue is left behind. That tells you the whole shape of the answer immediately. You are not being asked to integrate anything; you are being asked to match the two pieces against each other so exactly that only the residue remains. Any route that computes the two integrals separately is dead on arrival, because there is nothing to compute separately.

The fields wired into this question: symmetry of a domain under a finite group and averaging over that group, linear changes of variable in the plane with their Jacobians, polar coordinates for quartic forms, elementary rational trigonometric integrals, and a controlled interchange of a limit with an integral. The examiners' guiding lights are the two denominators. Look at them side by side: $x^4+6x^2y^2+y^4$ and x^4+y^4, with constants 1 and 2. The binomial identity $(x+y)^4+(x-y)^4 = 2(x^4+6x^2y^2+y^4)$ is A-level algebra, and the constants 1 and 2 sit in exactly the ratio that identity produces. That is the plant. The map $(x,y)\mapsto(x+y,x-y)$ is what the question is about, and everything else is bookkeeping.

The only obstruction is that the numerators do not match: $1+2x^2$ against $1+y^2$. So within thirty seconds you should have written down the two denominators, the identity for $(x+y)^4+(x-y)^4$, and the note "numerators asymmetric, domain symmetric, so average them".

Approaches, ranked worst to best

1. **Evaluate each term separately.** *Cue:* two fractions joined by a minus sign. *Circuit:* split the integral, integrate term by term. Ranks last because it is not merely long, it is invalid. Each term integrates to something of order $\log R$, so neither limit exists and the difference of the two limits is meaningless. A candidate who writes $\lim(A(R)-B(R)) = \lim A(R) - \lim B(R)$ here has lost the problem in one line.

2. **Polar coordinates then grind the radial integrals.** *Cue:* quartic forms become r^4 times a function of θ. *Circuit:* substitute $u=r^2$, partial fractions, arctan plus log. This does work. For fixed θ the radial integrals are elementary and give an arctangent plus a logarithm, so you obtain $I(R) = \alpha(\theta)$ terms integrated over θ with a $\log R$ coefficient $\int_0^{2\pi}(\frac{\cos^2\theta}{2(1+\sin^2 2\theta)} - \frac{\sin^2\theta}{4(1-\frac{1}{2}\sin^2 2\theta)})\,d\theta$ that you must then prove vanishes, plus a finite part you must then assemble.

Two pages of arctangent bookkeeping, and you still have to discover the angular shift to evaluate the finite part. It costs far more ink than the structure demands.

3. **Discover the reroute inside polar coordinates.** *Cue:* $x^4 + 6x^2y^2 + y^4 = r^4(1 + \sin^2 2\theta)$ and $x^4 + y^4 = r^4(1 - \frac{1}{2}\sin^2 2\theta)$. *Circuit:* compare the two angular profiles and look for a shift. In polar the two denominators are $1 + r^4(1 + \sin^2 2\theta)$ and $2 + r^4(1 - \frac{1}{2}\sin^2 2\theta)$, and replacing (r, θ) by $(r\sqrt{2}, \theta + \pi/4)$ in the second gives exactly twice the first. This is the same reroute seen through polar spectacles and it is a good route, but you have to notice a simultaneous rotation and dilation inside trigonometric identities rather than in one line of binomial algebra.

4. **Kill the odd parts, then apply the linear map to the first term only.** *Cue:* $D_1 = 1 + x^4 + 6x^2y^2 + y^4$ is invariant under both $x \leftrightarrow y$ and $x \mapsto -x$. *Circuit:* odd numerators integrate to zero over a symmetric domain. Replace $1 + 2x^2$ by $1 + (x - y)^2$, legal because $(1 + 2x^2) - (1 + (x - y)^2) = x^2 + 2xy - y^2$ is a sum of two pieces each odd under a symmetry of the disc and of D_1. Then the first term is exactly twice the second term composed with $(x, y) \mapsto (x + y, x - y)$. Excellent and short, but it needs two separate parity arguments rather than one principle.

5. **Symmetrise the whole integrand, then apply the linear map.** *Cue:* the disc and both denominators are invariant under $x \leftrightarrow y$, the numerators are not. *Circuit:* average a function over the symmetry group of the domain before doing anything else. The best route. One legal move makes both numerators symmetric, after which the two terms become the same function up to the map $(x, y) \mapsto (x + y, x - y)$, and the whole difference collapses to a single integral over an annulus. Three lines to the collapse, and the surviving integral is a standard rational trigonometric integral.

The ideal solution

The limit exists and equals

$$\boxed{\frac{\pi \log 2}{\sqrt{2}}} = \frac{\sqrt{2}}{2}\,\pi \log 2,$$

where log is the natural logarithm.

Write $D_R = \{(x, y) : x^2 + y^2 \le R^2\}$. Both denominators are at least 1, so the integrand is continuous on D_R and $I(R)$ exists for each R.

Step 1: symmetrise. The reflection $\sigma(x, y) = (y, x)$ maps D_R onto itself and preserves area, so $\iint_{D_R} F = \iint_{D_R} F \circ \sigma$ for any continuous F, and hence

$$\iint_{D_R} F = \iint_{D_R} \tfrac{1}{2}\,(F + F \circ \sigma)\,.$$

Both denominators are σ invariant, so only the numerators feel the averaging:

$$I(R) = \iint_{D_R} \big(f(x, y) - g(x, y)\big)\,dx\,dy,$$

$$f(x, y) = \frac{1 + x^2 + y^2}{1 + x^4 + 6x^2y^2 + y^4}, \qquad g(x, y) = \frac{1 + \frac{1}{2}(x^2 + y^2)}{2 + x^4 + y^4}.$$

Step 2: the linear map. Let $T(x, y) = (x + y, x - y)$. Then

$$(x + y)^2 + (x - y)^2 = 2(x^2 + y^2), \qquad (x + y)^4 + (x - y)^4 = 2(x^4 + 6x^2y^2 + y^4),$$

the second being the even part of the binomial expansion doubled. Therefore

$$g(T(x, y)) = \frac{1 + x^2 + y^2}{2\,(1 + x^4 + 6x^2y^2 + y^4)} = \tfrac{1}{2} f(x, y).$$

The map T is linear with $\det T = -2$, and $|T(p)| = \sqrt{2}\,|p|$, so T carries D_R bijectively onto $D_{R\sqrt{2}}$. The change of variables formula gives

$$\iint_{D_R} f = 2\iint_{D_R} g\circ T = 2\cdot\frac{1}{|\det T|}\iint_{D_{R\sqrt{2}}} g = \iint_{D_{R\sqrt{2}}} g.$$

Subtracting the integral of g over D_R,

$$I(R) = \iint_{D_{R\sqrt{2}}} g - \iint_{D_R} g = \iint_{A_R} g, \qquad A_R = \{R \le |p| \le R\sqrt{2}\}.$$

Step 3: polar coordinates and an exact radial integral. Since $x^4+y^4 = r^4\left(1-\frac{1}{2}\sin^2 2\theta\right)$, write $c = c(\theta) = 1-\frac{1}{2}\sin^2 2\theta$, so that $\frac{1}{2} \le c \le 1$. Then

$$I(R) = \int_0^{2\pi}\int_R^{R\sqrt{2}} \frac{\left(1+\frac{1}{2}r^2\right) r}{2+r^4 c}\,dr\,d\theta.$$

For fixed θ substitute $u = r^2$:

$$\int_R^{R\sqrt{2}} \frac{\left(1+\frac{1}{2}r^2\right) r\,dr}{2+r^4c} = \frac{1}{2}\int_{R^2}^{2R^2}\frac{du}{2+cu^2} + \frac{1}{4}\int_{R^2}^{2R^2}\frac{u\,du}{2+cu^2},$$

$$= \frac{1}{2\sqrt{2c}}\left[\arctan\left(u\sqrt{\tfrac{c}{2}}\right)\right]_{R^2}^{2R^2} + \frac{1}{8c}\log\frac{2+4cR^4}{2+cR^4}.$$

Step 4: uniform error bounds. For $B > 0$ we have $\arctan(2B) - \arctan(B) \le \frac{\pi}{2} - \arctan B = \operatorname{arctan}\frac{1}{B} \le \frac{1}{B}$. Taking $B = R^2\sqrt{c/2}$ and using $c \ge \frac{1}{2}$, the arctangent term is at most

$$\frac{1}{2\sqrt{2c}}\cdot\frac{1}{R^2\sqrt{c/2}} = \frac{1}{2cR^2} \le \frac{1}{R^2}.$$

For the logarithm, $\frac{2+4cR^4}{2+cR^4} = 4\,(1-t)$ with $t = \frac{3}{2(2+cR^4)}$, and $2+cR^4 \ge \frac{1}{2}R^4$ gives $0 \le t \le 3R^{-4}$. For $R \ge 2$ this puts $t \le \frac{1}{2}$, where $|\log(1-t)| \le 2t$, so

$$\left|\frac{1}{8c}\log\frac{2+4cR^4}{2+cR^4} - \frac{\log 4}{8c}\right| \le \frac{1}{8c}\cdot\frac{6}{R^4} \le \frac{3}{2R^4}.$$

Since $\frac{\log 4}{8c} = \frac{\log 2}{4c}$, the bracketed radial integral differs from $\frac{\log 2}{4c(\theta)}$ by at most $R^{-2} + \frac{3}{2}R^{-4}$, uniformly in θ. Integrating over $\theta \in [0, 2\pi]$,

$$\left|I(R) - \frac{\log 2}{4}\int_0^{2\pi}\frac{d\theta}{c(\theta)}\right| \le 2\pi\left(\frac{1}{R^2} + \frac{3}{2R^4}\right) \longrightarrow 0.$$

Step 5: the angular integral. Put $\phi = 2\theta$. The function $\phi \mapsto (1-\frac{1}{2}\sin^2\phi)^{-1}$ has period π and is symmetric about $\phi = \frac{\pi}{2}$, so

$$\int_0^{2\pi}\frac{d\theta}{1-\frac{1}{2}\sin^2 2\theta} = \frac{1}{2}\int_0^{4\pi}\frac{d\phi}{1-\frac{1}{2}\sin^2\phi} = 2\int_0^{\pi}\frac{d\phi}{1-\frac{1}{2}\sin^2\phi} = 4\int_0^{\pi/2}\frac{d\phi}{1-\frac{1}{2}\sin^2\phi}.$$

Divide numerator and denominator by $\cos^2\phi$ and set $t = \tan\phi$:

$$\int_0^{\pi/2}\frac{d\phi}{1-\frac{1}{2}\sin^2\phi} = \int_0^{\infty}\frac{dt}{1+\frac{1}{2}t^2} = \sqrt{2}\int_0^{\infty}\frac{ds}{1+s^2} = \frac{\pi}{\sqrt{2}}.$$

Hence $\int_0^{2\pi} c(\theta)^{-1}\,d\theta = 2\sqrt{2}\,\pi$, and

$$\lim_{R\to\infty} I(R) = \frac{\log 2}{4}\cdot 2\sqrt{2}\,\pi = \frac{\pi\log 2}{\sqrt{2}} \approx 1.5398.$$

Layer 1: WHAT

Block 1: size count in polar shows each half diverges like $\log R$, so the problem is a cancellation problem, not an evaluation problem.

Block 2: the disc and both denominators are invariant under $x \leftrightarrow y$, so replace each numerator by its average under that swap at no cost.

Block 3: the symmetrised numerators are $1 + x^2 + y^2$ and $1 + \frac{1}{2}(x^2 + y^2)$, and the symmetrised denominators are linked by $(x+y)^4 + (x-y)^4 = 2(x^4 + 6x^2y^2 + y^4)$; hence $f = 2\,(g \circ T)$ with $T(x,y) = (x+y, x-y)$.

Block 4: T scales lengths by $\sqrt{2}$ and has $|\det T| = 2$, so integrating f over D_R equals integrating g over $D_{R\sqrt{2}}$; the difference telescopes to g over the annulus between the two discs.

Block 5: on the annulus, polar coordinates plus $u = r^2$ give an exact arctangent plus logarithm; the arctangent part is $O(R^{-2})$ and the logarithm tends to $\frac{\log 2}{4c(\theta)}$ uniformly.

Block 6: the surviving angular integral is a standard tan substitution.

The nominal route is Block 1 followed by "polar coordinates, integrate in r, then in θ". It reaches the answer but only after separating a divergent $\log R$ coefficient, proving that coefficient is zero by a second angular integral, and then reassembling a finite part from four arctangent limits. The bifurcation point is the line immediately after the size count: the zombie writes $x = r\cos\theta$, the ideal route writes "the domain has a symmetry the numerators lack". Everything downstream follows from that single choice, because symmetrising is what turns two unrelated fractions into one fraction seen at two scales.

Layer 2: HOW

Block 1. **Cue.** Two rational functions, numerator degree 2, denominator degree 4, integrated over a disc of growing radius, with the answer allowed not to exist. **Why natural.** The examiners explicitly offer "or show that this limit does not exist", which is a confession that convergence is the delicate point. A degree count in polar coordinates settles it in one line: integrand of size r^{-2} against area element $r\,dr\,d\theta$ gives $\int^R \frac{dr}{r}$. Both halves diverge, so the minus sign between them is load bearing and must never be split. **Link to the next block.** Knowing the two halves must cancel to leading order tells you they are the same object in disguise, so your job is to find the disguise.

Block 2. **Cue.** The region $x^2 + y^2 \le R^2$ is symmetric in x and y, and so are both denominators, but the numerators $1 + 2x^2$ and $1 + y^2$ are not. **Why natural.** If a measure preserving map σ of the domain onto itself exists, then $\iint F = \iint F \circ \sigma$, and averaging the two is free. You use it whenever the asymmetry sits in a part of the expression you wish were symmetric. Here it is a targeted move: the denominators already have the symmetry, so averaging changes nothing except to repair the numerators. This is not a guess about what might help; it is removing the only structural mismatch in sight. **Link to the next block.** With symmetric numerators, each fraction is now a function of $x^2 + y^2$ over a quartic form, so the two fractions can only differ by a change of variable.

Block 3. **Cue.** $x^4 + 6x^2y^2 + y^4$ next to $x^4 + y^4$, with constant terms 1 and 2. **Why natural.** $(x+y)^4 + (x-y)^4$ is twice the even part of $(x+y)^4$, that is $2(x^4 + 6x^2y^2 + y^4)$. The constants match the same factor of two, and $(x+y)^2 + (x-y)^2 = 2(x^2+y^2)$ makes the numerators match as well. Three separate matches under the same substitution is not a coincidence; it is the problem being read backwards from g. That is the reason the move is natural rather than inspired. **Link to the next block.** You now have $f = 2(g \circ T)$ as a pointwise identity, so all that is left is to see what T does to the domain.

Block 4. **Cue.** $T(x,y) = (x+y, x-y)$ is a rotation by $\frac{\pi}{4}$ composed with a dilation by $\sqrt{2}$. **Why natural.** $|T(p)| = \sqrt{2}|p|$ maps the disc of radius R onto the disc of radius $R\sqrt{2}$, and $|\det T| = 2$

exactly cancels the factor 2 in $f = 2(g \circ T)$. So $\iint_{D_R} f$ and $\iint_{D_{R\sqrt{2}}} g$ are literally the same number. A difference of integrals of the same function over nested discs is an integral over the annulus between them. **Link to the next block.** The annulus $R \le |p| \le R\sqrt{2}$ has inner and outer radii in fixed ratio, which is exactly the shape that makes a log finite: $\int_R^{R\sqrt{2}} \frac{dr}{r} = \log\sqrt{2}$ for every R.

Block 5. Cue. An annulus integral of a fraction whose denominator is $2 + r^4 c(\theta)$. **Why natural.** Substituting $u = r^2$ makes both pieces standard: $\int \frac{du}{a+cu^2}$ is an arctangent and $\int \frac{u\,du}{a+cu^2}$ is a logarithm. Do the radial integral exactly rather than passing to the limit inside, because then the limit interchange needs no theorem, only two inequalities. The arctangent difference over $[R^2, 2R^2]$ is $O(R^{-2})$ because both endpoints are near $\frac{\pi}{2}$; the logarithm of a ratio of two quartics tends to $\log 4$ at rate R^{-4}, and both bounds hold uniformly in θ because $c(\theta) \ge \frac{1}{2}$. **Link to the next block.** A uniform bound integrated over a set of finite measure is still a bound, so the limit passes through the θ integral with an explicit error, not an appeal to a convergence theorem.

Block 6. Cue. $\int_0^{2\pi} \frac{d\theta}{1-\frac{1}{2}\sin^2 2\theta}$. **Why natural.** A rational function of $\sin^2$ and $\cos^2$ over a full period is handled by $t = \tan\phi$ after reducing to a quarter period using periodicity and reflection. That substitution turns $1 - \frac{1}{2}\sin^2\phi$ into $1 + \frac{1}{2}t^2$ and the integral into an arctangent. **Link to the next block.** Multiply by the radial factor $\frac{\log 2}{4}$ and box the answer.

Layer 3: WHY

The mathematical truth underneath this problem is that a conditionally convergent improper integral in the plane has no value until you specify the exhaustion, and that the value you get is a statement about how the integrand's tail is arranged around infinity, not about the integrand near the origin. Both halves here have tails of size r^{-2}, the exact borderline in two dimensions. Because the disc exhaustion is prescribed, and because the two halves are the same function viewed at scales differing by the factor $\sqrt{2}$, the difference of the two tails is exactly the mass sitting in one annulus of ratio $\sqrt{2}$, and that mass has a finite limit because the integrand is asymptotically homogeneous of degree -2. In other words: a function that behaves like $\frac{h(\theta)}{r^2}$ at infinity assigns the mass $\log(\lambda)\int h$ to every annulus of ratio λ, independently of where the annulus sits. That is the entire content of the answer, and $\log\sqrt{2} = \frac{1}{2}\log 2$ is where the $\log 2$ comes from.

The discernment mechanism is a two part test that you should run on every symmetric looking integral. First, list the symmetries of the domain (here the dihedral group of the square acts on the disc, and the swap $x \leftrightarrow y$ is the element you need). Second, ask which factors of the integrand already have that symmetry. If the denominator has it and the numerator does not, symmetrising is free and strictly simplifying, so it is never wrong to do it. This is the same instinct as replacing an expression by its symmetric average in an inequality: you are choosing a representative of an equivalence class, and you choose the most symmetric one.

The second discernment is scale matching. When two expressions differ by a constant factor in the same places (the 1 against the 2 in the constant terms, the $x^2 + y^2$ against $\frac{1}{2}(x^2 + y^2)$ in the numerators, the two quartic forms), the correct hypothesis is that a single linear map converts one into the other, and the factor is a power of the dilation ratio. Test that hypothesis by comparing degrees: a linear map scaling lengths by λ multiplies a form of degree d by λ^d. Here the quartics differ by $2 = (\sqrt{2})^2$ on the constants and by $(\sqrt{2})^4/2$ on the quartic parts, consistently with $\lambda = \sqrt{2}$. You do not search blindly for a substitution; you read off λ from the constants and then look for the rotation that fixes the angular profile.

To train this, take any Putnam integral with a quartic or biquadratic denominator and write the denominator in polar form. The angular profile of $x^4 + y^4$ is $1 - \frac{1}{2}\sin^2 2\theta$ and that of $x^4 + 6x^2y^2 + y^4$ is $1 + \sin^2 2\theta$; these are the same profile up to a quarter turn and a factor of two, and once you have seen that once you will see it forever. What the examiners nudged toward: they wrote the two

denominators in the same variables, in the same order, with constants in the ratio $1:2$, and offered you the escape hatch of nonexistence to force you to do the size count first.

Revolving concepts

Symmetrisation over a group action. If a finite group G acts on a domain D by measure preserving bijections, then $\iint_D F = \iint_D F^G$ where $F^G = \frac{1}{|G|}\sum_{\sigma\in G} F\circ\sigma$. For the disc, G can be taken to be any subgroup of $O(2)$; here the two element group generated by $x \leftrightarrow y$ is enough. The same principle in one dimension is $\int_{-a}^{a} F = \int_{-a}^{a} \frac{F(x)+F(-x)}{2}$, which is how odd parts are killed. See Book 1, field: Calculus and integrals, topic: symmetry reductions.

Linear change of variables in the plane. For an invertible linear T, $\iint_{T(E)} h = |\det T| \iint_E h\circ T$. The two facts you need about $T(x,y) = (x+y, x-y)$ are $|\det T| = 2$ and $|T(p)| = \sqrt{2}|p|$; the latter says T is $\sqrt{2}$ times an orthogonal map, namely a reflection composed with a rotation by $\frac{\pi}{4}$. See Book 1, field: Linear algebra, topic: similarity transformations and Jacobians.

Quartic forms in polar coordinates. $x^2+y^2 = r^2$, $x^4+y^4 = r^4(1-\frac{1}{2}\sin^2 2\theta)$, $x^4+6x^2y^2+y^4 = r^4(1+\sin^2 2\theta)$, $x^4-6x^2y^2+y^4 = r^4\cos 4\theta$, and $x^2y^2 = \frac{1}{4}r^4\sin^2 2\theta$. Every symmetric biquadratic is a combination of r^4 and $r^4\cos 4\theta$, which is why quarter turns keep appearing. See Book 1, field: Geometry, topic: invariant forms of the dihedral group.

Homogeneous tails and annulus mass. If $F(r,\theta) = \frac{h(\theta)}{r^2} + O(r^{-3})$ then $\iint_{\rho\le|p|\le\lambda\rho} F \to \log\lambda \int_0^{2\pi} h(\theta)\,d\theta$ as $\rho\to\infty$. This is the exact statement that borderline r^{-2} tails are logarithmic, and it is worth carrying as a formula. The general recursion hiding here is geometric rather than arithmetic: the annuli $A_R, A_{R\sqrt{2}}, A_{2R}, \dots$ each carry the same limiting mass, and the sum of k of them is $\iint_{|p|\le R2^{k/2}} \sim \frac{k}{2}\log 2 \int h$, which is the $\log R$ divergence you diagnosed in Block 1, recovered as a telescoping sum. Generalise: a function asymptotically homogeneous of degree $-n$ in n dimensions has scale invariant annulus mass, and the divergence of its integral is exactly logarithmic; for degree $-n-\varepsilon$ the annulus masses form a geometric sequence with ratio $\lambda^{-\varepsilon}$ and the total converges. See Book 1, field: Real analysis, topic: convergence tests for multiple integrals.

Standard rational trigonometric integrals. $\int_0^{\pi/2} \frac{d\phi}{a\cos^2\phi + b\sin^2\phi} = \frac{\pi}{2\sqrt{ab}}$ by $t = \tan\phi$, and $\int_0^{2\pi} \frac{d\theta}{a+b\cos\theta} = \frac{2\pi}{\sqrt{a^2-b^2}}$ for $a > |b|$ by the half angle substitution $t = \tan\frac{\theta}{2}$ or by a residue computation. Either gives the $2\sqrt{2}\pi$ above. See Book 1, field: Calculus and integrals, topic: trigonometric rational integrals.

Interchanging a limit with an integral. The clean tools are dominated convergence and uniform convergence on a set of finite measure. On the Putnam, the version that costs least ink and needs no citation is an explicit uniform error bound: show $|F_R(\theta) - F(\theta)| \le \varepsilon(R)$ for all θ with $\varepsilon(R)\to 0$, then integrate the inequality. See Book 1, field: Real analysis, topic: uniform convergence.

Circuit Bank

- **WHEN** a difference of two expressions is integrated over an unbounded or growing region **DO** check the size of each piece separately before splitting anything **BECAUSE** if each piece diverges, the minus sign is structural and splitting the integral is not merely inefficient, it is false
- **WHEN** the domain of integration has a symmetry that the denominator has but the numerator lacks **DO** replace the numerator by its average over that symmetry **BECAUSE** averaging over a measure preserving symmetry of the domain never changes the integral, so it is a free simplification that can only reveal structure
- **WHEN** two expressions in the same variables differ by matching constant factors on matching degrees **DO** hypothesise a single linear map and read the dilation ratio off the constants

BECAUSE a linear map scaling lengths by λ multiplies each homogeneous part of degree d by λ^d, so matching ratios across degrees determines λ before you have found the map

- **WHEN** you have $\iint_{D_1} h - \iint_{D_2} h$ with $D_2 \subset D_1$ **DO** write it as one integral over $D_1 \setminus D_2$ **BECAUSE** a difference of integrals of the same function over nested regions is the mass of the region between them, and that region is usually where all the analysis lives
- **WHEN** a limit must pass through an integral in a competition write up **DO** do the inner integral exactly first, then bound the error uniformly in the outer variable **BECAUSE** an explicit bound is shorter than invoking a convergence theorem and leaves a grader nothing to object to

Backtesting

1. First useful cue: numerator of degree 2 over denominator of degree 4 in the plane, which is the borderline r^{-2} tail, so each half diverges logarithmically and only the difference can converge.
2. Method the expression suggested: the pair $x^4 + 6x^2y^2 + y^4$ and $x^4 + y^4$ with constants 1 and 2 is the signature of $(x+y)^4 + (x-y)^4 = 2(x^4 + 6x^2y^2 + y^4)$, so the intended move is the linear map $(x, y) \mapsto (x+y, x-y)$.
3. Where you would hesitate, and the thought to reinforce: the numerators do not match, which stalls the substitution. The thought to install is that the disc is symmetric in x and y and so are both denominators, so you are entitled to average the numerators first. Asymmetry in a numerator over a symmetric domain is repairable, always, at zero cost.
4. The trap the question sets: computing the two integrals separately, or passing to the limit inside the θ integral without a bound. The first is fatal, the second loses presentation marks and can be fixed in two lines.
5. What makes you recognise it faster next time: memorise the polar profiles of the three symmetric biquadratics, and treat a growing disc with a r^{-2} tail as an annulus problem from the first line.
6. The reusable decision rule: symmetrise before you substitute, then match constants across degrees to find the linear map, then telescope nested discs into an annulus.

Mirror drills

1. Evaluate $\lim_{R\to\infty} \iint_{x^2+y^2\le R^2} \left(\frac{x^2}{1+x^4+y^4} - \frac{y^2}{1+x^4+y^4} \right) dx\, dy$. *Answer:* zero, and you should write one line: the integrand is odd under $x \leftrightarrow y$ while the disc is invariant, so every $I(R)$ is zero, no analysis needed.
2. Show that $\int_0^{2\pi} \frac{d\theta}{1+\sin^2 2\theta} = \sqrt{2}\,\pi$. *Answer:* periodicity reduces to $4\int_0^{\pi/2}$, then $t = \tan\phi$ gives $4\int_0^{\infty} \frac{dt}{1+2t^2} = 4 \cdot \frac{\pi}{2\sqrt{2}}$.
3. Let F be continuous on $\mathbb{R}^2$ with $F(x,y) = \frac{h(\theta)}{r^2}$ exactly, for $r \ge 1$, where h is continuous and 2π periodic. Compute $\iint_{1\le|p|\le\lambda} F$ and deduce for which h the integral over the whole plane converges. *Answer:* it equals $\log\lambda \int_0^{2\pi} h$, so it converges as $\lambda \to \infty$ only when $\int_0^{2\pi} h = 0$, which is precisely the cancellation the main problem engineers.

5.5 A5. Power sums over the units modulo 2021

Let A be the set of all integers n such that $1 \leq n \leq 2021$ and $\gcd(n, 2021) = 1$. For every nonnegative integer j, let

$$S(j) = \sum_{n \in A} n^j.$$

Determine all values of j such that $S(j)$ is a multiple of 2021.

Read it out loud

Read the definition of A before you read the sum. The set of integers in $[1, 2021]$ coprime to 2021 is not a random set: it is a complete set of representatives for the unit group $(\mathbb{Z}/2021\mathbb{Z})^\times$. So $S(j)$ is not a sum over an interval, it is a sum over a group, and $n \mapsto n^j$ is a group homomorphism on that group. Once you have said that sentence out loud, the problem has already changed character: sums of a homomorphism over a whole group are governed by one principle, and the only question left is when the homomorphism is trivial.

Second, read the modulus. The question asks when $S(j)$ is a multiple of 2021, and $2021 = 43 \times 47$ with both factors prime. A divisibility statement modulo a product of distinct primes is exactly the conjunction of two divisibility statements, one modulo each prime. So the answer will have the shape "condition at 43 and condition at 47", and any answer of a single condition is suspect on sight. The competition year being 43×47 is not decoration; it is the instruction.

The fields wired in: elementary number theory (Fermat's little theorem, primitive roots), the Chinese remainder theorem as an isomorphism of unit groups rather than a solving device, and the orthogonality principle for characters of finite abelian groups, which at this level is one three line argument rather than a theory. What is really being tested is whether you know that $(\mathbb{Z}/p\mathbb{Z})^\times$ is cyclic while $(\mathbb{Z}/2021\mathbb{Z})^\times$ is not, and whether you therefore refuse to run the argument at the composite modulus.

Within thirty seconds you should have written three things: $2021 = 43 \cdot 47$; $|A| = \phi(2021) = 42 \cdot 46 = 1932$; and the note "$A$ is the unit group, so multiply the index by a unit". The two numbers 42 and 46 are the orders of the two cyclic factors, and they are going to be the answer.

Approaches, ranked worst to best

1. **Compute $S(j)$ for many j and pattern match.** *Cue:* a free parameter j and a request to determine all values. *Circuit:* tabulate and guess. Ranks last: $S(1)$ alone is a sum of 1932 terms, and even a correct guess of the answer earns nothing without the two congruence arguments, which are the whole problem. Experiment is fine as private reconnaissance, but here the structure is visible without it.

2. **Faulhaber and inclusion exclusion.** *Cue:* a sum of jth powers over a range. *Circuit:* write $\sum_{k=1}^{m} k^j$ by Bernoulli polynomials. By inclusion exclusion, $S(j) = T_j(2021) - 43^j T_j(47) - 47^j T_j(43) + 2021^j$ where $T_j(m) = \sum_{k=1}^{m} k^j$. Each T_j is a Bernoulli polynomial evaluation with rational coefficients whose denominators must then be tracked modulo 43 and 47. It is correct and it is punishing, and the answer never becomes visible. It also fights the structure: the coprimality condition is a group condition, and inclusion exclusion is the wrong tool for a group.

3. **Multiply the summation variable by a unit, working modulo 2021.** *Cue:* A is closed under multiplication by any u coprime to 2021. *Circuit:* reindex a sum over a group by a translation. Take u coprime to 2021; then $n \mapsto un$ permutes A modulo 2021, so $S(j) \equiv u^j S(j)$ and $2021 \mid (u^j - 1)S(j)$. If you can choose u with $u^j - 1$ invertible modulo 2021, you get $S(j) \equiv 0$ at once. This delivers the sufficient direction in three lines and is a genuinely good move. It

cannot deliver necessity, because when $u^j - 1$ is a zero divisor the conclusion is empty, and $(\mathbb{Z}/2021\mathbb{Z})^\times \cong C_{42} \times C_{46}$ is not cyclic, so zero divisors are unavoidable. Ranks here: half a solution, correctly reasoned.

4. **Pair n with $2021 - n$.** *Cue:* the set A is symmetric about $2021/2$. *Circuit:* involution pairing to kill odd powers. Since $n \in A$ if and only if $2021 - n \in A$, and $(2021 - n)^j \equiv (-n)^j \pmod{2021}$, every odd j gives $S(j) \equiv -S(j)$, and 2021 being odd gives $S(j) \equiv 0$. One line, and it settles every odd j for free. It is not a full solution because 42 and 46 are even, so all the interesting cases are even j, but it is the correct first probe and it is your check on the final answer.

5. **Split by the Chinese remainder theorem, then a primitive root at each prime.** *Cue:* "multiple of 2021" with $2021 = 43 \cdot 47$. *Circuit:* reduce a composite modulus to prime moduli, where the unit group is cyclic. The complete route. Reducing A modulo 43 hits each nonzero class exactly 46 times, so $S(j) \equiv 46 \sum_{a=1}^{42} a^j \pmod{43}$, and the classical power sum lemma at a prime finishes it. Shortest, fully rigorous, and the only route that explains why the answer has two conditions.

The ideal solution

The answer: $S(j)$ is a multiple of 2021 precisely for those j that are

$$\boxed{\text{neither a multiple of 42 nor a multiple of 46.}}$$

Lemma 5.5.1. *Let p be a prime and let $j \geq 0$ be an integer. Then*

$$\sum_{n=1}^{p-1} n^j \equiv \begin{cases} -1 \pmod{p} & \text{if } (p-1) \mid j, \\ 0 \pmod{p} & \text{if } (p-1) \nmid j. \end{cases}$$

Proof. Suppose $(p-1) \mid j$. If $j = 0$ then $n^j = 1$ for every n; if $j > 0$ then $n^j = (n^{p-1})^{j/(p-1)} \equiv 1 \pmod{p}$ for $1 \leq n \leq p-1$ by Fermat's little theorem. Either way the sum is congruent to $p - 1 \equiv -1$.

Suppose $(p-1) \nmid j$. Write $S = \sum_{n=1}^{p-1} n^j$ and let g be a primitive root modulo p, which exists because $(\mathbb{Z}/p\mathbb{Z})^\times$ is cyclic of order $p-1$. Multiplication by g permutes the nonzero residue classes modulo p, so reindexing the sum by $n \mapsto gn$ gives

$$S \equiv \sum_{n=1}^{p-1} (gn)^j = g^j S \pmod{p}.$$

Since g has order exactly $p-1$ and $(p-1) \nmid j$, we have $g^j \not\equiv 1$, so $g^j - 1$ is a nonzero element of the field $\mathbb{Z}/p\mathbb{Z}$ and hence invertible. From $(g^j - 1)S \equiv 0$ we conclude $S \equiv 0$. □

Now $2021 = 43 \cdot 47$ with 43 and 47 distinct primes, so $2021 \mid S(j)$ if and only if both $43 \mid S(j)$ and $47 \mid S(j)$.

The set A is a complete set of representatives for $(\mathbb{Z}/2021\mathbb{Z})^\times$, and by the Chinese remainder theorem the reduction map

$$(\mathbb{Z}/2021\mathbb{Z})^\times \longrightarrow (\mathbb{Z}/43\mathbb{Z})^\times \times (\mathbb{Z}/47\mathbb{Z})^\times, \qquad n \longmapsto (n \bmod 43,\ n \bmod 47)$$

is a bijection. Consequently, for each fixed nonzero class a modulo 43, the number of $n \in A$ with $n \equiv a \pmod{43}$ equals the number of choices of the second coordinate, namely $\phi(47) = 46$. Therefore

$$S(j) \equiv 46 \sum_{a=1}^{42} a^j \pmod{43},$$

and symmetrically, each nonzero class modulo 47 is hit $\phi(43) = 42$ times, so

$$S(j) \equiv 42 \sum_{b=1}^{46} b^j \pmod{47}.$$

Since $46 \equiv 3 \pmod{43}$ and $42 \not\equiv 0 \pmod{47}$, both multipliers are invertible, so they may be cancelled. Applying the lemma with $p = 43$ (where $p - 1 = 42$) and with $p = 47$ (where $p - 1 = 46$):

$$43 \mid S(j) \iff 42 \nmid j, \qquad 47 \mid S(j) \iff 46 \nmid j.$$

Hence $2021 \mid S(j)$ if and only if $42 \nmid j$ and $46 \nmid j$, as claimed.

Two checks. First, $j = 0$: here $S(0) = |A| = \phi(2021) = 42 \cdot 46 = 1932$, which is not a multiple of 2021, and indeed $42 \mid 0$, so $j = 0$ is correctly excluded. Second, every odd j should qualify, since 42 and 46 are even; and indeed the involution $n \mapsto 2021 - n$ on A gives $S(j) \equiv -S(j) \pmod{2021}$ for odd j, so $S(j) \equiv 0$. The two arguments agree.

Layer 1: WHAT

Block 1: read A as the unit group $(\mathbb{Z}/2021\mathbb{Z})^\times$, not as a filtered interval.

Block 2: factor $2021 = 43 \cdot 47$ and replace the single divisibility by the pair of divisibilities.

Block 3: use the Chinese remainder theorem as a counting statement: reducing A modulo 43 covers each nonzero class exactly 46 times, so $S(j) \equiv 46 \sum_{a=1}^{42} a^j \pmod{43}$.

Block 4: check that the multiplicity 46 is invertible modulo 43, so it can be cancelled and the problem reduces to a power sum over $\mathbb{F}_{43}^\times$.

Block 5: prove the prime power sum lemma by reindexing with a primitive root, which gives $(g^j - 1)S \equiv 0$ with $g^j - 1$ invertible exactly when $(p - 1) \nmid j$.

Block 6: assemble the two conditions and verify against $j = 0$ and against the odd j pairing.

The nominal route treats the phrase "multiple of 2021" literally and stays at the composite modulus: pick a unit u, get $S(j) \equiv u^j S(j)$, and then stall, because $u^j - 1$ can be divisible by exactly one of 43 and 47 and there is nothing to cancel. The bifurcation point is the very first line after reading the modulus: the zombie writes "let u be a unit modulo 2021", the ideal route writes "$2021 = 43 \cdot 47$, so it suffices to work modulo each prime". Everything else is identical machinery; the only decision is where you run it. The reason the split is mandatory rather than convenient is that the multiplier argument needs a field, and $\mathbb{Z}/2021\mathbb{Z}$ is not one.

Layer 2: HOW

Block 1. **Cue.** "all integers n such that $1 \le n \le 2021$ and $\gcd(n, 2021) = 1$". **Why natural.** That is the verbatim definition of a reduced residue system: a complete set of representatives for the unit group modulo 2021. The size is $\phi(2021) = 1932$. Naming the object correctly is the whole first move, because sums over groups obey a rule that sums over intervals do not. **Link to the next block.** Since the index set is a group and $n \mapsto n^j$ respects multiplication, the sum is a character sum, and the only structural question about a character sum is whether the character is trivial.

Block 2. **Cue.** "is a multiple of 2021" with $2021 = 43 \cdot 47$. **Why natural.** An integer is divisible by a product of distinct primes if and only if it is divisible by each. That converts one hard statement into two statements over fields, and fields are where cancellation is legal. You should test any four digit modulus for factorisation on reflex; $2021 = 2025 - 4 = 45^2 - 2^2 = 43 \cdot 47$ is a difference of two squares, so the factorisation costs one line. **Link to the next block.** Working modulo 43 requires knowing how often each residue class modulo 43 appears among the elements of A.

Block 3. **Cue.** A is defined by a coprimality condition at both primes at once. **Why natural.** The Chinese remainder theorem says the reduction map from $(\mathbb{Z}/2021\mathbb{Z})^\times$ to the product of the two prime unit groups is a bijection. Bijection means the fibre over each class modulo 43 has size exactly $|(\mathbb{Z}/47\mathbb{Z})^\times| = 46$. This is the theorem used as a counting device, which is its most useful form on the Putnam, rather than as a machine for solving simultaneous congruences. **Link to the next block.** The sum therefore factorises as a constant multiplicity times a power sum over $\mathbb{F}_{43}^\times$, and the constant must be checked for invertibility before it is cancelled.

Block 4. **Cue.** The multiplier 46 modulo 43, and 42 modulo 47. **Why natural.** $46 \equiv 3$ and $42 \equiv 42$, both nonzero, hence invertible in the respective fields. This is not a formality: if the multiplicity were divisible by the prime, the congruence would hold for every j and the answer at that prime would be vacuous. Take $m = 21 = 3 \cdot 7$ and the same computation gives $S(j) \equiv 6 \sum_{a=1}^{2} a^j \equiv 0 \pmod 3$ for every j, so the condition at 3 disappears entirely. The examiners chose 43 and 47 so that neither multiplicity collapses. **Link to the next block.** With the multiplier cancelled, everything rests on the classical power sum over the nonzero residues of a prime.

Block 5. **Cue.** $\sum_{n=1}^{p-1} n^j$ with j free. **Why natural.** The index set is the cyclic group $\mathbb{F}_p^\times$, so multiplication by a primitive root g permutes it. Reindexing gives $S \equiv g^j S$, hence $(g^j - 1)S \equiv 0$. In a field one of the two factors must vanish, and $g^j - 1$ vanishes exactly when the order $p - 1$ divides j. The case $(p-1) \mid j$ is then Fermat's little theorem term by term, giving $p - 1 \equiv -1$. The two cases are the two ways a character can behave: trivial characters sum to the size of the group, nontrivial characters sum to zero. **Link to the next block.** Both prime conditions are now explicit, so the final answer is their conjunction.

Block 6. **Cue.** The answer is a pair of noncongruences, and $j = 0$ sits at the boundary. **Why natural.** $j = 0$ is divisible by everything, so the answer must exclude it, and the direct computation $S(0) = 1932$ confirms this. The odd j pairing gives an independent confirmation on an infinite family. Always spend the two lines: a boundary case and an independent family, checked, is what separates a graded ten from a graded eight. **Link to the next block.** Write the answer as "j not divisible by 42 and not divisible by 46" and stop.

Layer 3: WHY

The mathematical truth beneath the whole problem is orthogonality. Let G be a finite abelian group and let $\chi : G \to k^\times$ be a group homomorphism into the multiplicative group of a field. Then

$$\sum_{g \in G} \chi(g) = \begin{cases} |G| \cdot 1_k & \text{if } \chi \text{ is trivial,} \\ 0 & \text{otherwise,} \end{cases}$$

and the proof is the reindexing you have just used: pick h with $\chi(h) \neq 1$, then $\Sigma = \chi(h)\Sigma$ forces $\Sigma = 0$. Here $G = \mathbb{F}_p^\times$, $k = \mathbb{F}_p$ and $\chi(n) = n^j$. So the lemma is not an isolated fact about power sums; it is the single most used identity in all of finite abelian character theory, and it will reappear on the Putnam as roots of unity filters, as Gauss sums, and as the evaluation of $\sum_{k=0}^{n-1} \omega^{jk}$.

The discernment mechanism is a three part test that you should run whenever a sum is taken over a set defined by a coprimality or a congruence condition. First: is the index set a group? If yes, name it. Second: is the summand a homomorphism on that group? If yes, you are looking at a character sum and orthogonality settles it. Third: is the coefficient ring a field? If not, split the modulus until it is, because cancellation is the engine of the whole argument and cancellation needs the absence of zero divisors. The composite modulus 2021 fails the third test, and that is the only reason the problem is not a two line exercise.

There is a real generalisation worth carrying, and it comes with a caveat that this problem was designed to dodge. Let $m = p_1 p_2 \cdots p_k$ be squarefree with distinct odd primes, and let $S(j)$ be the sum of jth powers over the reduced residues modulo m. The same counting gives, for each i,

$$S(j) \equiv \left(\prod_{l \neq i} (p_l - 1)\right) \sum_{a=1}^{p_i - 1} a^j \pmod{p_i},$$

so by the lemma $S(j) \equiv 0 \pmod{p_i}$ unless both $(p_i - 1) \mid j$ and $p_i \nmid \prod_{l \neq i}(p_l - 1)$. In other words the clean answer "$S(j)$ is divisible by m exactly when no $p_i - 1$ divides j" holds only when each multiplicity $\phi(m)/(p_i - 1)$ is invertible modulo p_i. For $m = 2021$ that check passes at both primes. For $m = 21$ it fails at $p = 3$ and the true answer becomes "$21 \mid S(j)$ if and only if $6 \nmid j$". Train the habit by always writing the multiplicity down explicitly and reducing it modulo the prime before cancelling anything.

One more structural fact worth lighting up: as a function of j, $S(j)$ mod 2021 is periodic. Its period divides the exponent of the group $(\mathbb{Z}/2021\mathbb{Z})^\times \cong C_{42} \times C_{46}$, which is $\operatorname{lcm}(42, 46) = 966$, the Carmichael function $\lambda(2021)$. So the answer set is a union of arithmetic progressions, and the exceptional j (those where $2021 \nmid S(j)$) form the union of the multiples of 42 and the multiples of 46, a set of density $\frac{1}{42} + \frac{1}{46} - \frac{1}{966}$. Notice that the naive guess "exceptional exactly when $966 \mid j$", which is what you would predict if you wrongly assumed $(\mathbb{Z}/2021\mathbb{Z})^\times$ were cyclic of order $\phi(2021)$ or of order $\lambda(2021)$, is far too small a set. The failure of cyclicity is the content of the problem.

Revolving concepts

Reduced residue system and Euler's function. The integers in $[1, m]$ coprime to m form a complete set of representatives for $(\mathbb{Z}/m\mathbb{Z})^\times$, of size $\phi(m)$, and ϕ is multiplicative on coprime arguments with $\phi(p) = p - 1$. Here $\phi(2021) = 42 \cdot 46 = 1932$. See Book 1, field: Number theory, topic: Euler's totient and unit groups.

Fermat and Euler. $a^{p-1} \equiv 1 \pmod{p}$ for $p \nmid a$, and more generally $a^{\phi(m)} \equiv 1 \pmod{m}$ for $\gcd(a, m) = 1$. The sharp exponent is the Carmichael function $\lambda(m)$, the exponent of the unit group; $\lambda(2021) = \operatorname{lcm}(42, 46) = 966 < 1932$. See Book 1, field: Number theory, topic: orders and Fermat Euler.

Primitive roots. $(\mathbb{Z}/p\mathbb{Z})^\times$ is cyclic of order $p - 1$ for every prime p; a generator is a primitive root. Cyclicity holds for p^e and $2p^e$ and fails for products of two distinct odd primes, which is exactly the failure exploited here. See Book 1, field: Number theory, topic: primitive roots and cyclicity.

Chinese remainder theorem as an isomorphism. For coprime m_1, m_2, the reduction map $\mathbb{Z}/m_1 m_2\mathbb{Z} \to \mathbb{Z}/m_1\mathbb{Z} \times \mathbb{Z}/m_2\mathbb{Z}$ is a ring isomorphism, and it restricts to a group isomorphism on unit groups. Used as a counting device it says: each class modulo m_1 is realised by exactly $\phi(m_2)$ units modulo $m_1 m_2$. See Book 1, field: Number theory, topic: Chinese remainder theorem.

Character sums and orthogonality. For a finite abelian group G and a homomorphism $\chi : G \to k^\times$, $\sum_{g \in G} \chi(g)$ is $|G|$ if χ is trivial and 0 otherwise. The special case $\chi(n) = n^j$ on $\mathbb{F}_p^\times$ is the lemma above; the special case $G = \mathbb{Z}/n\mathbb{Z}$ and $\chi(k) = \omega^k$ with ω a primitive nth root of unity is the roots of unity filter $\frac{1}{n}\sum_{t=0}^{n-1} \omega^{-tr}\omega^{tk} = [k \equiv r]$. See Book 1, field: Abstract algebra, topic: characters of finite abelian groups.

Periodicity of $S(j)$ in j, as a recursion. Because $n^{j+\lambda(m)} \equiv n^j$ for every unit n, the sequence $j \mapsto S(j) \bmod m$ satisfies the exact recursion $S(j + \lambda(m)) \equiv S(j)$, that is, a linear recurrence of order $\lambda(m)$ with characteristic polynomial $x^{\lambda(m)} - 1$. Generalise: any sequence of the form $j \mapsto \sum_{n \in G} \chi_n(g)^j$, where each χ_n takes values in a finite group of exponent e, is periodic in j with period dividing e, and its values are determined by the multiset of orders appearing. This is the same phenomenon as the eventual periodicity of $j \mapsto a^j \bmod m$, of Fibonacci residues modulo m (the Pisano period), and of any linear recurrence over a finite ring: the state space is finite and the transition is invertible, so the orbit is purely periodic. See Book 1, field: Sequences and recurrences, topic: periodicity modulo m.

The involution pairing. If a summation set A is closed under $n \mapsto m - n$ then for odd j the sum of jth powers is $\equiv 0$ modulo m when m is odd. This is the additive twin of the multiplicative reindexing and is worth trying first on any symmetric index set. See Book 1, field: Number theory, topic: symmetry of residue systems.

Circuit Bank

- **WHEN** a divisibility question modulo a composite m **DO** factor m and replace the statement by the conjunction of the statements at each prime power **BECAUSE** cancellation, primitive roots and the field axioms are available at a prime and not at a composite, and $x \equiv 0 \pmod{m}$ is equivalent to the conjunction of $x \equiv 0$ at each prime power dividing m
- **WHEN** a sum whose index set is all of a finite group **DO** reindex by multiplying the index by a fixed group element **BECAUSE** the reindexing is a bijection so the sum is unchanged, which forces $(\chi(h) - 1)\Sigma = 0$ and kills Σ whenever $\chi(h) \neq 1$ is invertible
- **WHEN** a set defined by coprimality to a composite, reduced modulo one prime factor **DO** count the multiplicity by the Chinese remainder theorem and reduce that multiplicity modulo the prime before cancelling it **BECAUSE** the multiplicity is $\phi(m)/(p-1)$ and it can itself be divisible by p, in which case the congruence is vacuous and the condition at that prime disappears
- **WHEN** a sum of jth powers with j a free parameter **DO** ask only whether $x \mapsto x^j$ is the trivial character on the relevant group **BECAUSE** orthogonality makes every nontrivial character sum vanish, so the answer is always a statement about which j make the exponent map trivial, that is about $\mathrm{ord}(x) \mid j$
- **WHEN** an index set symmetric under $n \mapsto m - n$ with m odd **DO** test odd j separately in one line **BECAUSE** the pairing gives $S \equiv -S$, hence $S \equiv 0$, which both solves an infinite family for free and gives an independent check on your final answer

Backtesting

1. First useful cue: A is the reduced residue system modulo 2021, so the sum is over a group and $n \mapsto n^j$ is a homomorphism on it.
2. Method the expression suggested: reindex the sum by multiplication by a unit, which is the standard proof of character orthogonality; but this only bites over a field, so factor $2021 = 43 \cdot 47$ first and run it at each prime.
3. Where you would hesitate, and the thought to reinforce: at the composite modulus the argument stalls because $u^j - 1$ may be a zero divisor. The thought to install is that $(\mathbb{Z}/m\mathbb{Z})^\times$ is cyclic only for m equal to $1, 2, 4, p^e, 2p^e$, so for $m = 43 \cdot 47$ there is no primitive root and you must split before you cancel.
4. The trap the question sets: answering "all j not divisible by 966", which is what you get if you assume a primitive root exists modulo 2021. The exceptional set is much larger than that.
5. What makes you recognise it faster next time: any four digit modulus in a Putnam number theory problem should be factored on sight ($2021 = 45^2 - 2^2$), and any sum over a coprimality condition should be renamed as a sum over a unit group in the first line.
6. The reusable decision rule: split the modulus into primes, count multiplicities by the Chinese remainder theorem, check the multiplicity is invertible, then apply orthogonality at each prime and take the conjunction.

Mirror drills

1. Evaluate $\sum_{n=1}^{p-1} n^{p-1} \bmod p$ and $\sum_{n=1}^{p-1} n \bmod p$ for an odd prime p. *Answer:* the first is $p-1 \equiv -1$ by Fermat; the second is $\frac{p(p-1)}{2} \equiv 0$, consistent with the lemma since $(p-1) \nmid 1$ for $p > 2$.
2. Determine all $j \geq 0$ for which 15 divides $\sum_n n^j$, the sum being over $n \in [1, 15]$ coprime to 15. *Answer:* modulo 3 the multiplicity is $\phi(5) = 4 \equiv 1$, so $3 \mid S(j)$ iff $2 \nmid j$; modulo 5 the multiplicity is $\phi(3) = 2$, invertible, so $5 \mid S(j)$ iff $4 \nmid j$. Since j odd already forces $4 \nmid j$, the answer is exactly the odd j. Check $j = 1$: the sum is 60.
3. Show in one line that $2021 \mid S(j)$ for every odd j, without using the lemma. *Answer:* $n \in A \iff 2021 - n \in A$, and $(2021 - n)^j \equiv -n^j \pmod{2021}$ for odd j, so $S(j) \equiv -S(j)$ and 2021 is odd.

5.6 A6. Binary digit polynomials and composite values

Let $P(x)$ be a polynomial whose coefficients are all either 0 or 1. Suppose that $P(x)$ can be written as a product of two nonconstant polynomials with integer coefficients. Does it follow that $P(2)$ is a composite integer?

Read it out loud

Say what the two hypotheses actually are. The coefficients of P lie in $\{0,1\}$, so $P(2)$ is precisely the integer whose binary digits are those coefficients; the problem is a statement about binary expansions dressed as a statement about polynomials. And P factors over $\mathbb{Z}$ as QR with both factors nonconstant, so $P(2) = Q(2)R(2)$ is a factorisation of that integer into two integers. The question is whether that integer factorisation is nontrivial.

That reduction is the whole problem, and you should reach it in one line. $P(2) = Q(2)R(2)$ is automatic. What is not automatic is that neither factor is ± 1. So the target is: for every nonconstant integer factor Q of P, show $|Q(2)| \geq 2$. Note that $Q(2) = 0$ is impossible, since P is monic with nonnegative coefficients and hence $P(2) \geq 2^{\deg P} > 0$.

Now the obstruction. You cannot argue that Q inherits nonnegative coefficients from P, because it does not: $x^4 + x^3 + x + 1 = (x+1)^2(x^2 - x + 1)$ has the factor $x^2 - x + 1$ with a negative middle coefficient. So the constraint on the coefficients of P has to be transmitted to Q through something invariant under factorisation, and there is exactly one such thing: the roots. Every root of Q is a root of P, and $Q(2) = \prod_\alpha (2 - \alpha)$ over the roots of Q counted with multiplicity, once Q has been normalised to be monic. So the question becomes: how far can the complex roots of a polynomial with 0 and 1 coefficients travel towards the point 2?

The fields wired in are therefore root location for polynomials with bounded coefficients (a geometric series estimate applied to the reversed polynomial), factorisation of real polynomials into real linear and quadratic factors, the easy half of stability theory (a monic real polynomial with all roots in the open left half plane has all coefficients positive), and the intermediate value theorem for an integrality argument at the end. Within thirty seconds you should have written: "answer is yes; suffices to prove $|Q(2)| \geq 2$; $Q(2) = \prod(2 - \alpha)$; so bound the roots of P". Everything after that is the execution of a plan you already have.

Approaches, ranked worst to best

1. **Search for a counterexample.** *Cue:* a yes or no question. *Circuit:* test small cases before committing. As reconnaissance this is fine and it is quick: run over all 0 and 1 polynomials of degree at most twelve, factor each, and check that no reducible one has prime value at 2. It buys you the correct answer and nothing else, and a Putnam grader awards nothing for it. Ranks last as a solution, first as a five minute sanity check.

2. **Force the factors to have nonnegative coefficients.** *Cue: P* has nonnegative coefficients. *Circuit:* positivity is inherited by factors. It ranks here because it is false and the counterexample is small: $x^4 + x^3 + x + 1 = (x+1)^2(x^2 - x + 1)$. Knowing the counterexample immediately is worth more than the attempt, because it tells you the constraint must travel through the roots and not through the coefficients.

3. **Work modulo small primes or with the binary digits directly.** *Cue:* $P(2)$ is the integer with those binary digits. *Circuit:* congruence conditions on digit sums. There is no congruence obstruction available: $P(2)$ can be any integer with the right digits, and reducibility of P is not detectable modulo any fixed integer. A digit based argument cannot see the factorisation of P over $\mathbb{Z}$, so this route has nowhere to go.

4. **Show no root of P lies in the closed disc $|z-2| \le 1$.** *Cue:* $|Q(2)| = \prod |2-\alpha|$, so $|Q(2)| > 1$ would follow. *Circuit:* make every factor of a product exceed one. This is the right instinct and the right shape of conclusion, and it deserves respect. The problem is the bookkeeping: the bounds you can actually prove are $|\alpha| < \frac{1+\sqrt{5}}{2}$ when $\mathrm{Re}(\alpha) \ge 0$, and $|\alpha| < 1.466$ when $|\arg\alpha| \le \frac{\pi}{4}$, and neither excludes points such as $1.4 + 0.3i$, which lies inside that disc. So the route stalls short of the finish for want of a sharper estimate, and you should abandon it rather than push.

5. **Locate the roots, then shift to the midpoint of 1 and 2.** *Cue:* you want to compare $Q(2)$ with $Q(1)$, and $Q(1)$ is an integer you can bound below. *Circuit:* translate so that a comparison becomes a parity statement about coefficients. The complete route. Prove every root of P has real part less than $\frac{3}{2}$, shift by $\frac{3}{2}$ so that all roots move into the open left half plane, deduce that the shifted factor has strictly positive coefficients, and read off $Q(2) > Q(1)$ because 2 and 1 are symmetric about $\frac{3}{2}$. Then $Q(1) \ge 1$ by the intermediate value theorem, so $Q(2) \ge 2$. Every constant in this argument is forced by the previous line, none is guessed.

The ideal solution

The answer is $\boxed{\text{yes}}$: $P(2)$ must be composite. Recall that 1 is neither prime nor composite, so ruling out both $P(2) = 1$ and $P(2)$ prime is the content.

Write $P(x) = a_0 + a_1 x + \cdots + a_n x^n$ with every $a_i \in \{0, 1\}$ and $a_n = 1$, so P is monic. Since P is a product of two nonconstant polynomials, $n \ge 2$.

Lemma 5.6.1. *$P(x) > 0$ for every real $x > 0$. In particular P has no positive real root.*

Proof. All terms are nonnegative and the leading term x^n is positive. □

Lemma 5.6.2. *If α is a root of P with $\mathrm{Re}(\alpha) \ge 0$, then $|\alpha| < \varphi := \frac{1+\sqrt{5}}{2}$.*

Proof. If $|\alpha| \le 1$ there is nothing to prove, so assume $|\alpha| > 1$ and put $t = |\alpha|^{-1} \in (0, 1)$. Dividing $P(\alpha) = 0$ by α^n and separating the first two terms,

$$1 + a_{n-1}\alpha^{-1} = -\sum_{k=2}^{n} a_{n-k}\alpha^{-k}.$$

Since $\alpha^{-1} = \overline{\alpha}/|\alpha|^2$, the hypothesis $\mathrm{Re}(\alpha) \ge 0$ gives $\mathrm{Re}(\alpha^{-1}) \ge 0$, so the left side has real part at least 1 and therefore modulus at least 1. The right side has modulus at most

$$\sum_{k=2}^{n} t^k < \sum_{k=2}^{\infty} t^k = \frac{t^2}{1-t}.$$

Hence $1 - t < t^2$, that is $t^2 + t - 1 > 0$, that is $t > \frac{\sqrt{5}-1}{2} = \varphi^{-1}$, and so $|\alpha| = t^{-1} < \varphi$. □

Lemma 5.6.3. *Every root α of P satisfies $\mathrm{Re}(\alpha) < \frac{3}{2}$.*

Proof. If $\mathrm{Re}(\alpha) \le 0$ there is nothing to prove, so assume $\mathrm{Re}(\alpha) > 0$; in particular $\alpha \ne 0$.

Suppose first that $|\arg\alpha| > \frac{\pi}{4}$. Then $\mathrm{Re}(\alpha) = |\alpha|\cos(\arg\alpha) < \frac{|\alpha|}{\sqrt{2}} < \frac{\varphi}{\sqrt{2}} = \frac{1+\sqrt{5}}{2\sqrt{2}} < 1.145 < \frac{3}{2}$, using the previous lemma.

Suppose instead that $|\arg\alpha| \le \frac{\pi}{4}$. Then $\arg(\alpha^{-1}) \in [-\frac{\pi}{4}, \frac{\pi}{4}]$ and $\arg(\alpha^{-2}) \in [-\frac{\pi}{2}, \frac{\pi}{2}]$, so both $\mathrm{Re}(\alpha^{-1}) \ge 0$ and $\mathrm{Re}(\alpha^{-2}) \ge 0$. Dividing $P(\alpha) = 0$ by α^n and separating the first three terms,

$$1 + a_{n-1}\alpha^{-1} + a_{n-2}\alpha^{-2} = -\sum_{k=3}^{n} a_{n-k}\alpha^{-k},$$

where an empty sum is 0. The left side has real part at least 1, hence modulus at least 1. If $|\alpha| \le 1$ then $\mathrm{Re}(\alpha) \le 1 < \frac{3}{2}$ and we are done; otherwise put $t = |\alpha|^{-1} \in (0,1)$ and bound the right side by

$$\sum_{k=3}^{n} t^k < \frac{t^3}{1-t},$$

so $t^3 + t - 1 > 0$. The function $x \mapsto x^3 + x - 1$ is strictly increasing on $[0,\infty)$ and has a unique positive root τ; since $(\frac{2}{3})^3 + \frac{2}{3} - 1 = -\frac{1}{27} < 0$ we get $\tau > \frac{2}{3}$. Therefore $t > \tau > \frac{2}{3}$ and $|\alpha| < \frac{3}{2}$, so $\mathrm{Re}(\alpha) \le |\alpha| < \frac{3}{2}$. □

Lemma 5.6.4. *Let $F \in \mathbb{R}[x]$ be monic of degree $d \ge 1$ with every root of negative real part. Then every coefficient of F is strictly positive.*

Proof. Over $\mathbb{R}$, F factors into monic linear factors $x - \beta$ with β a real root, and monic quadratic factors $(x-\alpha)(x-\overline{\alpha}) = x^2 - 2\mathrm{Re}(\alpha)x + |\alpha|^2$ coming from conjugate pairs of nonreal roots. In the first case $-\beta > 0$, so $x - \beta = x + (-\beta)$ has positive coefficients; in the second case $-2\mathrm{Re}(\alpha) > 0$ and $|\alpha|^2 > 0$, so again all coefficients are positive. Finally, if $G = \sum_{i=0}^{p} g_i x^i$ and $H = \sum_{j=0}^{q} h_j x^j$ have all coefficients positive, then for each $0 \le m \le p+q$ the coefficient of x^m in GH is $\sum g_i h_j$ over the pairs with $i + j = m$, $0 \le i \le p$, $0 \le j \le q$; this index set is nonempty (take i between $\max(0, m-q)$ and $\min(p, m)$) and every term is positive. Induction over the factors completes the proof. □

Proof of the statement. Let $P = QR$ with $Q, R \in \mathbb{Z}[x]$ nonconstant. Since P is monic, the leading coefficients of Q and R are integers whose product is 1, so both equal 1 or both equal -1; replacing the pair (Q, R) by $(-Q, -R)$ if necessary, we may assume both are monic. This changes neither P nor the product $Q(2)R(2)$.

Every root of Q is a root of P, so by the third lemma every root of Q has real part less than $\frac{3}{2}$. Hence $\widetilde{Q}(x) := Q\left(x + \frac{3}{2}\right)$ is a monic real polynomial of degree $d = \deg Q \ge 1$ all of whose roots have negative real part, so by the fourth lemma $\widetilde{Q}(x) = \sum_{i=0}^{d} c_i x^i$ with every $c_i > 0$. Since 2 and 1 are symmetric about $\frac{3}{2}$,

$$Q(2) - Q(1) = \widetilde{Q}\left(\tfrac{1}{2}\right) - \widetilde{Q}\left(-\tfrac{1}{2}\right) = \sum_{i=0}^{d} c_i \left(2^{-i} - (-2)^{-i}\right) = 2\sum_{i \text{ odd}} c_i 2^{-i} > 0,$$

the last inequality because $d \ge 1$ guarantees that the index $i = 1$ occurs and $c_1 > 0$.

Next, $Q(1) \ge 1$. Indeed $Q(1)$ is an integer, and if $Q(1) \le 0$ then, Q being monic, $Q(x) \to +\infty$ as $x \to +\infty$, so by the intermediate value theorem Q would have a real root in $[1,\infty)$; that root would be a positive real root of P, contradicting the first lemma.

Therefore $Q(2) > Q(1) \ge 1$, and $Q(2)$ is an integer, so $Q(2) \ge 2$. The identical argument gives $R(2) \ge 2$. Hence $P(2) = Q(2)R(2)$ is a product of two integers each at least 2, so $P(2)$ is composite. ■

Layer 1: WHAT

Block 1: $P(2) = Q(2)R(2)$, so the task is exactly to prove $|Q(2)| \ge 2$ for every nonconstant integer factor Q; the value 0 is impossible since $P(2) \ge 2^n$.

Block 2: the coefficient hypothesis is not inherited by Q (counterexample $x^2 - x + 1$), so it must be transmitted through the roots, since $Q(2) = \prod(2 - \alpha)$ once Q is monic.

Block 3: to get a lower bound on $Q(2)$, compare it with $Q(1)$, because $Q(1)$ is an integer that is at least 1 by the intermediate value theorem plus the absence of positive real roots of P.

Block 4: a comparison of F at two points symmetric about c is a statement about the parity of the coefficients of $F(x + c)$; here $c = \frac{3}{2}$ is forced as the midpoint of 1 and 2.

Block 5: those shifted coefficients are all positive exactly when all roots of Q lie to the left of $\frac{3}{2}$, which is the easy half of stability theory.

Block 6: prove that every root of P has real part below $\frac{3}{2}$ by dividing $P(\alpha) = 0$ by α^n, using that α^{-1} and α^{-2} have nonnegative real part in the sector $|\arg \alpha| \leq \frac{\pi}{4}$, and bounding the tail by a geometric series.

Block 7: assemble, $Q(2) > Q(1) \geq 1$ forces $Q(2) \geq 2$, same for R, done.

The nominal route runs Block 1 and then tries to prove something about the coefficients of Q, or hunts for a congruence obstruction on the binary digits. Both are dead: the coefficients of a factor are not constrained in sign, and reducibility over $\mathbb{Z}$ is invisible modulo any fixed integer. The bifurcation point is the sentence immediately after Block 1: the zombie asks "what do I know about the coefficients of Q", the ideal route asks "what do I know about the roots of Q". That single reframing is the entire problem, because roots are the only data that a factor is forced to share with P.

Layer 2: HOW

Block 1. **Cue.** "product of two nonconstant polynomials with integer coefficients" and the target "$P(2)$ composite". **Why natural.** Substituting $x = 2$ into the factorisation is free and it converts a polynomial statement into an integer statement. Composite means a product of two integers each of absolute value at least 2, so the only failure mode is a factor equal to ± 1 at $x = 2$. Naming the single failure mode is what turns a vague question into a target. **Link to the next block.** You now need a lower bound on $|Q(2)|$ that uses only the hypothesis on P, so ask what Q is forced to inherit from P.

Block 2. **Cue.** P has nonnegative coefficients, but its factors need not. **Why natural.** Test it: $x^4 + x^3 + x + 1 = (x+1)^2(x^2 - x + 1)$. Producing this in ten seconds saves you ten minutes of trying to prove a false lemma. What a factor does inherit is its root set: every root of Q is a root of P. And since P is monic, Q can be taken monic, whereupon $Q(2) = \prod_\alpha (2 - \alpha)$ exactly. **Link to the next block.** So the coefficient hypothesis must be converted into a region of the complex plane containing all roots of P, and the region must be positioned relative to the point 2.

Block 3. **Cue.** $Q(2)$ and $Q(1)$ are both integers, and $Q(1)$ has an easy lower bound. **Why natural.** P has no positive real root because all its coefficients are nonnegative and the leading one is 1. A monic Q with $Q(1) \leq 0$ would have a real root in $[1, \infty)$ by the intermediate value theorem, which P forbids. So $Q(1) \geq 1$ costs three lines. That is your anchor: if you can prove the single inequality $Q(2) > Q(1)$, integrality upgrades it to $Q(2) \geq 2$ and the problem is finished. **Link to the next block.** Comparing a polynomial at two points is easiest when they are symmetric about a centre, so shift to the midpoint.

Block 4. **Cue.** The two points are 1 and 2, with midpoint $\frac{3}{2}$. **Why natural.** Write $\widetilde{Q}(x) = Q(x + \frac{3}{2})$. Then $Q(2) = \widetilde{Q}(\frac{1}{2})$ and $Q(1) = \widetilde{Q}(-\frac{1}{2})$, so the difference is twice the sum of the odd degree terms of $\widetilde{Q}$ evaluated at $\frac{1}{2}$. If all coefficients of $\widetilde{Q}$ are positive, the difference is positive. This is why the constant $\frac{3}{2}$ appears: not because of any root bound, but because it is the midpoint of the two values you decided to compare. The root bound is then reverse engineered to fit it. **Link to the next block.** Positivity of the coefficients of a shifted polynomial is a statement about the location of its roots.

Block 5. **Cue.** Monic real polynomial, want all coefficients positive. **Why natural.** Factor over $\mathbb{R}$ into linear and quadratic pieces. A linear piece $x - \beta$ has positive coefficients exactly when $\beta < 0$; a quadratic piece $x^2 - 2\mathrm{Re}(\alpha)x + |\alpha|^2$ has positive coefficients exactly when $\mathrm{Re}(\alpha) < 0$. Products of polynomials with all coefficients positive have all coefficients positive. So "all roots in the open left half plane" implies "all coefficients positive", and this is the direction that is elementary. The converse is false and you must not use it. **Link to the next block.** Translating back, you need every root of P to satisfy $\mathrm{Re}(\alpha) < \frac{3}{2}$.

Block 6. Cue. Coefficients bounded by the leading coefficient, and a bound wanted on the roots. **Why natural.** The standard device is to divide $P(\alpha) = 0$ by α^n, which turns the polynomial into $1 + a_{n-1}\alpha^{-1} + a_{n-2}\alpha^{-2} + \cdots$ and makes the small quantity $|\alpha|^{-1}$ the variable. Keeping the first term alone gives the crude bound $|\alpha| < 2$; keeping two terms and using $\mathrm{Re}(\alpha^{-1}) \geq 0$ in the right half plane gives $|\alpha| < \varphi$; keeping three terms and using $\mathrm{Re}(\alpha^{-2}) \geq 0$ in the sector $|\arg \alpha| \leq \frac{\pi}{4}$ gives $|\alpha| < \frac{3}{2}$ there. Outside that sector, $\mathrm{Re}(\alpha) < \frac{|\alpha|}{\sqrt{2}} < \frac{\varphi}{\sqrt{2}} < \frac{3}{2}$ anyway. The number of terms you keep is dictated by the strength you need, and each extra term costs one sector condition. **Link to the next block.** All roots have real part below $\frac{3}{2}$, so the shifted factor has positive coefficients and the chain closes.

Block 7. Cue. $Q(2) > Q(1) \geq 1$ with $Q(2) \in \mathbb{Z}$. **Why natural.** A strict inequality between integers is an inequality with a gap of at least one, which is where the final ≥ 2 comes from. Applying the same to R gives two factors of size at least 2, which is the definition of composite. **Link to the next block.** Write the conclusion, and state explicitly that 1 is neither prime nor composite so the case $P(2) = 1$ is also excluded.

Layer 3: WHY

The mathematical truth under this problem is a theorem you should know by name. Cohn's irreducibility criterion says that if a prime p is written in base ten as $\sum a_i 10^i$, then $\sum a_i x^i$ is irreducible over $\mathbb{Z}$. Brillhart, Filaseta and Odlyzko proved in 1981 that the same holds in every base $b \geq 2$. Our problem is the contrapositive of that theorem in base 2, restricted to digits 0 and 1, with the extra observation that $P(2) = 1$ is also impossible. The mechanism in all these theorems is identical: bounded digits force all roots of the digit polynomial into a bounded region of the complex plane sitting strictly to the left of the base point b, and then no factor can be small at b.

Why does bounding the digits bound the roots? Because a root satisfies $|\alpha|^n = |\sum_{i<n} a_i \alpha^i| \leq \sum_{i<n} |\alpha|^i$, and once the coefficients are bounded the right side is a geometric series that cannot keep up with $|\alpha|^n$ unless $|\alpha|$ is small. That is the Cauchy bound and it gives $|\alpha| < 2$ in one line. The refinements used above are the same computation with more terms retained on the left, and each retained term buys a stronger bound at the price of a sector hypothesis that guarantees the retained terms do not cancel. This is a general and reusable pattern: to strengthen a modulus estimate, move terms from the estimated side to the exact side, and pay for it with an argument that the exact side cannot be small, usually a real part argument.

Now the discernment mechanism, which is what you must actually train. There are two decisions in this problem and both are forced by the question rather than invented.

First decision: coefficients or roots. The hypothesis is about coefficients of P; the conclusion is about a value of P at an integer, mediated by an unknown factor Q. Ask what survives factorisation. Coefficient positivity does not (one counterexample settles it). Root membership does, trivially and exactly. So the hypothesis must be pushed into root language, used there, and pulled back to a value. Whenever a problem gives you information about one polynomial and asks about its unknown factors, the transmission channel is the root set, every time.

Second decision: the choice of the comparison point and hence of the constant $\frac{3}{2}$. You want a lower bound on the integer $Q(2)$. The only cheap lower bound available anywhere in the problem is $Q(1) \geq 1$, which follows from P having no positive real root. So the natural target is $Q(2) > Q(1)$, and the natural technique for comparing a polynomial at two points is to centre at their midpoint, where the comparison becomes "the odd part is positive". The midpoint of 1 and 2 is $\frac{3}{2}$, and only now do you learn what you must prove about the roots. This is the opposite of the usual presentation, where $\frac{3}{2}$ appears first and looks like a rabbit from a hat. It is not a rabbit; it is $\frac{1+2}{2}$.

A concrete sanity example, worth running once by hand. Take $P(x) = x^4 + x^3 + x + 1 = (x+1)^2(x^2 - x + 1)$, so $P(2) = 27$. For $Q = x^2 - x + 1$, the shift gives $\widetilde{Q}(x) = (x + \frac{3}{2})^2 - (x + \frac{3}{2}) + 1 =$

$x^2 + 2x + \frac{7}{4}$, all coefficients positive as promised, and $\widetilde{Q}(\frac{1}{2}) = 3 = Q(2)$ while $\widetilde{Q}(-\frac{1}{2}) = 1 = Q(1)$. The inequality $3 > 1$ is exactly the mechanism, and $27 = 3 \times 9$ is the resulting factorisation of the binary number 11011_2.

Finally, the knowledge gaps, stated without disguise, because this is an A6 and pretending otherwise would be dishonest. To approach this problem at all you must have installed the following, none of which is in A-level Further Mathematics: (i) the fact that a real polynomial factors over $\mathbb{R}$ into linear and quadratic factors, with nonreal roots in conjugate pairs, which is the fundamental theorem of algebra plus a conjugation argument; (ii) the technique of bounding roots via the reversed polynomial and a geometric series, that is the Cauchy bound family; (iii) the easy direction of the Routh and Hurwitz stability circle of ideas, namely that all roots in the open left half plane forces all coefficients positive (and the knowledge that the converse fails, as $x^4 + x^3 + x^2 + x + 1$ shows, whose roots are primitive fifth roots of unity, two of which have positive real part); (iv) the habit of normalising a factorisation of a monic polynomial so that both factors are monic. If any of those four is missing you will not find this route, and no amount of cleverness substitutes for them. This is a knowledge gap, and knowledge gaps are named, not disguised.

Revolving concepts

Value at an integer as a base b expansion. If P has coefficients in $\{0, 1, \ldots, b-1\}$ then $P(b)$ is the integer with those base b digits, and conversely every positive integer determines a unique such P. Factorisations of P over $\mathbb{Z}$ therefore give factorisations of the integer, which is the bridge this problem is built on. See Book 1, field: Number theory, topic: base representations.

Cauchy bound and the reversed polynomial. For monic $P = x^n + \sum_{i<n} a_i x^i$, every root satisfies $|\alpha| \leq 1 + \max_i |a_i|$; for coefficients in $\{0, 1\}$ this gives $|\alpha| < 2$. The proof divides by α^n and sums a geometric series, which is the same as applying the trivial bound to the reversed polynomial $x^n P(1/x)$. Sharper versions retain more leading terms; the versions used above give $|\alpha| < \varphi$ in the closed right half plane and $|\alpha| < \frac{3}{2}$ in the sector $|\arg \alpha| \leq \frac{\pi}{4}$. See Book 1, field: Polynomials, topic: root location bounds.

Roots of unity and the golden ratio thresholds. The constants φ and τ (the real root of $x^3 + x - 1$) arise as the positive roots of $t^2 + t - 1$ and $t^3 + t - 1$, that is as the reciprocals of the thresholds at which a geometric tail $\sum_{k \geq m} t^k$ reaches 1. The general statement: $\sum_{k \geq m} t^k \geq 1$ if and only if $t^m + t \geq 1$, so retaining m leading terms produces the threshold polynomial $t^m + t - 1$, whose positive root increases to 1 as m grows. That is the general recursion behind the family of bounds, and it tells you in advance how much you can gain by retaining another term. See Book 1, field: Inequalities, topic: geometric series thresholds.

Real factorisation and conjugate pairs. A real polynomial factors over $\mathbb{R}$ as a product of monic linear factors and monic quadratics $x^2 - 2\mathrm{Re}(\alpha)x + |\alpha|^2$, one for each conjugate pair of nonreal roots. See Book 1, field: Polynomials, topic: factorisation over the reals.

Positivity from left half plane roots. If every root of a monic real F has negative real part then every coefficient of F is positive. The converse is false. This is the elementary half of the Routh and Hurwitz criterion, and on the Putnam it appears whenever a shift is used to convert a root location statement into a coefficient sign statement. See Book 1, field: Polynomials, topic: stability and coefficient signs.

Shifting to compare two values. For any polynomial F and any $a < b$, setting $c = \frac{a+b}{2}$ and $h = \frac{b-a}{2}$ gives $F(b) - F(a) = 2\sum_{i \text{ odd}} c_i h^i$ where $F(x + c) = \sum c_i x^i$. So sign information about the coefficients of the recentred polynomial is exactly sign information about $F(b) - F(a)$. See Book 1, field: Polynomials, topic: Taylor shifts.

Integrality upgrades strict inequalities. If $u > v$ with $u, v \in \mathbb{Z}$ then $u \geq v + 1$. Combined with a lower bound on v this is how a strict analytic inequality becomes an arithmetic conclusion, and it is the last step of this proof. See Book 1, field: Number theory, topic: integrality arguments.

Cohn, Brillhart, Filaseta and Odlyzko. If a prime is written in base $b \geq 2$ as $\sum a_i b^i$, then $\sum a_i x^i$ is

irreducible over $\mathbb{Z}$. The final step of the argument above, the shift by the midpoint, is due to Polya and Szego. See Book 1, field: Polynomials, topic: irreducibility criteria.

Circuit Bank

- **WHEN** a hypothesis about the coefficients of P and a question about an unknown factor Q **DO** translate the hypothesis into a region containing all roots of P, and use that every root of Q is a root of P **BECAUSE** sign and size conditions on coefficients are not inherited by factors, but the root set is inherited exactly, so the root set is the only reliable transmission channel
- **WHEN** you need a lower bound on $F(b)$ for a monic integer polynomial **DO** find a nearby point a where a lower bound is cheap, then prove $F(b) > F(a)$ by shifting to the midpoint of a and b **BECAUSE** after recentring, $F(b) - F(a)$ is twice the odd part of the shifted polynomial, so a coefficient sign statement settles the comparison, and integrality then buys a whole unit
- **WHEN** you want all coefficients of a real monic polynomial to be positive **DO** prove every root has negative real part and factor into linear and quadratic pieces **BECAUSE** each real factor $x + c$ with $c > 0$ and each quadratic $x^2 - 2\mathrm{Re}(\alpha)x + |\alpha|^2$ with $\mathrm{Re}(\alpha) < 0$ has positive coefficients, and products of such polynomials do too; the converse direction is false so never use it
- **WHEN** you need a bound on the roots of a polynomial with bounded coefficients **DO** divide by α^n and estimate the tail as a geometric series, retaining as many leading terms as the bound requires **BECAUSE** $|\alpha|^{-1}$ is the natural small variable, and retaining m terms yields the threshold $t^m + t - 1 > 0$, but only in a sector where the retained terms have nonnegative real part
- **WHEN** a polynomial has all coefficients nonnegative with a positive leading coefficient **DO** state at once that it has no positive real root **BECAUSE** every term is nonnegative and the leading term is strictly positive for $x > 0$, which is the cheapest root exclusion available and is often the anchor of an intermediate value argument

Backtesting

1. First useful cue: $P(2) = Q(2)R(2)$ is automatic, so the entire content is that neither factor equals ± 1 at $x = 2$.
2. Method the expression suggested: coefficients in $\{0, 1\}$ is a boundedness condition, and boundedness of coefficients is a root location condition via division by α^n; so bound the roots and then convert the bound into a statement about the value of a factor.
3. Where you would hesitate, and the thought to reinforce: the constant $\frac{3}{2}$ looks unmotivated. Install the reason: you chose to compare $Q(2)$ with $Q(1)$ because $Q(1) \geq 1$ is cheap, and the midpoint of 1 and 2 is $\frac{3}{2}$. The root bound is then designed to make the shift work, not the other way round.
4. The trap the question sets: assuming the factors inherit nonnegative coefficients. The counterexample $x^4 + x^3 + x + 1 = (x + 1)^2(x^2 - x + 1)$ should be in your hand within a minute.
5. What makes you recognise it faster next time: the phrase "coefficients all 0 or 1" together with an evaluation at an integer is a base representation problem, and base representation plus irreducibility is Cohn and Brillhart, Filaseta and Odlyzko. Recognising the family tells you the proof will be root location plus a shift.
6. The reusable decision rule: push coefficient hypotheses into root regions, compare values at two points by shifting to their midpoint, and finish with integrality.

Mirror drills

1. Show that every root of a monic P with coefficients in $\{0,1\}$ satisfies $|\alpha| < 2$, and explain in one sentence why this bound alone does not solve the problem. *Answer:* if $|\alpha| > 1$ then $|\alpha|^n \le \sum_{k<n} |\alpha|^k < \frac{|\alpha|^n}{|\alpha|-1}$, so $|\alpha| < 2$; it fails because it permits roots with real part close to 2, so the shift to $\frac{3}{2}$ would not send them into the left half plane.
2. Give a monic real polynomial with all coefficients positive that has a root with positive real part, and explain what it shows. *Answer:* $x^4 + x^3 + x^2 + x + 1$, whose roots are the primitive fifth roots of unity, two of which have real part $\cos 72^\circ > 0$; it shows the converse of the positivity lemma is false, so positivity of coefficients can never be used to deduce root location.
3. Deduce Cohn's criterion in base 2 from the result above: if P has coefficients in $\{0,1\}$ and $P(2)$ is prime, then P is irreducible over $\mathbb{Z}$. *Answer:* contrapositive, since a factorisation into nonconstant integer polynomials would make $P(2)$ composite.

5.7 B1. Random unit square avoiding lattice corners

Suppose that the plane is tiled with an infinite checkerboard of unit squares. If another unit square is dropped on the plane at random with position and orientation independent of the checkerboard tiling, what is the probability that it does not cover any of the corners of the squares of the checkerboard?

Read it out loud

Read the objects, not the story. The corners of the checkerboard are the integer lattice $\mathbb{Z}^2$. The dropped square is a rigid motion of $[0,1]^2$: a centre c and an angle θ. The phrase "position and orientation independent of the tiling" is the examiners handing you the probability measure: c uniform modulo the lattice, θ uniform, the two independent. So this is a geometric probability question of the Buffon family, wearing a tiling costume.

The fields wired in are integral geometry (a random rigid motion of a shape against a lattice), the symmetries of the two objects (the lattice under integer translations, the square under a quarter turn, which cut the sample space down to one cell times $[0, \pi/2)$), linearity of expectation, and one trigonometric integral at the end. What is really being tested is whether you compute a probability by drawing the forbidden region (zombie) or by counting.

The first useful cue: the dropped shape has area 1 and the lattice has one point per unit of area. Within thirty seconds you should have written $\mathbb{E}[N] = 1$, where N is the number of corners covered, for every fixed θ. That single line is the whole solution, because N can only be 0, 1 or 2, so $\mathbb{P}(N = 0) = \mathbb{P}(N = 2)$, and covering two adjacent corners is the intersection of two squares whose area is one line of trigonometry.

Approaches, ranked worst to best

1. **Forbidden-region bash.** *Cue:* "does not cover" read as "area of the safe region". *Circuit:* compute the complement of the union of four rotated unit squares centred at the corners of the cell. (Why worst: as soon as $\theta \neq 0$ the four squares overlap pairwise, since their width along each axis is $\sin\theta + \cos\theta > 1$; the union is a polygon whose vertices you would find by intersecting lines, a page of ink and three chances for a skipped-calculation error.)

2. **Circumscribed square.** *Cue:* "rotated square" suggests describing membership in the frame of the dropped square. *Circuit:* a square is $|s|, |t| \leq \frac{1}{2}$ in its own coordinates, so the safe centres form a smaller square inside the square circumscribed about the cell. (Why second: it is the official route and it is correct; for fixed θ the safe region is a square of side $\sin\theta + \cos\theta - 1$. But the converse direction, that every centre within $\frac{1}{2}$ of a side of the circumscribed square covers some corner, needs a case argument that must be self-generated in the arena.)

3. **Count, then compare.** *Cue:* area 1 dropped on a lattice of covolume 1. *Circuit:* the expected number of lattice points in a random translate of a set equals its area, and a variable in $\{0,1,2\}$ with known mean satisfies $\mathbb{P}(0) = \mathbb{P}(2) + 1 - \mathbb{E}$. (Why best: no region is drawn. The only geometry is the intersection of two unit squares offset by a unit vector, which in the rotated frame is a rectangle $(1-\cos\theta) \times (1-\sin\theta)$.)

The ideal solution

Let the dropped square have centre c and let θ be the angle its sides make with the axes. The square is invariant under rotation by $\pi/2$, so θ may be taken uniform on $[0, \pi/2)$; the lattice is invariant under integer translations, so c may be taken uniform on the cell $C = [0,1)^2$; the two are independent. Put $u = (\cos\theta, \sin\theta)$, $v = (-\sin\theta, \cos\theta)$ and $Q_0 = \{su + tv : \ |s| \leq \frac{1}{2},\ |t| \leq \frac{1}{2}\}$, the dropped square translated to the origin. A point P is covered iff $P - c \in Q_0$, iff (central symmetry,

$Q_0 = -Q_0$) $c \in P + Q_0$. Fix $\theta \in (0, \pi/2)$; the two endpoints carry probability zero. Let N be the number of lattice points covered.

Step 1: $\mathbb{E}[N] = 1$. Since $N = \sum_{P \in \mathbb{Z}^2} \mathbf{1}[c \in P + Q_0]$,

$$\mathbb{E}[N] = \sum_{P \in \mathbb{Z}^2} \operatorname{area}\big(C \cap (P + Q_0)\big) = \sum_{P \in \mathbb{Z}^2} \operatorname{area}\big((C - P) \cap Q_0\big) = \operatorname{area}(Q_0) = 1,$$

because the translates $C - P$, $P \in \mathbb{Z}^2$, partition the plane (only finitely many terms are nonzero).

Step 2: $N \le 2$. Let $P \neq P'$ be lattice points in the dropped square and $w = P' - P = (a, b)$. Then $|\langle w, u\rangle| \le 1$ and $|\langle w, v\rangle| \le 1$, that is, $|a\cos\theta + b\sin\theta| \le 1$ and $|-a\sin\theta + b\cos\theta| \le 1$. If $ab > 0$ the first quantity equals $|a|\cos\theta + |b|\sin\theta \ge \cos\theta + \sin\theta > 1$; if $ab < 0$ the second equals $|a|\sin\theta + |b|\cos\theta > 1$. So $ab = 0$. If $a = 0$ then $|b|\sin\theta \le 1$ and $|b|\cos\theta \le 1$, and $|b| \ge 2$ would force $\sin\theta, \cos\theta \le \frac{1}{2}$, impossible as $\sin^2\theta + \cos^2\theta = 1$; so $w = (0, \pm 1)$. Likewise $b = 0$ gives $w = (\pm 1, 0)$. Thus any two covered lattice points are adjacent. Three covered points would be pairwise adjacent, but $P_3 - P_2 = (P_3 - P_1) - (P_2 - P_1)$ is a difference of two distinct unit vectors, of squared length 2 or 4, hence not a unit vector. So $N \in \{0, 1, 2\}$.

Step 3. From $1 = \mathbb{E}[N] = \mathbb{P}(N = 1) + 2\,\mathbb{P}(N = 2)$ and $1 = \mathbb{P}(N = 0) + \mathbb{P}(N = 1) + \mathbb{P}(N = 2)$, subtraction gives $\mathbb{P}(N = 0) = \mathbb{P}(N = 2)$.

Step 4: the two-corner probability. By Step 2, $N = 2$ iff the square covers a pair $\{P, P + e_1\}$ or a pair $\{P, P + e_2\}$, and it covers at most one such pair. Hence

$$\mathbb{P}(N = 2) = \sum_P \mathbb{P}(P,\ P + e_1 \text{ covered}) + \sum_P \mathbb{P}(P,\ P + e_2 \text{ covered}).$$

Now P and $P + e_1$ are both covered iff $c - P \in K_1 := Q_0 \cap (e_1 + Q_0)$, and the partition argument of Step 1 gives $\sum_P \mathbb{P}(c - P \in K_1) = \operatorname{area}(K_1)$. In the coordinates (s, t) along u, v we have $Q_0 = [-\frac{1}{2}, \frac{1}{2}]^2$, and $e_1 + Q_0$ is Q_0 shifted by $(\langle e_1, u\rangle, \langle e_1, v\rangle) = (\cos\theta, -\sin\theta)$, so $K_1 = [\cos\theta - \frac{1}{2}, \frac{1}{2}] \times [-\frac{1}{2}, \frac{1}{2} - \sin\theta]$ has area $(1 - \cos\theta)(1 - \sin\theta)$. For e_2 the shift is $(\sin\theta, \cos\theta)$ and the area is the same. Therefore

$$\mathbb{P}(N = 0 \mid \theta) = \mathbb{P}(N = 2 \mid \theta) = 2(1 - \sin\theta)(1 - \cos\theta).$$

Step 5: average over θ.

$$\mathbb{P}(N = 0) = \frac{2}{\pi}\int_0^{\pi/2} 2(1 - \sin\theta)(1 - \cos\theta)\, d\theta = \frac{2}{\pi}\int_0^{\pi/2} \big(2 - 2\sin\theta - 2\cos\theta + \sin 2\theta\big)\, d\theta = \frac{2}{\pi}\big(\pi - 2 - 2 + 1\big).$$

The probability is $\boxed{2 - \dfrac{6}{\pi}} \approx 0.090$.

Layer 1: WHAT

Block 1: normalise the randomness (cell times quarter turn, independent) and fix the frame (u, v) of the dropped square, so that "covered" is two linear inequalities. Block 2: define the count N and compute $\mathbb{E}[N] = 1$ by the partition identity. Block 3: prove $N \le 2$ by the adjacency lemma. Block 4: two linear relations, one elimination: $\mathbb{P}(N = 0) = \mathbb{P}(N = 2)$. Block 5: $\mathbb{P}(N = 2)$ is the area of an intersection of two unit squares, read off in the (u, v) frame. Block 6: integrate the trigonometric polynomial over θ.

Juxtaposition. The nominal route: fix θ, draw the four forbidden squares around the corners of the cell, compute the area of the complement of their union. The ideal route: fix θ, ask for the mean of N. The bifurcation point is the sentence after "fix θ". The zombie writes "safe region equals cell minus a union of four squares"; you write "$\mathbb{E}[N] = 1$". Everything after that line is forced.

Layer 2: HOW

Block 1. Cue. "Position and orientation independent of the tiling", and a square (four-fold symmetric) against a lattice (translation invariant). **Why natural.** The probability space must be explicit before any computation, and the symmetries of both objects cut it to a unit cell times a quarter turn. The frame (u, v) is natural because the dropped square is the unit ball of the ℓ^∞ norm in its own coordinates, so membership is $|\langle P - c, u\rangle| \le \frac{1}{2}$, $|\langle P - c, v\rangle| \le \frac{1}{2}$, and nothing else in the problem is simpler than that. **Link to the next block.** With the frame fixed, every later membership test (Blocks 2, 3, 5) is a pair of linear inequalities.

Block 2. Cue. Unit area against unit covolume. **Why natural.** The expected number of lattice points in a uniformly random translate of a set K is $\mathrm{area}(K)$. It is double counting in continuous form: the pieces $(C - P) \cap Q_0$ over all P reassemble Q_0. There is no estimate here, only an identity, which is why it is free. **Link to the next block.** An expectation is not a probability. To convert, you need the range of N.

Block 3. Cue. A unit square has diameter $\sqrt{2} < 2$ and, in its own frame, width 1 in two perpendicular directions. **Why natural.** Two lattice points inside must differ by an integer vector whose projections on u and on v are both at most 1 in absolute value; integrality leaves only the four unit vectors. Pairwise adjacency of three lattice points is impossible. **Link to the next block.** With $N \in \{0, 1, 2\}$, the mean and total probability are two equations in three unknowns, and the unknown you want is expressible through the one you can compute.

Block 4. Cue. "N takes three values and I know its mean." **Why natural.** Total probability and expectation are independent linear relations; the combination eliminating $\mathbb{P}(N = 1)$ is their difference. The problem "probability of none" has become "probability of two", a much smaller and rigid event. **Link to the next block.** Compute the rigid event.

Block 5. Cue. "Two adjacent corners both covered." **Why natural.** That event is the intersection of two translates of Q_0. In the frame where Q_0 is axis-parallel the second translate is shifted by $(\cos\theta, -\sin\theta)$, and two axis-parallel unit squares offset by (p, q) with $|p|, |q| \le 1$ meet in a rectangle with sides $1 - |p|$ and $1 - |q|$. The lattice sum collapses by the same partition identity as Block 2. **Link to the next block.** The conditional probability is a trigonometric polynomial; integrate it.

Block 6. Cue. Uniform θ on $[0, \pi/2)$. **Why natural.** $\sin\theta\cos\theta = \frac{1}{2}\sin 2\theta$ and every term is elementary; the density is $2/\pi$. **Link to the next block.** Final answer.

Layer 3: WHY

The truth beneath the route: for a uniformly random translate (modulo the lattice) of a measurable set K, the number of lattice points inside has mean exactly $\mathrm{area}(K)$. This is Blichfeldt's observation, the engine of Minkowski's convex body theorem, and it is the same identity that makes Buffon's needle work (a random needle of length L on lines at spacing d crosses $2L/(\pi d)$ lines on average). It converts a hard probability into an easy expectation whenever the count is bounded by 2.

Why $N \le 2$ is the load-bearing fact: the examiners chose a unit square precisely because it has area 1 (so $\mathbb{E}[N] = 1$) and diameter $\sqrt{2}$ (too small to hold two non-adjacent lattice points, too large to be forced to hold one). The design of the problem is that the answer must be $\mathbb{P}(N = 2)$; everything else is decoration.

The discernment mechanism: the answer $2 - 6/\pi$ has a bare π in a denominator. That is the fingerprint of an average of a trigonometric polynomial over a uniformly random angle (Buffon's $2/\pi$ carries the same fingerprint). When the answer has this form the route is: conditional on

θ, obtain a polynomial in $\sin\theta$ and $\cos\theta$, then integrate. If your conditional expression is not a trigonometric polynomial, you have left the ideal route.

How to train it: every time a random shape meets a lattice or a family of lines, write the expected count first. Then ask for the maximal count. Then decide whether the probability of the maximal count is easier than the probability of zero; it almost always is, because the maximal configuration is rigid. The nudges were "unit" twice, "independent of the tiling", and "does not cover any": area equals expectation, uniform measure, and complement via the count.

Revolving concepts

Geometric probability and kinematic measure. A random rigid motion of the plane is (c, θ) with measure $dc\, d\theta$; Buffon's needle and Crofton's formula (the expected number of intersections of a random line with a curve is proportional to its length) live here. See Book 1, field: Probability, topic: geometric probability and expected counts.

Lattices and fundamental domains. The cell $[0,1)^2$ is a fundamental domain for $\mathbb{Z}^2$; its translates partition the plane; the covolume is 1. Blichfeldt's lemma: if $\text{area}(K) > 1$ then K contains two distinct points differing by a lattice vector. Minkowski: a convex, centrally symmetric K with $\text{area}(K) > 4$ contains a nonzero lattice point. See Book 1, field: Geometry, topic: lattices and fundamental domains.

The set of centres. The centres c for which $c + Q_0$ contains P form $P - Q_0$, which equals $P + Q_0$ by central symmetry. This is why the forbidden-region route exists and why it hurts: unions of translates overlap.

Norms. The square is the unit ball of the ℓ^∞ norm in its own frame; "covered" is a rotated ℓ^∞ inequality; the intersection of two ℓ^∞ balls is a box. See Book 1, field: Geometry, topic: norms and their unit balls.

Trigonometric integrals. $(\sin\theta + \cos\theta - 1)^2 = 2 + \sin 2\theta - 2\sin\theta - 2\cos\theta$, whose integral over $[0, \pi/2]$ is $\pi - 3$.

Recursion. None here; the only iteration is the sum over lattice translates, and the partition identity collapses it in one line.

Circuit Bank

- **WHEN** you see a random rigid motion of a shape relative to a lattice or a family of lines **DO** write $\mathbb{E}[\text{count}] = \text{area}$ (or length ratio) before anything else, then determine the possible values of the count **BECAUSE** the expectation is an identity, not an estimate, and a bounded count turns it into a probability
- **WHEN** you see "probability that none" with a count that is at most 2 **DO** write the total-probability and expectation equations and eliminate $\mathbb{P}(1)$ **BECAUSE** $\mathbb{P}(0) = \mathbb{P}(2) + 1 - \mathbb{E}$, and the event "two" is rigid and small
- **WHEN** you see a square in a rotated position **DO** describe membership as $|\langle P - c, u\rangle| \le \frac{1}{2}$, $|\langle P - c, v\rangle| \le \frac{1}{2}$ in the square's own frame; never in the ambient coordinates **BECAUSE** a square is an ℓ^∞ ball, and intersections of translates of ℓ^∞ balls are boxes with side $1 - |\text{shift}|$
- **WHEN** you see a final answer containing π in a denominator **DO** expect a trigonometric polynomial conditional on a uniform angle **BECAUSE** averaging sin and cos over a uniform angle is the only natural source of $1/\pi$

Backtesting

1. First useful cue: "unit square" dropped on "unit squares": area 1 against covolume 1, so $\mathbb{E}[N] = 1$.

2. Method the expression suggested: count, do not draw; $\mathbb{P}(N = 0) = \mathbb{P}(N = 2)$ plus one intersection area.
3. Where you would hesitate, and the thought to reinforce: proving $N \leq 2$ properly, and justifying $\sum_P \text{area}(C \cap (P + K)) = \text{area}(K)$. The thought: the translates of the cell partition the plane; write the one-line identity and move on. The adjacency lemma is two lines of integrality.
4. The trap the question sets: normalising θ on $[0, 2\pi)$ with density $1/(2\pi)$ and then integrating a formula valid on $[0, \pi/2)$ (fatal), and silently assuming only the four corners of one cell can be covered (true because the circumradius is $\sqrt{2}/2 < 1$, but it must be said, or better, avoided by summing over all P as above).
5. What makes you recognise it faster next time: the answer's fingerprint π in a denominator; the phrase "independent of the tiling"; any Buffon-type set-up with a shape of area equal to the covolume.
6. The reusable decision rule: random shape versus lattice: the expectation of the count is the area; the probability of the extreme count is the area of a rigid configuration; the probability of zero follows by elimination.

Mirror drills

1. A unit segment is dropped at random on a plane ruled with parallel lines one unit apart. Find the probability that it crosses a line. *Answer:* for fixed angle θ to the lines the expected number of crossings is $|\sin\theta|$; averaging over uniform θ gives $2/\pi$; since at most one line can be crossed, the probability is $2/\pi$.
2. A disc of radius $r < \frac{1}{2}$ is dropped at random on the unit lattice. Find the probability that it covers no lattice point. *Answer:* the count is 0 or 1 (diameter less than 1) and its mean is πr^2, so the probability is $1 - \pi r^2$.
3. A unit square is dropped at random on the unit lattice with its orientation fixed at $\pi/4$. Find the probability that it covers exactly two lattice points. *Answer:* $2(1 - \frac{\sqrt{2}}{2})^2 = 3 - 2\sqrt{2}$.

5.8 B2. Weighted geometric means and tuned AM-GM

Determine the maximum value of the sum

$$S = \sum_{n=1}^{\infty} \frac{n}{2^n} (a_1 a_2 \cdots a_n)^{1/n}$$

over all sequences $a_1, a_2, a_3, \ldots$ of nonnegative real numbers satisfying

$$\sum_{k=1}^{\infty} a_k = 1.$$

Read it out loud

Say what the object is, not what the story is. Write $G_n = (a_1 a_2 \cdots a_n)^{1/n}$, the running geometric mean of the first n terms, and $w_n = n/2^n$. The quantity is $S = \sum_{n \geq 1} w_n G_n$, and the only constraint is on the linear functional $\sum_k a_k$. So the entire problem reads: bound a weighted sum of prefix geometric means by a multiple of the sum of the terms, and make the multiple sharp. That is Carleman's inequality with a weight inserted, and the useful thing you own is not the statement of Carleman but its proof, which is a design procedure with a free parameter in it.

The fields wired in are inequalities (AM-GM, and specifically the fact that AM-GM has a free rescaling built into it), double series with nonnegative terms (so Tonelli lets you swap the order of summation with no hypothesis to check), the two geometric sums $\sum_{n \geq k} x^n$ and $\sum n x^n$, and equality analysis. What is really being tested is whether you treat AM-GM as a fixed statement (zombie) or as a one-parameter family of statements that you tune to fit the constraint (ideal).

The first useful cue is the phrase "geometric mean of a prefix", and the second is that $\sum a_k$, not $\sum$ of anything else, is what you are given. Within thirty seconds you should have written, with the positive numbers $c_1, c_2, \ldots$ left undetermined,

$$G_n = \Big(\prod_{k=1}^{n} c_k\Big)^{-1/n} \Big(\prod_{k=1}^{n} c_k a_k\Big)^{1/n} \leq \Big(\prod_{k=1}^{n} c_k\Big)^{-1/n} \cdot \frac{1}{n} \sum_{k=1}^{n} c_k a_k.$$

You do not choose the c_k yet. You choose them at the end, from a design equation.

There is a second free piece of information in the wording: the question says "maximum", not "supremum", so the value is attained. AM-GM is an equality exactly when all the $c_k a_k$ agree, so the extremal sequence must be $a_k \propto 1/c_k$. You therefore get the extremiser for free the moment you get the weights, and you can check the answer twice from one calculation.

Approaches, ranked worst to best

1. **Lagrange multipliers on infinitely many variables.** *Cue:* "maximise subject to a linear constraint". *Circuit:* stationary point of $S - \lambda \sum a_k$. (Why worst: $\partial S / \partial a_j = \frac{1}{a_j} \sum_{n \geq j} \frac{G_n}{2^n}$, so the stationarity conditions are an infinite nonlinear system coupling every variable to every later one. You would still have to justify that a maximiser exists in an infinite-dimensional set, and that no boundary point with some $a_j = 0$ beats it. Pages of ink, no certificate.)

2. **Carleman off the shelf.** *Cue:* prefix geometric means summed. *Circuit:* $\sum_{n \geq 1} G_n \leq e \sum_k a_k$. (Why second worst: it is a correct inequality and it is the right family, but $n/2^n \leq \frac{1}{2}$ only gives $S \leq e/2 \approx 1.359$. The weights $n/2^n$ are the whole content of the problem, and throwing them away throws away the sharp constant.)

3. **Guess the extremiser inside the geometric family.** *Cue:* equality cases of AM-GM are geometric because the weights are exponential. *Circuit:* set $a_k = (1-r)r^{k-1}$ and optimise one variable. (Why third: it is honest reconnaissance and it takes two minutes. With $s = \sqrt{r}$ you

get $S = \frac{2(1-s^2)}{(2-s)^2}$, whose derivative is $\frac{4-8s}{(2-s)^3}$, so $s = \frac{1}{2}$, $r = \frac{1}{4}$, $S = \frac{2}{3}$. This tells you the answer and the extremiser, but it proves nothing: you have optimised over one family, not over all sequences.)

4. **AM-GM with undetermined weights, then a design equation.** *Cue:* the constraint is $\sum a_k$, so the bound must collapse to a constant times $\sum a_k$. *Circuit:* insert c_k, apply AM-GM, swap the order of summation, then choose c_k so that every a_k receives the same coefficient. (Why best: the weights are not guessed, they are forced. One line of AM-GM, one Tonelli swap, one geometric series, and the equality case falls out of the same calculation. This is exactly the proof of Carleman's inequality with a different weight sequence, so it costs you nothing new.)

The ideal solution

The answer is $\boxed{\frac{2}{3}}$, attained at $a_k = 3 \cdot 4^{-k}$.

All terms are nonnegative, so S is a well defined element of $[0, \infty]$ and every rearrangement below is legitimate by Tonelli's theorem for nonnegative double series.

The bound. Since $1 + 2 + \cdots + n = \frac{n(n+1)}{2}$,

$$\Big(\prod_{k=1}^{n} 4^k\Big)^{1/n} = 4^{(n+1)/2} = 2^{n+1},$$

so for every $n \geq 1$, applying AM-GM to the n nonnegative numbers $4a_1, 4^2a_2, \ldots, 4^n a_n$,

$$2^{n+1}(a_1 a_2 \cdots a_n)^{1/n} = \Big(\prod_{k=1}^{n} 4^k a_k\Big)^{1/n} \leq \frac{1}{n}\sum_{k=1}^{n} 4^k a_k.$$

(The weight 4^k is not guessed; Block 2 of Layer 2 derives it from a single design equation.) Multiplying by $\frac{n}{2^n} \cdot \frac{1}{2^{n+1}}$,

$$\frac{n}{2^n}(a_1 \cdots a_n)^{1/n} \leq \frac{1}{2} \cdot \frac{1}{4^n}\sum_{k=1}^{n} 4^k a_k.$$

Summing over $n \geq 1$ and exchanging the two summations,

$$2S \leq \sum_{n=1}^{\infty}\sum_{k=1}^{n} 4^{k-n} a_k = \sum_{k=1}^{\infty} a_k \sum_{n=k}^{\infty} 4^{k-n} = \sum_{k=1}^{\infty} a_k \cdot \frac{1}{1-\frac{1}{4}} = \frac{4}{3}\sum_{k=1}^{\infty} a_k = \frac{4}{3}.$$

Hence $S \leq \frac{2}{3}$ for every admissible sequence.

Attainment. Take $a_k = 3 \cdot 4^{-k}$. Then $\sum_{k\geq 1} a_k = 3 \cdot \frac{1/4}{1-1/4} = 1$, so the sequence is admissible. Every AM-GM above is an equality because $4^k a_k = 3$ for all k. Explicitly,

$$(a_1 \cdots a_n)^{1/n} = \big(3^n 4^{-n(n+1)/2}\big)^{1/n} = 3 \cdot 2^{-(n+1)},$$

so

$$S = \sum_{n=1}^{\infty} \frac{n}{2^n} \cdot \frac{3}{2^{n+1}} = \frac{3}{2}\sum_{n=1}^{\infty} \frac{n}{4^n} = \frac{3}{2} \cdot \frac{1/4}{(1-1/4)^2} = \frac{3}{2} \cdot \frac{4}{9} = \frac{2}{3}.$$

Therefore the maximum value of S is $\frac{2}{3}$.

Layer 1: WHAT

Block 1: name the object as $\sum_n w_n G_n$ with G_n a prefix geometric mean, and note that the constraint is on $\sum a_k$, so the target of the bound is $C \sum a_k$. Block 2: rescale before applying AM-GM, with weights $c_k = t^k$ left undetermined, and read off the coefficient that each a_k finally receives. Block 3: impose

the design equation "that coefficient does not depend on k", which forces $t = 4$ and hands you $C = \frac{2}{3}$. Block 4: run the actual proof: AM-GM at fixed n, swap the order of the double sum, sum the geometric series in n. Block 5: equality in AM-GM for every n means $4^k a_k$ is constant; the constraint normalises it to $a_k = 3 \cdot 4^{-k}$; verify directly.

Juxtaposition. The nominal route fixes AM-GM in its bare form, $G_n \le \frac{1}{n}(a_1 + \cdots + a_n)$, and then discovers that $\sum_n \frac{n}{2^n} \cdot \frac{1}{n} \sum_{k \le n} a_k$ has the coefficient of a_k equal to $\sum_{n \ge k} 2^{-n} = 2^{1-k}$, which is not constant, is largest at $k = 1$, and yields only $S \le 1$. From there the zombie starts patching. The ideal route never applies AM-GM to a_k; it applies AM-GM to $c_k a_k$ and treats c_k as an unknown to be solved for.

The bifurcation point is the very first inequality you write. The zombie writes $(a_1 \cdots a_n)^{1/n} \le \frac{1}{n} \sum_{k \le n} a_k$. You write $(a_1 \cdots a_n)^{1/n} = \left(\prod_{k \le n} c_k\right)^{-1/n} \left(\prod_{k \le n} c_k a_k\right)^{1/n}$ and stop.

Layer 2: HOW

Block 1. **Cue.** A geometric mean of the first n terms, summed against weights, with a constraint on the plain sum $\sum a_k$. **Why natural.** AM-GM is the only elementary bridge from a product to a sum, and the constraint tells you what the right hand side has to look like when you are finished: a constant times $\sum_k a_k$. So the plan is fixed before any computation: turn each G_n into a linear combination of the a_k, swap the order of summation, and collect the coefficient of each a_k. **Link to the next block.** The bare AM-GM produces the coefficient 2^{1-k}, which decays in k. Something must be inserted to flatten it.

Block 2. **Cue.** The geometric mean is multiplicative and homogeneous of degree one: replacing a_k by $c_k a_k$ multiplies G_n by the purely n-dependent factor $(\prod_{k \le n} c_k)^{1/n}$. **Why natural.** That is exactly why weights cost nothing. The rescaling is invisible to the structure of the problem and gives you an infinite supply of AM-GM statements, one for each positive sequence (c_k). Since the weights $n/2^n$ are exponential in n, try $c_k = t^k$, for which $\left(\prod_{k \le n} t^k\right)^{1/n} = t^{(n+1)/2}$, and everything stays geometric. Then

$$S \le \sum_{n \ge 1} \frac{n}{2^n} t^{-(n+1)/2} \frac{1}{n} \sum_{k=1}^{n} t^k a_k = \frac{1}{\sqrt{t}} \sum_{k \ge 1} t^k a_k \sum_{n \ge k} (2\sqrt{t})^{-n},$$

and since $\sum_{n \ge k} (2\sqrt{t})^{-n} = \frac{2\sqrt{t}}{2\sqrt{t}-1} (2\sqrt{t})^{-k}$, the coefficient of a_k is

$$\frac{2}{2\sqrt{t}-1} \left(\frac{\sqrt{t}}{2}\right)^k.$$

Link to the next block. That coefficient must not depend on k, because the only information you have is $\sum a_k = 1$. This is the design equation.

Block 3. **Cue.** "The coefficient of a_k must be constant in k." **Why natural.** $(\sqrt{t}/2)^k$ is constant precisely when $\sqrt{t} = 2$, that is $t = 4$, and then the constant is $\frac{2}{2 \cdot 2 - 1} = \frac{2}{3}$. Nothing was guessed: the exponent base 4 is the unique solution of a linear equation in $\log t$. As a bonus, if $\sqrt{t} < 2$ the coefficient decays and the best you can extract is its value at $k = 1$, namely $\frac{\sqrt{t}}{2\sqrt{t}-1}$, which is a decreasing function of $\sqrt{t}$ on $(\frac{1}{2}, 2]$ and is therefore also minimised at $t = 4$; if $\sqrt{t} > 2$ the coefficients are unbounded and the method dies. So $t = 4$ is optimal within the family as well as forced by the design equation. **Link to the next block.** With t known, rewrite the argument cleanly with 4^k in place of t^k and hide the search.

Block 4. **Cue.** A double sum of nonnegative terms. **Why natural.** Tonelli's theorem says a double series of nonnegative terms may be summed in either order, with the same value in $[0, \infty]$. No

absolute convergence needs to be established first, which matters because you do not yet know S is finite. The inner sum $\sum_{n\ge k} 4^{k-n} = \frac{4}{3}$ is one geometric series. **Link to the next block.** The bound is now exactly $\frac{2}{3}\sum_k a_k = \frac{2}{3}$.

Block 5. Cue. The word "maximum" in the question. **Why natural.** AM-GM is an equality if and only if all its arguments agree, so equality in every step needs $4^k a_k$ independent of k, that is $a_k = C4^{-k}$; the constraint gives $C = 3$. The verification then needs $\sum_{n\ge1} nx^n = \frac{x}{(1-x)^2}$ at $x = \frac{1}{4}$, which is the derivative of the geometric series. **Link to the next block.** Both halves agree at $\frac{2}{3}$, so the bound is sharp and the maximum is attained.

Layer 3: WHY

The mathematical truth underneath is that AM-GM is not one inequality but a one-parameter family, indexed by the rescalings $a_k \mapsto c_k a_k$, and that the family is closed in exactly the right way: rescaling changes the geometric mean by a factor depending on n only. Whenever you must bound $\sum_n w_n (a_1 \cdots a_n)^{1/n}$ by a multiple of $\sum_k a_k$, the general machine is

$$\sum_{n\ge1} w_n G_n \le \sum_{k\ge1} \Big(c_k \sum_{n\ge k} \frac{w_n}{n} \Big(\prod_{j\le n} c_j \Big)^{-1/n} \Big) a_k,$$

and the whole art is choosing (c_k) to make the bracket constant, or at least bounded. That is a design equation, not a guess, and it is the reason the constant that comes out is sharp: the same choice that flattens the bracket is the choice that makes AM-GM tight along the extremiser $a_k \propto 1/c_k$.

Carleman's inequality is the same machine with $w_n = 1$. There the bracket is flattened by $c_k = (k+1)^k/k^{k-1}$, for which $\prod_{j\le n} c_j = (n+1)^n$ telescopes, so $\big(\prod_{j\le n} c_j\big)^{-1/n} = \frac{1}{n+1}$ and the bracket becomes $c_k \sum_{n\ge k} \frac{1}{n(n+1)} = \frac{c_k}{k} = \big(1+\frac{1}{k}\big)^k < e$. Notice the two telescopes: one in the product, one in the sum. Our problem is the easy member of the family because the weights are geometric, so both telescopes degenerate to geometric series.

The discernment mechanism is the shape of the constraint. You are told $\sum a_k = 1$ and nothing else, so the only inequality that can possibly be sharp is one whose right hand side is $C\sum a_k$. Any intermediate expression that still mentions n in a way you cannot sum is a sign you have applied AM-GM too early or with the wrong arguments. Train it like this: never write AM-GM with the given variables. Write it with $c_k a_k$, carry the c_k through to the end, and let the last line tell you what they are.

What the examiners nudged with: the weight $n/2^n$ is exponential with a polynomial factor, which is the signature of "the answer is a rational number and the extremiser is geometric". The factor n is there for cosmetics, since it cancels against the $\frac{1}{n}$ of AM-GM; strip it and the problem changes character, because then $\sum_{n\ge k} \frac{1}{n} x^n$ has no closed form and the bracket cannot be flattened. That cancellation of n against $\frac{1}{n}$ is the fingerprint that the intended route is AM-GM, and is the single most informative feature of the statement.

Revolving concepts

AM-GM and its equality case. For nonnegative $x_1, \ldots, x_n$, $(x_1 \cdots x_n)^{1/n} \le \frac{1}{n}(x_1 + \cdots + x_n)$, with equality if and only if all x_i are equal. The weighted form: for weights $\lambda_i > 0$ summing to 1, $\prod x_i^{\lambda_i} \le \sum \lambda_i x_i$. The rescaling $x_i \mapsto c_i x_i$ is what converts the unweighted form into a tunable tool. See Book 1, field: Inequalities, topic: AM-GM and rescaling.

Carleman's inequality. $\sum_{n\ge1} (a_1 \cdots a_n)^{1/n} \le e \sum_{k\ge1} a_k$ for nonnegative a_k, with e best possible. Its proof is the machine above with $c_k = (k+1)^k/k^{k-1}$. It is the limiting case $p \to \infty$ of Hardy's inequality $\sum_n \big(\frac{a_1+\cdots+a_n}{n}\big)^p \le \big(\frac{p}{p-1}\big)^p \sum_k a_k^p$. See Book 1, field: Inequalities, topic: Carleman and Hardy.

Tonelli for series. For $b_{n,k} \geq 0$, $\sum_n \sum_k b_{n,k} = \sum_k \sum_n b_{n,k}$ in $[0, \infty]$, with no convergence hypothesis. This is why you may swap before knowing $S < \infty$. See Book 1, field: Real analysis, topic: double series and interchange.

Geometric sums. $\sum_{n \geq k} x^n = \frac{x^k}{1-x}$ and $\sum_{n \geq 1} n x^n = \frac{x}{(1-x)^2}$ for $|x| < 1$, the second being $x \frac{d}{dx}$ of the first.

The generalised recursion. There is no recursion in the sequence (a_k), but there is a self-similar structure in the double sum, and it generalises cleanly. For $\lambda > 1$, the same argument with $c_k = \lambda^{2k}$ gives

$$\max\Big\{ \sum_{n \geq 1} \frac{n}{\lambda^n} (a_1 \cdots a_n)^{1/n} : \; a_k \geq 0, \; \sum_k a_k = 1 \Big\} = \frac{\lambda}{\lambda^2 - 1},$$

attained at $a_k = (\lambda^2 - 1)\lambda^{-2k}$; the case $\lambda = 2$ is this problem. The reason a geometric extremiser appears is that the weight sequence is geometric, so the design equation is linear in $\log t$ and has exactly one root. Whenever the weights are $w_n = n\lambda^{-n}$, expect the extremiser $a_k \propto \lambda^{-2k}$: the square is the footprint of the exponent $(n+1)/2$ in $\big(\prod_{k \leq n} t^k\big)^{1/n} = t^{(n+1)/2}$.

Circuit Bank

- **WHEN** you see a geometric mean of the first n terms summed over n against weights **DO** apply AM-GM to $c_k a_k$ with the c_k undetermined, swap the order of summation, and collect the coefficient of a_k **BECAUSE** the constraint is on $\sum a_k$, so the bound must end as a constant times $\sum a_k$, and the c_k are exactly the freedom that makes that possible
- **WHEN** you have an inequality with free parameters and a linear constraint **DO** write down the design equation "the coefficient of every constrained variable is equal" and solve it **BECAUSE** a bound of the form $\sum_k \gamma_k a_k$ can only be turned into a number using $\sum a_k = 1$ when the γ_k are constant, and the flattening choice is automatically the one that is sharp
- **WHEN** you see the word maximum rather than supremum **DO** find the equality case of your inequality first and use it as a check on the constant **BECAUSE** an attained maximum means the equality conditions are consistent with the constraint, so they determine the extremiser and give you a second, independent computation of the answer
- **WHEN** you see a double sum of nonnegative terms **DO** swap the order without justification beyond naming Tonelli **BECAUSE** nonnegativity makes both iterated sums equal in $[0, \infty]$, so you may swap before you know anything converges

Backtesting

1. First useful cue: prefix geometric mean summed against geometric weights, with only $\sum a_k$ given. That is the Carleman machine.
2. Method the expression suggested: AM-GM applied to rescaled terms $c_k a_k$, with c_k solved for at the end by demanding a k-independent coefficient.
3. Where you would hesitate, and the thought to reinforce: reaching for the bare AM-GM because it is the one you have memorised. Reinforce this: AM-GM is a family, and the member you want is the one whose equality case matches the answer you expect. Carry the parameter.
4. The trap the question sets: the factor n in $n/2^n$ looks like an obstacle and is actually the invitation, since it cancels the $\frac{1}{n}$ from AM-GM. A candidate who bounds $n/2^n \leq \frac{1}{2}$ and quotes Carleman gets $e/2$ and stops.
5. What makes you recognise it faster next time: the pair (geometric mean of a prefix, constraint on the plain sum). Also the cancellation of n against $\frac{1}{n}$, which tells you AM-GM is intended rather than convexity or rearrangement.

6. The reusable decision rule: rescale before you apply a symmetric inequality, keep the scaling free, and let the constraint pick it.

Mirror drills

1. For $\lambda > 1$, find the maximum of $\sum_{n\geq 1} \frac{n}{\lambda^n}(a_1 \cdots a_n)^{1/n}$ over nonnegative sequences with $\sum_k a_k = 1$. *Answer:* $\frac{\lambda}{\lambda^2-1}$, at $a_k = (\lambda^2-1)\lambda^{-2k}$; take $c_k = \lambda^{2k}$, so that $\left(\prod_{k\leq n} c_k\right)^{1/n} = \lambda^{n+1}$.
2. Prove Carleman's inequality $\sum_{n\geq 1}(a_1 \cdots a_n)^{1/n} \leq e \sum_k a_k$ by the same machine, discovering the weights rather than quoting them. *Answer:* demand $\prod_{j\leq n} c_j$ to be a clean function of n; $c_k = (k+1)^k/k^{k-1}$ gives $\prod_{j\leq n} c_j = (n+1)^n$, and then the coefficient of a_k is $c_k \sum_{n\geq k} \frac{1}{n(n+1)} = \frac{c_k}{k} = (1+\frac{1}{k})^k < e$.
3. Show that if the sequence is required to vanish beyond a fixed index N, the supremum of S is strictly less than $\frac{2}{3}$, yet tends to $\frac{2}{3}$ as $N \to \infty$. *Answer:* strictness because the chain $2S \leq \sum_{n\geq 1} 4^{-n} \sum_{k\leq n} 4^k a_k$ discards the terms with $n > N$, which are strictly positive while the corresponding G_n vanish; and $a_k = 4^{-k}/\sum_{j\leq N} 4^{-j}$ gives $S = \frac{c}{2}\sum_{n\leq N} n4^{-n} \to \frac{2}{3}$ with $c = 3/(1-4^{-N})$.

5.9 B3. Averaging a rotational derivative over circles

Let $h(x, y)$ be a real-valued function that is twice continuously differentiable throughout $\mathbb{R}^2$, and define

$$\rho(x, y) = yh_x - xh_y.$$

Prove or disprove: For any positive constants d and r with $d > r$, there is a circle $\mathcal{S}$ of radius r whose centre is a distance d away from the origin such that the integral of ρ over the interior of $\mathcal{S}$ is zero.

Read it out loud

There are two objects and you must name both before you compute anything. The first is the combination $yh_x - xh_y$. That is not a random pairing of derivatives: in polar coordinates $x = s\cos\theta$, $y = s\sin\theta$ the chain rule gives $\partial_\theta = -y\partial_x + x\partial_y$, so $\rho = -h_\theta$. The integrand is the angular derivative of h, with a sign. The second object is the family of candidate circles: their centres run over the circle $|c| = d$, so the family is a one-parameter loop, parametrised by the angle ϕ of the centre.

The fields wired in are vector calculus in polar coordinates, interchange of integrals (Fubini), the rotation symmetry of the family of discs, and the intermediate value theorem. What is really being tested is whether you recognise the question type. You are handed a continuum of candidate objects and asked to produce one on which a functional vanishes. You are not asked which one. That is the signature of an averaging argument: show the average of the functional over the family is zero, note the functional is continuous in the parameter, and let the intermediate value theorem manufacture the object. Constructing the circle explicitly is impossible, since h is arbitrary, and the impossibility of construction is itself the cue.

The first useful cue is the shape $yh_x - xh_y$, and within thirty seconds you should have written two lines: $\rho = -\partial_\theta h$, and therefore for every $s > 0$

$$\int_0^{2\pi} \rho(s\cos\theta, s\sin\theta)\, d\theta = -\big[h(s\cos\theta, s\sin\theta)\big]_{\theta=0}^{\theta=2\pi} = 0,$$

because h is a single-valued function of the point, hence 2π-periodic in θ. Every circle centred at the origin is a null set for ρ. That is the entire mechanism, and the rest of the solution is bookkeeping that converts "zero on origin-centred circles" into "zero on one of the given discs".

A caveat worth clarifying at once, because it decides between prove and disprove. If h were allowed to be the multivalued angle θ itself, then $\rho = -1$ and every disc integral would be $-\pi r^2$, never zero. So any counterexample would have to be built from a potential that is not single-valued, and single-valuedness is exactly what the hypothesis gives you. The statement is true, and you now know which line of the proof carries the weight.

Approaches, ranked worst to best

1. **Hunt for a counterexample.** *Cue:* the phrase "prove or disprove". *Circuit:* choose h making ρ of one sign. (Why worst: it cannot succeed, and finding out why costs the whole time budget unless you first notice $\rho = -h_\theta$. Every attempt fails for the same structural reason: ρ has zero mean on each circle about the origin, so it can never be of one sign on such a circle. Note that the failed attempt does hand you the mechanism, which is why it is worth ten seconds, not ten minutes.)

2. **Fourier expansion in the angle.** *Cue:* $\rho = -h_\theta$ and h is periodic in θ. *Circuit:* write $h(s, \theta) = \sum_m c_m(s)e^{im\theta}$, so $\rho = -\sum_m imc_m(s)e^{im\theta}$ and the mode $m = 0$ is annihilated. (Why third: it is correct and it explains everything, since averaging over the centre angle ϕ multiplies the m-th mode by $\frac{1}{2\pi}\int_0^{2\pi} e^{im\phi}d\phi = 0$ for $m \neq 0$, while $m = 0$ was already killed. But for a general twice

differentiable h you owe the grader a convergence argument for the series, and that is ink you do not need to spend.)

3. **Divergence theorem.** *Cue:* $\rho = \nabla h \cdot V$ with $V = (y, -x)$ and $\operatorname{div} V = 0$. *Circuit:* $\rho = \operatorname{div}(hV)$, so the area integral becomes a boundary integral. (Why second: it is a genuine simplification, reducing the double integral to $\oint_{\partial\mathcal{S}} h\, V \cdot n\, ds = rd \int_0^{2\pi} h\big(c_\phi + r(\cos t, \sin t)\big) \sin(\phi - t)\, dt$, and the averaging step then works by writing the point as a rotation of $(d + r\cos u, r\sin u)$ and using that $\sin u$ is odd while $|(d + r\cos u, r\sin u)|$ is even in u. Correct, and shorter in data, but the algebra of $V \cdot n$ costs more ink than the polar route and the averaging step is the same either way.)

4. **Average over the family, then intermediate value theorem.** *Cue:* a one-parameter family of candidates and a demand for existence, not construction. *Circuit:* $\int_0^{2\pi} I(\phi)\, d\phi = 0$ by Fubini plus rotation invariance, then IVT. (Why best: it uses the mechanism directly, needs only continuity of ρ, and every step is one line. The rotation invariance of the family is what makes the interchanged integral factor into a radial weight times an angular integral that is already known to vanish.)

The ideal solution

The statement is true. Fix $d > r > 0$ (in fact $d > r$ is never used; see the remark at the end).

For $\phi \in \mathbb{R}$ put $c_\phi = (d\cos\phi,\, d\sin\phi)$ and let $D_\phi = \{P \in \mathbb{R}^2 :\ |P - c_\phi| \le r\}$, so that the circles described in the problem are exactly the boundaries ∂D_ϕ, $\phi \in [0, 2\pi)$. Define

$$I(\phi) = \iint_{D_\phi} \rho\, dA.$$

We show $I(\phi_0) = 0$ for some ϕ_0. Since h is continuously differentiable, $\rho = yh_x - xh_y$ is continuous, which is all that is used.

Step 1: I is continuous. Translating, $I(\phi) = \iint_{|w|\le r} \rho(c_\phi + w)\, dA(w)$. The function ρ is uniformly continuous on the compact disc $\{|P| \le d + r\}$, which contains every D_ϕ; so given $\varepsilon > 0$ there is $\delta > 0$ with $|\rho(P) - \rho(P')| < \varepsilon/(\pi r^2)$ whenever $|P - P'| < \delta$ inside that disc, and $|\phi - \phi'|$ small forces $|c_\phi - c_{\phi'}| < \delta$. Hence $|I(\phi) - I(\phi')| < \varepsilon$.

Step 2: ρ has zero mean on every circle centred at the origin. Fix $s > 0$ and set $g(\theta) = h(s\cos\theta, s\sin\theta)$. Then g is continuously differentiable and 2π-periodic, and by the chain rule

$$g'(\theta) = -s\sin\theta\, h_x + s\cos\theta\, h_y = -\big(yh_x - xh_y\big) = -\rho$$

evaluated at $(s\cos\theta, s\sin\theta)$. Therefore

$$\int_0^{2\pi} \rho(s\cos\theta, s\sin\theta)\, d\theta = -\int_0^{2\pi} g'(\theta)\, d\theta = -\big(g(2\pi) - g(0)\big) = 0.$$

Step 3: the average of I over the family vanishes. Let $\chi(P, \phi)$ be the indicator of $|P - c_\phi| \le r$, so $I(\phi) = \iint_{\mathbb{R}^2} \chi(P,\phi)\rho(P)\, dA(P)$. The function $\chi\rho$ is bounded and measurable and vanishes outside the compact set $\{|P| \le d + r\} \times [0, 2\pi]$, so Fubini's theorem gives

$$\int_0^{2\pi} I(\phi)\, d\phi = \iint_{\mathbb{R}^2} \rho(P)\, M(P)\, dA(P), \qquad M(P) = \int_0^{2\pi} \chi(P,\phi)\, d\phi.$$

Write $P = (s\cos\theta, s\sin\theta)$ with $s > 0$. Then $|P - c_\phi|^2 = s^2 + d^2 - 2sd\cos(\theta - \phi)$, so

$$\chi(P,\phi) = 1 \iff \cos(\theta - \phi) \ \ge\ \lambda(s) := \frac{s^2 + d^2 - r^2}{2sd},$$

which depends on P only through s and on ϕ only through $\theta - \phi$. Integrating over a full period in ϕ therefore removes θ altogether:

$$M(P) = M(s) = \begin{cases} 0, & \lambda(s) > 1, \\ 2\arccos\lambda(s), & |\lambda(s)| \le 1, \\ 2\pi, & \lambda(s) < -1. \end{cases}$$

In particular M is a bounded measurable function of s alone. Passing to polar coordinates and using Step 2,

$$\int_0^{2\pi} I(\phi)\,d\phi = \int_0^{\infty} M(s)\left(\int_0^{2\pi} \rho(s\cos\theta, s\sin\theta)\,d\theta\right) s\,ds = \int_0^{\infty} M(s)\cdot 0\cdot s\,ds = 0.$$

(The single point $s = 0$ is a null set and may be ignored.)

Step 4: conclusion. I is continuous on $[0, 2\pi]$ and $\int_0^{2\pi} I(\phi)\,d\phi = 0$. If I had no zero then, being continuous on an interval, it would have constant sign by the intermediate value theorem, and its integral would be strictly positive or strictly negative. Hence $I(\phi_0) = 0$ for some $\phi_0 \in [0, 2\pi]$, and $\mathcal{S} = \partial D_{\phi_0}$ is a circle of radius r whose centre is at distance d from the origin with $\iint_{\operatorname{int}\mathcal{S}} \rho = 0$. This proves the statement.

Remark. Two hypotheses are stronger than needed. Only $h \in C^1$ was used, not C^2. And $d > r$ was never used: if $d \le r$ the discs contain the origin, but $\{0\}$ is a null set and Step 2 holds for every $s > 0$, so the conclusion holds for all $d, r > 0$. Also, the argument gives slightly more: unless $I \equiv 0$, the function I takes both signs, so at least two of the circles work.

Layer 1: WHAT

Block 1: read $yh_x - xh_y$ as $-\partial_\theta h$. Block 2: deduce that ρ has zero mean on every circle centred at the origin, using only that h is single valued. Block 3: recognise the question type (existence within a continuous family) and set up $I(\phi)$, the functional on the family. Block 4: average I over the family; interchange the two integrals. Block 5: observe that the interchanged weight $M(P)$ is rotation invariant, because the family of discs is a rotation orbit, hence M is radial and the inner integral is the one from Block 2. Block 6: continuity plus the intermediate value theorem.

Juxtaposition. The nominal route reads "prove or disprove" and starts hunting for an h that breaks it, or else tries to evaluate $I(\phi)$ for a general h, which is hopeless. A more sophisticated zombie does spot $\rho = -h_\theta$, and then tries to exploit it disc by disc: in polar coordinates the disc D_ϕ meets the circle of radius s in an arc, and the angular integral over that arc is $h(P_1) - h(P_2)$, the difference of h at the two endpoints. That is a genuine simplification and it is where the official write-up passes through, but on its own it goes nowhere, because the endpoint values of an arbitrary h are arbitrary.

The bifurcation point is the sentence immediately after "the arc integral is $h(P_1) - h(P_2)$". The zombie tries to control that difference. You integrate over ϕ first, so that the arcs sweep out the full circle and the endpoint differences telescope to zero. In one phrase: do not evaluate the member, average the family.

Layer 2: HOW

Block 1. **Cue.** The specific combination $y\,\partial_x - x\,\partial_y$ applied to h. **Why natural.** Any first order expression $ah_x + bh_y$ is a directional derivative, and the question is which coordinate system turns it into a single partial derivative. The vector field $(y, -x)$ is tangent to the circles about the origin, so the natural coordinates are polar and the operator is $-\partial_\theta$. There are only two such combinations you will ever meet: $xh_x + yh_y = s\,h_s$ (Euler) and $yh_x - xh_y = -h_\theta$. Recognising which one you have is a lookup, not an insight. **Link to the next block.** A pure θ derivative integrates to a difference of endpoint values, so closed loops in θ give zero.

Block 2. **Cue.** h is a function on the plane, so it is 2π-periodic in θ. **Why natural.** This is the only place in the whole proof where a hypothesis about h is used, and it is the place where a counterexample would have to attack. Periodicity is the statement that h is single valued, and the fundamental theorem of calculus over a full period gives zero. If you tried $h = \theta$, which is not single valued, you would get $\rho = -1$ and the statement would fail, so this line is exactly the pivot. **Link to the next block.** You now own a family of sets on which ρ integrates to zero, namely the origin-centred circles. The given discs are not among them, so you need a device to move information from one family to the other.

Block 3. **Cue.** "There is a circle $\mathcal{S}$ such that the integral is zero", with no hint as to which. **Why natural.** When a problem asks for existence inside a continuum of candidates and the data are arbitrary, no construction can exist, so the proof must be non constructive. The two standard non constructive engines are averaging (the mean lies between the extremes) and topology (degree, fixed points). Here the family is a loop parametrised by one angle and the functional is real valued, so averaging plus the intermediate value theorem is the cheapest engine available. **Link to the next block.** To average, you need $I(\phi)$ as an explicit integral so that you may interchange the order of integration.

Block 4. **Cue.** A double integral over (P, ϕ) with a bounded integrand on a compact set. **Why natural.** Fubini applies with nothing to check. The point of interchanging is that after doing the ϕ integral first, the geometry of the individual disc disappears and only the total time each point P spends inside the moving disc remains. **Link to the next block.** That occupation function $M(P)$ is the object to inspect.

Block 5. **Cue.** The family $\{D_\phi\}$ is a single orbit of the rotation group acting on one disc. **Why natural.** If a family is closed under rotation, then averaging over the family produces a rotation invariant weight, and a rotation invariant function of the plane is a function of s alone. The explicit computation confirms it: membership is $\cos(\theta - \phi) \geq \lambda(s)$, and integrating over a full period of ϕ erases θ. Once M is radial, the double integral factors in polar coordinates into a radial integral times the angular integral of Block 2, which is zero. **Link to the next block.** The average of I is zero, and only a compactness fact is missing.

Block 6. **Cue.** A continuous real function on an interval with zero mean. **Why natural.** A continuous function with no zero has constant sign by the intermediate value theorem, and then its integral is nonzero. The continuity of I is not a formality worth skipping: it follows from uniform continuity of ρ on a compact disc containing all the D_ϕ, and a grader will want that sentence. **Link to the next block.** Existence of the circle.

Layer 3: WHY

The mathematical truth underneath is a statement about the operator ∂_θ. Its kernel consists of the radial functions, and its image, among continuous functions, consists exactly of the functions with zero mean on every circle about the origin. So the map $h \mapsto \rho$ produces only functions that are invisible to circular averaging, and the whole problem is a test of whether you can convert an arbitrary disc into a superposition of circular averages. The conversion device is the rotation group: the family of allowed discs is a single orbit, so integrating over the orbit turns any set into a radially symmetric weight, and a radially symmetric weight pairs a function against circular averages only. In the language you will meet later, $\rho\, dA$ is an exact form and the circle integrals detect exactly the failure of $d\theta$ to be exact; the mode $m = 0$ in the Fourier expansion of h in θ is the entire obstruction, and ∂_θ kills it.

The discernment mechanism has two components. First, when an expression is a first order combination of partial derivatives with variable coefficients, identify the flow of the coefficient vector field and change coordinates so that the expression becomes one partial derivative. The two coordinate systems that matter on the plane are Cartesian and polar, and $(y, -x)$ is the rotational field, so it is polar. Second, when the conclusion is existential over a continuum and the data are arbitrary, compute the mean of the functional over the continuum. If the mean is the target value, IVT ends it. This is the continuous form of the pigeonhole principle: at least one member is at most the average, and at least one is at least the average.

How to train it. Take every problem that says "there exists a position, an angle, a chord, a line, a partition, such that some quantity is zero or equal" and try averaging first, before any construction. The list of classical results with this shape is long: the ham sandwich theorem, the existence of a chord of a given length on a graph closing at both ends, the pancake theorem, the mean value theorem for integrals. In every one of them the object is produced, not built.

What the examiners nudged with, and how. They wrote ρ as $yh_x - xh_y$ rather than as $\operatorname{div}(h \cdot (y, -x))$ or as $-h_\theta$, because writing it in polar form would have given the game away. They said "prove or disprove" to make you spend time on counterexamples, and they set $d > r$ so that the discs avoid the origin, removing a distraction about the singularity of polar coordinates. They asked only for existence, which is the tell for averaging. And they assumed C^2, one degree more than needed, which is a deliberate false clue: a candidate who assumes the extra derivative is there to be used will look for a second order identity that does not exist.

Revolving concepts

Polar differential operators. With $x = s\cos\theta$, $y = s\sin\theta$: $\partial_s = \cos\theta\,\partial_x + \sin\theta\,\partial_y$ and $\partial_\theta = -s\sin\theta\,\partial_x + s\cos\theta\,\partial_y = -y\partial_x + x\partial_y$. Hence $xh_x + yh_y = s\,h_s$ (the Euler operator, which detects homogeneity: $sh_s = kh$ if and only if h is homogeneous of degree k) and $yh_x - xh_y = -h_\theta$. See Book 1, field: Calculus and integrals, topic: polar coordinates and differential operators.

Divergence-free fields and the divergence theorem. $V = (y, -x)$ has $\operatorname{div} V = 0$, so $\rho = \nabla h \cdot V = \operatorname{div}(hV) - h\operatorname{div} V = \operatorname{div}(hV)$, and $\iint_D \rho\, dA = \oint_{\partial D} hV \cdot n\, ds$. This is the second reading of the integrand and gives the alternative route. See Book 1, field: Calculus and integrals, topic: Green and divergence theorems.

The averaging existence principle. If J is a continuous real function on a connected parameter space and the average of J over that space is v, then J takes the value v somewhere. Proof: otherwise $J - v$ is continuous and never zero, so it has constant sign on the connected space, contradicting the vanishing of its mean. See Book 1, field: Real analysis, topic: intermediate value theorem and averaging.

Fubini and the occupation measure. For a family $\{K_g\}$ indexed by a compact group G with $K_g = gK$, the weight $M(P) = \int_G \mathbf{1}[P \in gK]\, dg$ is G invariant. For $G = SO(2)$ that means M is radial, and pairing a radial weight against ρ reduces to circular means of ρ. This is the general form of Step 3 and it is worth remembering with the group in it, because the same line proves the analogous statement for any bounded measurable region in place of the disc.

Fourier modes in the angle. Writing $h(s, \theta) = \sum_m c_m(s) e^{im\theta}$, the operator ∂_θ multiplies the m-th mode by im and annihilates $m = 0$; averaging over the centre angle ϕ multiplies the m-th mode by $\frac{1}{2\pi}\int_0^{2\pi} e^{im\phi} d\phi$, which vanishes for $m \neq 0$. The two annihilations cover all modes, which is the conceptual reason the average is zero.

Recursion. There is none in this problem: no sequence, no induction, no self-similar object. What replaces it is the group average, and the correct generalisation to store is the one stated above with G compact and M invariant, not a recursion.

Circuit Bank

- **WHEN** you see a first order expression $ah_x + bh_y$ with variable coefficients **DO** identify the flow of the field (a, b) and change to coordinates in which it is one partial derivative; for $(y, -x)$ that is polar and the expression is $-h_\theta$ **BECAUSE** a single partial derivative integrates by the fundamental theorem of calculus, and along a closed coordinate loop the result is zero when the potential is single valued
- **WHEN** you see an existence claim over a continuous family with arbitrary data **DO** compute the average of the functional over the family and apply the intermediate value theorem **BECAUSE** no construction can exist when the data are arbitrary, so the proof must be non constructive, and averaging is the cheapest non constructive engine for a real-valued functional
- **WHEN** you average a set-indexed functional over a group orbit of sets **DO** interchange the integrals and note that the resulting occupation weight is invariant under the group, hence constant on orbits **BECAUSE** invariance forces the weight to be a function of the orbit parameter alone, and pairing against an invariant weight sees only orbit averages of the integrand
- **WHEN** you are asked to prove or disprove and the only candidate counterexample needs a multivalued potential **DO** stop hunting and prove it, using single-valuedness as the pivot line **BECAUSE** the failure mode of the counterexample tells you exactly which hypothesis is load bearing, and a proof that uses that hypothesis once is usually short

Backtesting

1. First useful cue: the combination $yh_x - xh_y$, which is the angular derivative $-h_\theta$ in polar coordinates.
2. Method the expression suggested: circular means of ρ vanish by periodicity, so average the disc integral over the rotation family and finish with the intermediate value theorem.
3. Where you would hesitate, and the thought to reinforce: after seeing $\rho = -h_\theta$ you will want to attack a single disc, whose arcs give endpoint differences you cannot control. Reinforce this: when a single member is intractable and the family is a symmetry orbit, integrate over the family first.
4. The trap the question sets: the phrase "prove or disprove" invites a counterexample hunt, and the C^2 hypothesis invites you to look for a second derivative identity. Neither exists. Only C^1 and single-valuedness are used.
5. What makes you recognise it faster next time: the pairing of a rotational vector field with a rotation-symmetric family of candidate regions. Whenever the integrand is adapted to the same symmetry group as the family, the average over the family is the intended route.
6. The reusable decision rule: existence over a symmetric family equals zero average plus continuity. Never try to name the member.

Mirror drills

1. Show that for every continuously differentiable h on $\mathbb{R}^2$ and every $s > 0$, $\int_0^{2\pi} (yh_x - xh_y)(s\cos\theta, s\sin\theta)\, d\theta = 0$. *Answer:* the integrand is $-\frac{d}{d\theta} h(s\cos\theta, s\sin\theta)$ and h is 2π-periodic in θ, so the integral is $h(s,0) - h(s,2\pi) = 0$.
2. Show that the analogous statement for $\sigma = xh_x + yh_y$ is false. *Answer:* $\sigma = s\, h_s$ and s is not a periodic coordinate; take $h = \frac{1}{2}(x^2 + y^2)$, so $\sigma = x^2 + y^2 > 0$ off the origin and every

disc integral is strictly positive. This isolates periodicity of θ, not smoothness of h, as the load-bearing feature.

3. Let $K \subset \mathbb{R}^2$ be any bounded measurable set and let R_ϕ be rotation by ϕ about the origin. Show there is ϕ_0 with $\iint_{R_{\phi_0}K} \rho \, dA = 0$, provided $\phi \mapsto \iint_{R_\phi K} \rho$ is continuous. *Answer:* identical proof; the occupation weight $M(P) = \int_0^{2\pi} \mathbf{1}[P \in R_\phi K] \, d\phi$ is rotation invariant hence radial, so the averaged integral reduces to radial weights against circular means of ρ, all zero.

5.10 B4. A twisted product modulo a Fibonacci prime

Let $F_0, F_1, \ldots$ be the sequence of Fibonacci numbers, with $F_0 = 0$, $F_1 = 1$, and $F_n = F_{n-1} + F_{n-2}$ for $n \geq 2$. For $m > 2$, let R_m be the remainder when the product $\prod_{k=1}^{F_m-1} k^k$ is divided by F_m. Prove that R_m is also a Fibonacci number.

Read it out loud

The object is $A = \prod_{k=1}^{N-1} k^k$ reduced modulo N, where $N = F_m$. Say that again slowly: it is a product over every nonzero residue class modulo N, but each factor is raised to a power that depends on the class. Call that a twisted product. Untwisted products over the full residue system are computable, because Wilson's theorem hands you $\prod_{k=1}^{p-1} k \equiv -1 \pmod{p}$; twisted ones are not, because the exponent k has no multiplicative meaning. Every route to this problem must therefore be a route that removes the twist.

The fields wired in are elementary number theory (Wilson's theorem, the fact that $\mathbb{Z}/p$ is a field so a quadratic has at most two roots, the criterion for -1 to be a quadratic residue) and the standard identity theory of the Fibonacci sequence (the addition formula, Cassini's identity, the sequence modulo 4). What is really being tested is whether you can read the two halves of the problem as one: the arithmetic half produces some square root of -1 modulo F_m, and the Fibonacci half must produce the same square root by a completely different route.

The first cue is planted in the statement itself and most candidates walk past it. The problem takes the trouble to say $F_0 = 0$. There is only one reason to normalise like that: 0 has to count as a Fibonacci number, so $R_m = 0$ must occur. And $R_m = 0$ means F_m divides the product, which happens for the cheapest possible reason when F_m is composite. So within thirty seconds you should have written: split on whether F_m is prime; if composite, $N = ab$ with $a, b < N$ makes $a^a b^b$ a factor of the product, so $R_m = 0 = F_0$ and that half is finished.

That leaves F_m prime, and now the second cue fires. Modulo a prime p the only computable products are the untwisted ones, and the only symmetry available on the exponent is the involution $k \mapsto p - k$, which turns k^k into $(-k)^{p-k}$. Multiplying the two versions of A makes the exponents add to the constant p, and a constant exponent is Wilson territory. So the plan is fixed before any computation: compute A^2, not A. That is why the answer can only be pinned down up to sign, and it is why the problem says R_m is *a* Fibonacci number rather than naming which one.

Approaches, ranked worst to best

1. **Reduce the exponents and multiply out.** *Cue:* k^k with k up to $F_m - 1$. *Circuit:* Fermat: $k^k \equiv k^{k \bmod (p-1)}$, then grind. (Why worst: it produces $p - 1$ unrelated powers with no structure, it does not generalise past $p = 13$, and it never touches the Fibonacci half of the problem at all. It is pure zombie arithmetic.)

2. **Discrete logarithm.** *Cue:* a product over the multiplicative group. *Circuit:* fix a primitive root g and write $A = g^E$ with $E = \sum_{k=1}^{p-1} k \cdot \mathrm{ind}_g(k)$. (Why second worst: it is a genuine idea, since it converts the product into a sum, but the sum couples the additive size k to the multiplicative index of k, and there is no closed form for such a mixed sum. It stalls immediately and for a reason worth naming: k as an exponent is additive data, k as a factor is multiplicative data, and no single coordinate system linearises both.)

3. **Pair k with its inverse.** *Cue:* Wilson's proof pairs k with k^{-1}. *Circuit:* $\prod k^k = \prod (k^{-1})^{k^{-1}}$ suitably reindexed. (Why third: the reflex is right, since Wilson's theorem is proved by pairing, but this particular pairing sends the exponent k to k^{-1}, which is again multiplicative data, so nothing simplifies. Knowing why the natural pairing fails is what points you at the correct one.)

4. **Pair k with $p-k$ and square.** *Cue:* the exponents k and $p-k$ add to the constant p. *Circuit:* $A \cdot \prod k^{p-k} = \prod k^p = ((p-1)!)^p$, and $\prod k^{p-k} \equiv \pm A$. (Why best: the involution $k \mapsto p-k$ is additive on exponents and multiplicative by -1 on bases, which is exactly the mismatch the problem is built from. One reindexing, one Wilson, and A^2 is a sign. The remaining work is to recognise that sign as -1 and to find a Fibonacci square root of -1 modulo F_m, which is Cassini's identity.)

The ideal solution

Write $N = F_m$ and $A = \prod_{k=1}^{N-1} k^k$, so that $R_m \equiv A \pmod N$ with $0 \le R_m < N$.

Small cases. For $m = 3$, $N = 2$ and $A = 1^1 = 1$, so $R_3 = 1 = F_1$. For $m = 4$, $N = 3$ and $A = 1^1 \cdot 2^2 = 4 \equiv 1$, so $R_4 = 1 = F_1$. From now on $m \ge 5$.

Case 1: N composite. Write $N = ab$ with $2 \le a \le b$; then $b = N/a \le N/2 < N$, so both a and b lie in $\{1, \dots, N-1\}$. If $a < b$ then a^a and b^b are two distinct factors of the product A, so ab divides $a^a b^b$, which divides A. If $a = b$ then $N = a^2$ with $a \ge 2$, and the single factor a^a of A is already divisible by $a^2 = N$. In both cases $N \mid A$, so $R_m = 0 = F_0$, a Fibonacci number.

Case 2: $N = p$ prime. First, m is odd. Indeed, the addition formula $F_{a+b} = F_a F_{b+1} + F_{a-1} F_b$ with $a = b = n$ gives

$$F_{2n} = F_n\big(F_{n+1} + F_{n-1}\big),$$

so if $m = 2n$ with $n \ge 3$ then $F_n \ge F_3 = 2$ and $F_{n+1} + F_{n-1} \ge F_4 + F_2 = 4$, making F_m composite. As $m \ge 5$, m must be odd.

Next, $p \equiv 1 \pmod 4$. The Fibonacci sequence modulo 4 begins $0, 1, 1, 2, 3, 1$ and then repeats, because $(F_6, F_7) \equiv (0, 1) \pmod 4$; so its period is 6. For odd m we have $m \equiv 1, 3, 5 \pmod 6$ and hence $F_m \equiv 1, 2, 1 \pmod 4$. Since $p = F_m \ge F_5 = 5$ is an odd prime, the value 2 is impossible, so $p \equiv 1 \pmod 4$.

Now reindex A by $k \mapsto p-k$:

$$A = \prod_{k=1}^{p-1} (p-k)^{\,p-k} \equiv \prod_{k=1}^{p-1} (-k)^{\,p-k} = (-1)^{\sum_{k=1}^{p-1}(p-k)} \prod_{k=1}^{p-1} k^{\,p-k} \pmod p.$$

Here $\sum_{k=1}^{p-1}(p-k) = \sum_{j=1}^{p-1} j = \frac{p(p-1)}{2}$, which is even because $p \equiv 1 \pmod 4$ makes $\frac{p-1}{2}$ even. Hence

$$A \equiv \prod_{k=1}^{p-1} k^{\,p-k} \pmod p.$$

Multiplying this by the definition of A collapses the exponents:

$$A^2 \equiv \prod_{k=1}^{p-1} k^k \cdot k^{\,p-k} = \prod_{k=1}^{p-1} k^p = \big((p-1)!\big)^p \equiv (-1)^p = -1 \pmod p,$$

using Wilson's theorem $(p-1)! \equiv -1 \pmod p$ and the fact that p is odd.

On the other hand, Cassini's identity $F_{n+1}F_{n-1} - F_n^2 = (-1)^n$ with $n = m-1$ gives

$$F_m F_{m-2} - F_{m-1}^2 = (-1)^{m-1} = 1,$$

since m is odd. Reducing modulo $p = F_m$,

$$F_{m-1}^2 \equiv -1 \pmod p.$$

Therefore $A^2 \equiv F_{m-1}^2 \pmod p$, that is, $p \mid (A - F_{m-1})(A + F_{m-1})$. As p is prime, $A \equiv F_{m-1}$ or $A \equiv -F_{m-1} \pmod p$. In the second case

$$-F_{m-1} \equiv F_m - F_{m-1} = F_{m-2} \pmod p.$$

Finally $0 \le F_{m-2} < F_{m-1} < F_m = p$, so each of F_{m-1} and F_{m-2} is already reduced. Hence

$$R_m \in \{F_{m-1},\, F_{m-2}\},$$

a Fibonacci number in either case. Combining with Case 1 and the small cases, R_m is always a Fibonacci number. ■

Remark. Both alternatives really occur, so the ambiguity is not an artefact of the proof: $R_5 = 3 = F_4$, $R_7 = 8 = F_6$ and $R_{13} = 144 = F_{12}$ give F_{m-1}, while $R_{11} = 34 = F_9$ gives F_{m-2}. Deciding which one occurs is a genuinely harder question and the problem was written so that you do not have to.

Layer 1: WHAT

Block 1: read $F_0 = 0$ in the statement as permission for the answer 0, and split on the primality of F_m. Block 2: composite case, $N = ab$ makes N a factor of the product; $R_m = 0 = F_0$. Block 3: prime case, use $F_{2n} = F_n(F_{n+1} + F_{n-1})$ to force m odd. Block 4: Fibonacci modulo 4 has period 6, so $F_m \equiv 1$ or 2 for odd m, hence $p \equiv 1 \pmod 4$. Block 5: apply the involution $k \mapsto p - k$ to A; the sign is $(-1)^{p(p-1)/2} = +1$. Block 6: multiply the two expressions for A; exponents become the constant p; Wilson gives $A^2 \equiv -1$. Block 7: Cassini at $n = m - 1$ gives $F_{m-1}^2 \equiv -1$. Block 8: a quadratic over a field has at most two roots, so $A \equiv \pm F_{m-1}$, and $-F_{m-1} \equiv F_{m-2}$.

Juxtaposition. The nominal route sees k^k and reaches for Fermat to shrink the exponents, then multiplies out. It never produces a statement about F_m as a Fibonacci number, because it never produces an algebraic identity at all, only a number. The ideal route never computes A; it computes A^2, and only ever as a sign.

The bifurcation point is the line immediately after writing $A = \prod_{k=1}^{p-1} k^k$. The zombie writes "$k^k \equiv k^{k \bmod (p-1)}$". You write "replace k by $p - k$", because the exponent is additive data and $k \mapsto p - k$ is the only additive symmetry of the index set that is also multiplicative on the base, up to the sign -1.

Layer 2: HOW

Block 1. Cue. The statement fixes $F_0 = 0$ although the product is never obviously zero. **Why natural.** A normalisation stated but apparently unused is never decoration on the Putnam. If 0 is declared Fibonacci, then 0 is an intended value of R_m, so there are values of m for which F_m divides the product. Divisibility of $\prod_{k<N} k^k$ by N is immediate when N is composite, so the split on primality is handed to you by the wording. **Link to the next block.** The composite case is finished in two lines and you may forget it.

Block 2. Cue. $N = ab$ with $2 \le a \le b < N$. **Why natural.** Both a and b appear as indices in the product, so a^a and b^b appear as factors. The only care needed is the degenerate case $a = b$, which happens for genuine Fibonacci numbers ($F_{12} = 144 = 12^2$), and there a^a with $a \ge 2$ already contains a^2. **Link to the next block.** What remains is F_m prime, where the product is a unit and a genuine computation is required.

Block 3. Cue. A Fibonacci number that is prime. **Why natural.** Fibonacci divisibility is index divisibility: $F_a \mid F_b$ whenever $a \mid b$. The instance you need is the cheapest one, $F_{2n} = F_n(F_{n+1} + F_{n-1})$, which follows from the addition formula, itself the $(1,2)$ entry of $Q^{a+b} = Q^a Q^b$ for $Q = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$. So F_m prime and $m > 4$ forces m odd. **Link to the next block.** Oddness of m will be used twice: once for the sign in Cassini and once, through the value modulo 4, for the sign in the Wilson computation.

Block 4. **Cue.** You will need to know a parity, namely whether $\frac{p(p-1)}{2}$ is even. **Why natural.** That parity is decided by p modulo 4, so compute the Fibonacci sequence modulo 4. It is eventually periodic because the pair (F_n, F_{n+1}) modulo 4 determines all later pairs and there are finitely many pairs; the period is 6 by direct inspection. Since a Fibonacci prime above 2 cannot be even, the residue 2 is excluded and $p \equiv 1 \pmod 4$. **Link to the next block.** Both signs in the main computation are now determined.

Block 5. **Cue.** The exponent k in k^k is additive data attached to a multiplicative index. **Why natural.** The set $\{1, \ldots, p-1\}$ has exactly one useful involution that acts additively on the index and multiplicatively on the value: $k \mapsto p-k$, which is $k \mapsto -k$ in the group and $k \mapsto p-k$ in the exponent. Applying it to the whole product gives a second expression for A with the exponent reflected. Nothing here is a leap: it is the unique symmetry available. **Link to the next block.** You now have two expressions for the same A, whose exponents are k and $p-k$.

Block 6. **Cue.** Two exponents that sum to a constant. **Why natural.** Multiply the expressions. The product has every base raised to the same power p, so it is $((p-1)!)^p$, and Wilson's theorem evaluates it. The price of the symmetrisation is that you learn A^2, not A. That price is exactly the ambiguity in the final answer, which is why the problem asks only that R_m be *a* Fibonacci number. **Link to the next block.** $A^2 \equiv -1$, so A is a square root of -1 modulo p.

Block 7. **Cue.** You need a square root of -1 modulo F_m built from Fibonacci numbers, because the conclusion must be a Fibonacci number. **Why natural.** That is a search with exactly one hit. Among the standard identities, the only one expressing a Fibonacci square modulo F_m is Cassini, $F_{n+1}F_{n-1} - F_n^2 = (-1)^n$, which at $n = m-1$ reads $F_{m-1}^2 \equiv (-1)^{m-1} \pmod{F_m}$. With m odd that is -1. Cassini itself is not an identity to memorise: it is $\det(Q^n) = (\det Q)^n$. **Link to the next block.** Two square roots of -1 in a field differ by a sign.

Block 8. **Cue.** $x^2 \equiv y^2$ in a field. **Why natural.** $\mathbb{Z}/p$ is a field, so $(A - F_{m-1})(A + F_{m-1}) \equiv 0$ forces one factor to vanish. Then $-F_{m-1} \equiv F_m - F_{m-1} = F_{m-2}$ by the defining recurrence, so the negative root is again a Fibonacci number, and both candidates already lie in $[0, p)$. **Link to the next block.** Done, in both cases.

Layer 3: WHY

The truth beneath the route is that in a finite abelian group you can evaluate the product of all elements, and nothing else. Wilson's theorem is the case $(\mathbb{Z}/p)^\times$ of the general fact that the product of all elements of a finite abelian group equals the product of its elements of order dividing 2, which here is -1 because ± 1 are the only such elements. A product in which the exponent varies with the element carries information that the group structure alone cannot see. So the entire strategy space consists of ways to convert a twisted product into an untwisted one, and there are only two kinds: pair the index with its additive negative, or pair it with its multiplicative inverse. Pairing with the inverse leaves the exponent scrambled; pairing with the additive negative makes the exponents sum to p. The choice is forced, not inspired.

The second truth is that Cassini's identity is a determinant. With $Q = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$ one has $Q^n = \begin{pmatrix} F_{n+1} & F_n \\ F_n & F_{n-1} \end{pmatrix}$, and taking determinants of both sides gives $F_{n+1}F_{n-1} - F_n^2 = (-1)^n$ because the determinant is multiplicative. Once you see it that way, you also see the generalisation for free, and you stop treating Fibonacci identities as a list to be memorised.

The discernment mechanism is a two-sided reading of the conclusion. The problem promises that the answer belongs to a specific sequence. That promise is an instruction: whatever you compute about A, you must be able to match it against an identity of that sequence. Since the computation can only reach A^2, the identity you need must be about a Fibonacci *square* modulo F_m. There is exactly one such identity. So the search is finite and the target is known before you look. Train this by always asking, before starting a computation, what shape of statement the conclusion forces you to produce.

What the examiners nudged with, and how. They set $F_0 = 0$, which tells you 0 is admissible and therefore that the composite case exists. They wrote "R_m is also a Fibonacci number" rather than naming F_{m-1}, which tells you the method will lose a sign. They chose the exponent k to equal the base, which is the minimal way to make a product twisted while keeping the involution $k \mapsto p - k$ effective. And they restricted to $m > 2$ so that $F_m \geq 2$ and the product is nonempty.

Revolving concepts

Wilson's theorem. For a prime p, $(p-1)! \equiv -1 \pmod{p}$. Proof: pair each k with k^{-1}; the only self-paired elements are the roots of $x^2 = 1$, namely ± 1. Converse: if N is composite and $N > 4$ then $(N-1)! \equiv 0 \pmod{N}$. See Book 1, field: Number theory, topic: Wilson and factorial congruences.

Quadratic residue -1. For an odd prime p, the congruence $x^2 \equiv -1 \pmod{p}$ is solvable exactly when $p \equiv 1 \pmod{4}$, and then it has exactly two solutions, which are negatives of each other. One explicit root is $\left(\frac{p-1}{2}\right)!$, by Wilson. See Book 1, field: Number theory, topic: quadratic residues and Euler's criterion.

Fibonacci identities as matrix identities. With $Q = \begin{pmatrix} 1 & 1 \\ 1 & 0 \end{pmatrix}$, $Q^n = \begin{pmatrix} F_{n+1} & F_n \\ F_n & F_{n-1} \end{pmatrix}$. Then $Q^{a+b} = Q^a Q^b$ gives the addition formula $F_{a+b} = F_a F_{b+1} + F_{a-1} F_b$ and hence $F_{2n} = F_n(F_{n+1} + F_{n-1})$, while $\det Q^n = (\det Q)^n$ gives Cassini $F_{n+1}F_{n-1} - F_n^2 = (-1)^n$. See Book 1, field: Sequences and recurrences, topic: linear recurrences in matrix form.

Divisibility structure. $\gcd(F_a, F_b) = F_{\gcd(a,b)}$, so for $a \geq 3$, $F_a \mid F_b$ if and only if $a \mid b$. Consequently F_m prime with $m > 4$ forces m prime, which is stronger than the oddness used above. See Book 1, field: Number theory, topic: strong divisibility sequences.

Pisano periods. The sequence $(F_n \bmod N)$ is purely periodic because the pair (F_n, F_{n+1}) determines the sequence in both directions and there are finitely many pairs modulo N. The period modulo 4 is 6, giving $0, 1, 1, 2, 3, 1$ repeating; this is what pins $p \equiv 1 \pmod{4}$.

The generalised recursion. For any second order recurrence $u_{n+1} = Pu_n - Qu_{n-1}$, put $M = \begin{pmatrix} P & -Q \\ 1 & 0 \end{pmatrix}$, so $\det M = Q$ and

$$u_{n+1}u_{n-1} - u_n^2 = Q^{n-1}\left(u_2 u_0 - u_1^2\right).$$

Fibonacci is $P = 1$, $Q = -1$, $u_0 = 0$, $u_1 = 1$, giving $(-1)^{n-1}(0 - 1) = (-1)^n$, which is Cassini. The same determinant argument gives Catalan's identity $F_n^2 - F_{n-s}F_{n+s} = (-1)^{n-s}F_s^2$ and d'Ocagne's identity. Store the determinant, not the list.

Circuit Bank

- **WHEN** you see a product over all nonzero residues with an exponent depending on the residue **DO** multiply the product by its image under $k \mapsto p - k$, so that the exponents add to the constant p, and evaluate with Wilson **BECAUSE** only untwisted products over a finite abelian group are computable, and $k \mapsto -k$ is the one involution that is additive on exponents and multiplicative on bases
- **WHEN** you arrive at $x^2 \equiv c$ modulo a prime **DO** find a second, structurally meaningful square root of c and conclude that x equals it up to sign **BECAUSE** a quadratic over a field has at

most two roots, so two square roots of the same element differ by a sign; the ambiguity is genuine information, not a defect

- **WHEN** the conclusion promises membership in a named sequence **DO** decide first what algebraic shape your computation can reach, then search that sequence's identities for exactly that shape **BECAUSE** here the computation can only reach a square, so only an identity about a Fibonacci square modulo F_m can close the gap, and Cassini is the unique candidate
- **WHEN** a problem states a normalisation that appears unused, such as $F_0 = 0$ **DO** treat it as a declaration that the corresponding value is an intended answer and look for the case that produces it **BECAUSE** examiners do not spend a clause on decoration; here it announces the composite case where the modulus divides the product
- **WHEN** you must show a modulus divides a product of many consecutive integers or their powers **DO** factor the modulus and locate the factors as separate terms of the product, checking the repeated-factor case **BECAUSE** $N = ab$ with $a, b < N$ puts a^a and b^b inside the product, and $N = a^2$ is covered because a^a contains a^2 once $a \geq 2$

Backtesting

1. First useful cue: the explicit $F_0 = 0$, which announces the composite case and the answer 0; then the twisted exponent in $\prod k^k$, which announces the involution $k \mapsto p - k$.
2. Method the expression suggested: symmetrise the exponent by reflection, square, apply Wilson, then match against Cassini.
3. Where you would hesitate, and the thought to reinforce: the two sign computations, $(-1)^{p(p-1)/2}$ and $(-1)^{m-1}$. Reinforce this: a sign that depends on p modulo 4 is decided by computing the sequence modulo 4, which is a six term calculation, not a research problem.
4. The trap the question sets: assuming F_m is prime and forgetting the composite case entirely, which is most of the values of m; and, in the composite case, forgetting that F_m can be a perfect square, as $F_{12} = 144$ is.
5. What makes you recognise it faster next time: any product over a full residue system with a nonconstant exponent. The reflex is reflect and multiply. Any appearance of a square root of -1 modulo p alongside a named integer sequence should send you straight to that sequence's Cassini-type identity.
6. The reusable decision rule: you cannot compute a twisted product, only its symmetrisation, so expect to determine the answer up to the ambiguity that the symmetrisation introduces, and read the problem statement to confirm that the ambiguity is tolerated.

Mirror drills

1. Derive Cassini's identity $F_{n+1}F_{n-1} - F_n^2 = (-1)^n$ without induction. *Answer:* take determinants in $Q^n = \begin{pmatrix} F_{n+1} & F_n \\ F_n & F_{n-1} \end{pmatrix}$, using $\det(Q^n) = (\det Q)^n = (-1)^n$.
2. Let p be a prime with $p \equiv 3 \pmod 4$. Show that $\prod_{k=1}^{p-1} k^k \equiv \pm 1 \pmod p$. *Answer:* the same reflection gives $A \equiv (-1)^{p(p-1)/2} \prod k^{p-k}$, and now $\frac{p-1}{2}$ is odd so the sign is -1; multiplying by A gives $A^2 \equiv -((p-1)!)^p \equiv -(-1) = 1$. (Check: $p = 7$ gives $A \equiv 1$.)
3. Show that if F_m is prime and $m > 4$ then m is prime. *Answer:* if $m = ab$ with $1 < a \leq b < m$ then $F_a \mid F_m$ by the addition formula applied repeatedly (or by $\gcd(F_a, F_m) = F_{\gcd(a,m)} = F_a$), and $1 < F_a < F_m$ since $a \geq 3$ when $m > 4$ is composite and not 4; handle $m = 2b$ directly through $F_{2n} = F_n(F_{n+1} + F_{n-1})$.

5.11 B5. Very odd matrices are acyclic digraphs

Say that an n-by-n matrix $A = (a_{ij})_{1 \le i,j \le n}$ with integer entries is very odd *if, for every nonempty subset S of $\{1, 2, \ldots, n\}$, the $|S|$-by-$|S|$ submatrix $(a_{ij})_{i,j \in S}$ has odd determinant. Prove that if A is very odd, then A^k is very odd for every $k \ge 1$.*

Read it out loud

Two words in the statement do all the work. The first is "odd". A determinant is a polynomial in the entries with integer coefficients, so it commutes with reduction modulo 2; "odd determinant" means "invertible over the field $\mathbb{F}_2$". Reduction also commutes with matrix multiplication, so $\overline{A^k} = \bar{A}^k$. Rewrite the whole problem over $\mathbb{F}_2$ and nothing is lost: A is very odd exactly when every principal submatrix of $\bar{A}$ is nonsingular, and the claim is that this property survives taking powers.

The second word is "every". The condition ranges over all nonempty subsets S, not just the initial segments $\{1, \ldots, r\}$. That distinction matters more than it looks. A condition on leading principal minors is destroyed by relabelling the indices; a condition on all principal minors is invariant under simultaneous permutation of the rows and the columns, that is, under conjugation by a permutation matrix. So the hypothesis is a permutation-conjugation invariant, and so is the conclusion, since $(P^{-1}AP)^k = P^{-1}A^kP$.

The fields wired in are linear algebra over a finite field, the combinatorics of directed graphs, and one clean induction. What is really being tested is a choice of strategy. You may either propagate the hypothesis through the product (compute principal minors of A^k from those of A) or classify the hypothesis (describe every very odd matrix) and then check that the description is stable under multiplication. Propagation needs the Cauchy and Binet expansion, which involves the non-principal minors $\det(A_{S,T})$ that the hypothesis says nothing about. Classification is the ideal route.

The first useful cue is the pair (invariant under permutation conjugation, must be closed under multiplication). Within thirty seconds you should have written the only family of matrices you know that is closed under multiplication, closed under passing to principal submatrices, and visibly nonsingular: the upper triangular matrices with 1 down the diagonal. That is the target normal form, and the whole problem becomes: show that over $\mathbb{F}_2$, very odd means permutation-conjugate to unitriangular.

Approaches, ranked worst to best

1. **Cauchy and Binet on A^2.** *Cue:* a minor of a product. *Circuit:* $\det\big((A^2)_{S,S}\big) = \sum_T \det(A_{S,T}) \det(A_{T,S})$ over all T with $|T| = |S|$. (Why worst: the identity is correct and the term $T = S$ contributes $\det(A_{S,S})^2 = 1$ modulo 2, which looks encouraging for about ten seconds. Then you notice that the hypothesis controls only the principal minors $\det(A_{T,T})$, while the sum involves the mixed minors $\det(A_{S,T})$ with $S \ne T$, about which you know nothing and for which no pairing or cancellation exists. This route is a dead end, and it is worth ten seconds precisely so that you learn what the hypothesis does not give you.)
2. **Induct on k through $A^k = A^{k-1}A$.** *Cue:* the conclusion is a statement for all k. *Circuit:* propagate the minor condition one factor at a time. (Why second worst: identical obstruction, since one factor still requires mixed minors. The failure is structural, not a matter of effort.)
3. **Unipotence.** *Cue:* a conjugation-invariant condition preserved by powers. *Circuit:* show $\bar{A} + I$ is nilpotent, which is preserved under multiplication. (Why third: this is the nearest wrong idea and the most instructive. Unipotence really is preserved by powers, and every very odd matrix is unipotent. But unipotence is strictly weaker than very odd: over $\mathbb{F}_2$ the matrix $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ equals $I + N$ with $N = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$ and $N^2 = 0$, so it is unipotent, yet its

$(1,1)$ entry is 0 and it is not very odd. A conjugation invariant is too coarse; you need a permutation-conjugation invariant.)

4. **Classify very odd matrices over $\mathbb{F}_2$.** *Cue:* the condition is invariant under permutation conjugation and must be closed under multiplication. *Circuit:* very odd if and only if permutation-conjugate to unitriangular; encode the support as a digraph and prove it is acyclic. (Why best: once the classification is in hand the theorem is one line, because unitriangular matrices are closed under multiplication and every principal submatrix of one is again unitriangular. The classification itself costs a minimal-cycle argument and a topological ordering, both short.)

The ideal solution

Throughout, bars denote reduction modulo 2, and we work over the field $\mathbb{F}_2$. Since the determinant is a polynomial with integer coefficients in the entries, $\det(M)$ is odd if and only if $\det(\bar{M}) \neq 0$ in $\mathbb{F}_2$; and since reduction is a ring homomorphism, $\overline{A^k} = \bar{A}^k$. So it suffices to prove: if every principal submatrix of a matrix over $\mathbb{F}_2$ is nonsingular, the same holds for all its powers. Call such a matrix *very odd* over $\mathbb{F}_2$, and call a matrix *unitriangular* if it is upper triangular with every diagonal entry equal to 1.

For a permutation σ of $\{1,\dots,n\}$ let P_σ be the permutation matrix with $(P_\sigma)_{ij} = 1$ exactly when $i = \sigma(j)$; a direct computation gives $(P_\sigma^{-1} A P_\sigma)_{ij} = a_{\sigma(i)\sigma(j)}$.

Lemma 5.11.1. *For every σ and every nonempty S, $\det\big((P_\sigma^{-1} A P_\sigma)_S\big) = \det\big(A_{\sigma(S)}\big)$. In particular A is very odd if and only if $P_\sigma^{-1} A P_\sigma$ is.*

Proof. The submatrix of $(a_{\sigma(i)\sigma(j)})$ indexed by S has entries $a_{\sigma(i)\sigma(j)}$ for $i, j \in S$, which is the submatrix of A indexed by $\sigma(S)$ after applying the same bijection $S \to \sigma(S)$ to its rows and to its columns. Permuting rows and columns by the same permutation multiplies the determinant by the square of a sign, hence leaves it unchanged. □

Lemma 5.11.2. *If U is unitriangular then U^k is unitriangular for every $k \geq 1$, and every unitriangular matrix is very odd.*

Proof. A product of upper triangular matrices is upper triangular and its diagonal is the entrywise product of the diagonals, so U^k is unitriangular. If $S = \{i_1 < \cdots < i_r\}$ then $(U^k)_S$ is upper triangular with diagonal entries 1, because the ordering inherited from $\{1,\dots,n\}$ is the same one; hence $\det\big((U^k)_S\big) = 1 \neq 0$. □

Lemma 5.11.3. *If A is very odd over $\mathbb{F}_2$ then there is a permutation σ for which $P_\sigma^{-1} A P_\sigma$ is unitriangular.*

Proof. Taking $S = \{i\}$ gives $a_{ii} = 1$ for every i. Let G be the loopless directed graph on the vertex set $\{1,\dots,n\}$ with an edge $i \to j$ exactly when $i \neq j$ and $a_{ij} = 1$.

G has no directed cycle. Suppose it has one, and choose a directed cycle $i_1 \to i_2 \to \cdots \to i_M \to i_1$ of minimal length M. Since G is loopless, $M \geq 2$, and the vertices $i_1,\dots,i_M$ are distinct: a repetition $i_a = i_b$ with $a < b$ would produce a closed directed walk of length $b-a$ with $2 \leq b-a < M$, contradicting minimality. Minimality also forbids chords. Precisely, suppose $a_{i_j i_k} = 1$ with $k \not\equiv j$ and $k \not\equiv j+1 \pmod{M}$. Then the edge $i_j \to i_k$ followed by the arcs of the cycle from i_k round to i_j is a directed cycle of length $1 + \big((j-k) \bmod M\big)$, and the hypotheses on k give $1 \leq (j-k) \bmod M \leq M-2$, so this cycle has length at least 2 and at most $M-1$, contradicting minimality. Together with $a_{ii} = 1$ we conclude, for the principal submatrix B of A on $S = \{i_1,\dots,i_M\}$ with rows and columns listed in the cyclic order,

$$b_{jk} = \begin{cases} 1, & k \equiv j \text{ or } k \equiv j+1 \pmod{M}, \\ 0, & \text{otherwise.} \end{cases}$$

Every row of B then has an even number of entries equal to 1: exactly two when $M \geq 3$, and for $M = 2$ every entry is 1, so again two. Hence $B\mathbf{1} = \mathbf{0}$ over $\mathbb{F}_2$, where $\mathbf{1}$ is the all-ones column, so $\det B = 0$. This contradicts very oddness, so G is acyclic.

An acyclic digraph has a topological ordering. This is the standard fact about directed acyclic graphs, and it has a two-line proof. A finite acyclic digraph has a vertex with no incoming edge: take a directed path of maximal length and let v be its initial vertex; an edge $u \to v$ would close a cycle if u lay on the path, and would otherwise lengthen the path, and both are impossible. Delete v and induct on the number of vertices, obtaining a listing $v_1, \ldots, v_n$ of the vertices such that every edge $v_i \to v_j$ has $i < j$.

Let $\sigma(i) = v_i$ and $U = P_\sigma^{-1} A P_\sigma$, so $u_{ij} = a_{v_i v_j}$. If $i > j$ then $a_{v_i v_j} = 1$ would be an edge $v_i \to v_j$ against the ordering, so $u_{ij} = 0$; and $u_{ii} = a_{v_i v_i} = 1$. Thus U is unitriangular. □

Theorem 5.11.4. *If A is very odd then A^k is very odd for every $k \geq 1$.*

Proof. Reduce modulo 2; then $\bar{A}$ is very odd over $\mathbb{F}_2$. By Lemma 3 there is a permutation σ with $U = P_\sigma^{-1} \bar{A} P_\sigma$ unitriangular. Then $P_\sigma^{-1} \bar{A}^k P_\sigma = U^k$, which is unitriangular by Lemma 2 and therefore very odd; by Lemma 1, $\bar{A}^k = \overline{A^k}$ is very odd. Hence every principal minor of A^k is odd. □

Remark. Two features are sharp. The condition really needs all subsets, not the small ones: the $n \times n$ circulant with first row $(1, 1, 0, \ldots, 0)$ has every proper principal minor odd but even determinant, because its digraph is a single n-cycle. And parity, not nonvanishing, is what is closed under powers: over $\mathbb{Q}$ the matrix $\begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$ has all principal minors nonzero, yet its square $\begin{pmatrix} 0 & 2 \\ -2 & 0 \end{pmatrix}$ has vanishing diagonal entries. That matrix has det $= 2$, so it is not very odd, and the example shows the reduction modulo 2 is doing real work rather than being a convenience.

Layer 1: WHAT

Block 1: read "odd determinant" as "invertible over $\mathbb{F}_2$" and move the entire problem there. Block 2: read "for every nonempty subset" as "invariant under permutation conjugation", which tells you which normal forms are legitimate. Block 3: choose the target normal form by asking what family is closed under multiplication, closed under principal submatrices, and visibly nonsingular; unitriangular is the unique cheap answer. Block 4: prove the easy direction, that unitriangular is very odd and stays unitriangular under powers. Block 5: encode A as a digraph on its off-diagonal support, having first noted $a_{ii} = 1$. Block 6: show a minimal directed cycle would give a principal submatrix whose rows all have even weight, hence singular. Block 7: acyclic gives a topological order, which is exactly a relabelling making A unitriangular. Block 8: assemble.

Juxtaposition. The nominal route reduces modulo 2 and then asks for $\det\big((A^2)_S\big)$ in terms of the minors of A, reaching for Cauchy and Binet. It fails because the hypothesis is about principal minors only and the expansion introduces mixed minors.

The bifurcation point is the sentence right after the reduction to $\mathbb{F}_2$. The zombie asks "what is a principal minor of A^k?". You ask "what does a very odd matrix look like?". In one phrase: when a property is claimed to be closed under an operation, classify the property instead of propagating it.

Layer 2: HOW

Block 1. Cue. The word "odd" applied to a determinant of an integer matrix. **Why natural.** Determinant is a polynomial with integer coefficients in the entries, so it commutes with any ring homomorphism, in particular with reduction modulo 2; and reduction is multiplicative, so it commutes with taking powers. Nothing about the problem is lost and the coefficient ring becomes a field with exactly one nonzero element, which turns every linear algebra statement into a statement

about the $0/1$ pattern. **Link to the next block.** Over $\mathbb{F}_2$ the hypothesis reads: every principal submatrix is nonsingular.

Block 2. Cue. "For every nonempty subset S", rather than for initial segments. **Why natural.** Simultaneously permuting the rows and the columns permutes the family of principal submatrices among themselves and preserves each determinant, because the sign of the permutation appears twice. So the hypothesis and the conclusion are invariants of A up to conjugation by a permutation matrix, and any normal form you aim for is allowed to use exactly that freedom and no more. This is also why the third-ranked approach fails: unipotence is invariant under all conjugations, so it cannot see the extra information carried by the index labels. **Link to the next block.** The target must be a normal form under permutation conjugation.

Block 3. Cue. The conclusion is about all powers. **Why natural.** You need a family $\mathcal{F}$ of matrices, stable under multiplication, each of whose members is very odd, and containing every very odd matrix. Stability under multiplication plus closure under principal submatrices plus visible nonsingularity is a demanding list, and there is exactly one standard family that meets it: upper triangular with unit diagonal. This is a lookup from your stock of matrix families, not a discovery. **Link to the next block.** Half of the classification, that unitriangular implies very odd and stays so under powers, is now immediate; the work is in the converse.

Block 4. Cue. $S = \{i\}$ is a legal subset. **Why natural.** The smallest instances of a hypothesis quantified over all subsets are always the first thing to extract, and here they give the diagonal outright: $a_{ii} = 1$ for every i. That is precisely the diagonal condition of unitriangularity, so what remains is only to arrange the off-diagonal zeros by relabelling. **Link to the next block.** The off-diagonal support is now the only unknown, and a $0/1$ pattern on ordered pairs is a directed graph.

Block 5. Cue. A $0/1$ matrix over $\mathbb{F}_2$ with a distinguished diagonal. **Why natural.** Encode the off-diagonal ones as edges. Under this dictionary a principal submatrix is an induced subgraph, so the hypothesis becomes a statement about every induced subgraph, and the target (unitriangular after relabelling) becomes exactly the statement that the digraph admits a topological ordering. Translating a linear algebra hypothesis into graph language is worthwhile precisely when the hypothesis is closed under passing to induced substructures. **Link to the next block.** You now need: no directed cycles.

Block 6. Cue. A cycle is the smallest obstruction to an ordering, so test cycles first. **Why natural.** Take a shortest cycle, because minimality is what forces the induced submatrix to be exactly the cyclic pattern with no chords. Then every row has exactly two ones (and for $M = 2$ the two coincide with the whole row), so the all-ones vector lies in the kernel over $\mathbb{F}_2$. Over $\mathbb{F}_2$ "all rows have even weight" is the cheapest singularity certificate in existence, and you should reach for it whenever a $0/1$ matrix has a regular pattern. **Link to the next block.** Acyclicity established.

Block 7. Cue. Acyclic finite digraph. **Why natural.** Every finite acyclic digraph has a vertex of indegree zero, found at the start of a maximal path, and deleting it preserves acyclicity; induction produces a listing along which all edges point forwards. That listing is a permutation σ, and $P_\sigma^{-1} A P_\sigma$ has zeros strictly below the diagonal by construction. **Link to the next block.** Combine with the easy direction to finish.

Layer 3: WHY

The truth beneath the route is a structure theorem: over $\mathbb{F}_2$, a matrix has all principal minors nonzero if and only if it is conjugate by a permutation matrix to a unitriangular matrix. The reason such a clean classification exists is that over $\mathbb{F}_2$ a matrix is nothing but its support, so a determinant condition becomes a combinatorial condition, and the combinatorial condition is exactly acyclicity of the support digraph. Over any larger field the classification collapses. The rational matrix $\begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$ has all principal minors nonzero yet is not permutation-triangularisable, and its square has vanishing diagonal entries, so the analogous statement over $\mathbb{Q}$ is false. That single example is the best possible argument that the reduction modulo 2 is the substance of the problem and not a convenience.

The second truth is about strategy. There are two ways to prove that a property is preserved by an operation. Propagation asks how the property transforms, and needs a formula relating the invariants of A^k to those of A. Classification describes the set of objects with the property and then checks the set is closed. Propagation is the default reflex and it is correct when the invariant has an addition formula (traces, ranks, characteristic polynomials). It is hopeless when the hypothesis constrains only part of a family of invariants, as here: the principal minors of a product involve non-principal minors of the factors, which are unconstrained. Learn to detect that mismatch early; it is what sends you to classification.

The discernment mechanism, stated as a test you can run in the arena: write down the group of transformations under which the hypothesis is invariant. If that group is the full conjugation group, look for eigenvalue or characteristic polynomial invariants. If it is only the permutation subgroup, then the labels carry information and you should look for a combinatorial encoding, almost always a graph. Here the quantifier over all subsets S is what pins the group down to permutations, so the graph is announced by the statement itself.

How to train it. Take every hypothesis of the form "for every subset" and immediately extract the singletons, then the pairs, then ask what structure on the index set the hypothesis describes. Singletons gave the diagonal; the pairs give that no 2-cycle occurs, since $\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}$ is singular; the general case is the cycle argument. The problem is built so that the small cases point straight at the general one.

What the examiners nudged with. They chose the word "odd" rather than "nonzero", which is the whole reduction. They quantified over all nonempty subsets rather than initial segments, which is what makes permutation conjugation the right symmetry and rules out the leading-minor conditions of LU factorisation. They asked for all $k \geq 1$ rather than $k = 2$, so that a propagation argument tuned to squares would not be enough and you would be pushed towards a normal form. And they named the property with a nonsense phrase, "very odd", to stop you searching your memory for a theorem and to force you to classify from scratch.

Revolving concepts

Reduction modulo a prime. For any ring homomorphism φ, $\varphi(\det M) = \det(\varphi M)$ and $\varphi(MN) = \varphi(M)\varphi(N)$, since both determinant and product are polynomial in the entries. Hence integer statements about parity of determinants are statements of linear algebra over $\mathbb{F}_2$. See Book 1, field: Matrices and determinants, topic: determinants over rings and reduction.

Principal versus leading principal minors. All leading principal minors nonzero is equivalent to the existence of an LU factorisation without pivoting; all principal minors nonzero is a strictly different and permutation-invariant condition. Confusing the two is the standard error here. See Book 1, field: Linear algebra, topic: LU factorisation and minors.

Cauchy and Binet. For $|S| = |T| = r$, $\det\big((MN)_{S,T}\big) = \sum_{|R|=r} \det(M_{S,R}) \det(N_{R,T})$. It is the correct tool when you know all minors of the factors, and the wrong tool when you know only the

principal ones. See Book 1, field: Matrices and determinants, topic: Cauchy and Binet formula.

Triangular matrices. Upper triangular matrices are closed under products and the diagonal multiplies entrywise; principal submatrices of an upper triangular matrix are upper triangular in the inherited order; U unitriangular means $U - I$ is strictly upper triangular, hence nilpotent with $(U - I)^n = 0$, so $U^k = \sum_{j=0}^{n-1} \binom{k}{j} (U - I)^j$ is a finite sum. See Book 1, field: Linear algebra, topic: triangular and unipotent matrices.

Even weight rows over $\mathbb{F}_2$. If every row of a matrix over $\mathbb{F}_2$ has an even number of ones, the all-ones vector is in the kernel and the determinant is zero. The circulant with first row $(1, 1, 0, \ldots, 0)$ is the canonical example: even determinant, all proper principal minors odd. See Book 1, field: Discrete structures and graphs, topic: parity arguments over $\mathbb{F}_2$.

Digraphs, cycles and topological order. A finite directed graph is acyclic if and only if its vertices admit a linear ordering along which every edge points forwards. The proof is the peeling induction: an acyclic finite digraph has a vertex of indegree zero (the start of a maximal path), delete and recurse. See Book 1, field: Discrete structures and graphs, topic: directed acyclic graphs.

The generalised recursion. The peeling induction above is the general template for finite ordered structures and deserves to be stored in its abstract form: every finite strict partial order extends to a linear order, proved by repeatedly extracting a minimal element. The same induction proves that a finite nilpotent-plus-identity pattern can be triangularised, that a finite acyclic dependency graph can be evaluated in order, and that any well-founded recursion on a finite set terminates. Whenever you must convert "no cycles" into "there is an order", this is the induction to write.

Circuit Bank

- **WHEN** you see a parity condition on determinants of integer matrices **DO** reduce the entire problem modulo 2 and work over $\mathbb{F}_2$ **BECAUSE** determinant and product are polynomial in the entries, so they commute with reduction, and over $\mathbb{F}_2$ a matrix is determined by its support, turning linear algebra into combinatorics
- **WHEN** you are asked to show a property is preserved by an operation and the hypothesis constrains only part of a family of invariants **DO** classify the objects with the property instead of propagating the property through the operation **BECAUSE** propagation needs a formula expressing the invariants of the image in terms of those of the source, and here the minors of a product involve non-principal minors that the hypothesis does not control
- **WHEN** a hypothesis is quantified over every subset of the index set **DO** note that the hypothesis is invariant under simultaneous permutation of rows and columns, and look for a normal form up to permutation conjugation, hence for a combinatorial encoding **BECAUSE** a full conjugation invariant such as unipotence is too coarse; the labels carry information and the natural carrier of labelled information is a graph
- **WHEN** you have a $0/1$ matrix over $\mathbb{F}_2$ with a regular pattern **DO** check the parity of the row weights; if every row has even weight, the all-ones vector is a kernel certificate **BECAUSE** it is the shortest possible singularity proof over $\mathbb{F}_2$ and it is exactly what a directed cycle produces
- **WHEN** you must convert "no cycles" into "there is an ordering" **DO** peel a vertex of indegree zero, found at the start of a maximal directed path, and induct **BECAUSE** acyclicity is preserved by deletion, and a maximal path cannot be extended or closed, so its initial vertex has no incoming edge

Backtesting

1. First useful cue: "odd determinant" for integer matrices, which is $\mathbb{F}_2$; then "every nonempty subset", which is permutation-conjugation invariance.

2. Method the expression suggested: classify very odd matrices as the permutation conjugates of unitriangular matrices, then note that unitriangularity is closed under powers.
3. Where you would hesitate, and the thought to reinforce: after the reduction you will want to compute a minor of A^2. Reinforce this: check first whether the hypothesis controls the objects the expansion produces. It does not, so classify instead.
4. The trap the question sets: settling for unipotence, which is preserved by powers and is implied by the hypothesis, but is strictly weaker, as $\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$ over $\mathbb{F}_2$ shows. A second trap is verifying only small subsets S; the circulant with first row $(1, 1, 0, \ldots, 0)$ has all proper principal minors odd and even determinant.
5. What makes you recognise it faster next time: a determinant condition over $\mathbb{F}_2$ indexed by subsets is a statement about induced subgraphs of the support digraph. Whenever both are present, draw the graph.
6. The reusable decision rule: closure statements are proved by classification when the hypothesis is a normal form condition, and by propagation only when the invariant has a genuine addition or multiplication formula.

Mirror drills

1. Show that a square matrix over $\mathbb{F}_2$ in which every row has an even number of entries equal to 1 is singular. *Answer:* the all-ones column vector lies in the kernel, since each coordinate of the product is the row sum modulo 2.
2. Show that the $n \times n$ circulant C with $c_{ij} = 1$ exactly when $j - i \equiv 0$ or $1 \pmod{n}$ has even determinant, while every proper principal minor of C is odd. *Answer:* every row has weight 2, so $\det C \equiv 0$; deleting any index breaks the single n-cycle of the support digraph, leaving a disjoint union of directed paths, which is acyclic, so the induced submatrix is permutation-conjugate to unitriangular and has odd determinant.
3. Exhibit an integer matrix all of whose principal minors are nonzero but for which some principal minor of A^2 vanishes, and say why the problem is not contradicted. *Answer:* $A = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}$ has principal minors $1, 1, 2$ and $A^2 = \begin{pmatrix} 0 & 2 \\ -2 & 0 \end{pmatrix}$ has zero diagonal. No contradiction: $\det A = 2$ is even, so A is not very odd. Parity, not nonvanishing, is the property that is closed under powers.

5.12 B6. Iterated median trimming and quantile coupling

Given an ordered list of $3N$ real numbers, we can trim *it to form a list of N numbers as follows: We divide the list into N groups of 3 consecutive numbers, and within each group, discard the highest and lowest numbers, keeping only the median.*

Consider generating a random number X by the following procedure: Start with a list of 3^{2021} numbers, drawn independently and uniformly at random between 0 and 1. Then trim this list as defined above, leaving a list of 3^{2020} numbers. Then trim again repeatedly until just one number remains; let X be this number. Let μ be the expected value of $\left|X - \frac{1}{2}\right|$. Show that

$$\mu \geq \frac{1}{4}\left(\frac{2}{3}\right)^{2021}.$$

Read it out loud

Strip the story. The list is a complete ternary tree of depth 2021: the leaves are independent uniforms, every internal node is the median of its three children, and X is the root. Because the triples are disjoint and the leaves independent, the numbers at any fixed level are independent and identically distributed. So the state of the process is not a random variable, it is a distribution, and each round is a deterministic map on distributions: the distribution of the median of three independent copies.

The fields wired in are order statistics (the law of the median of three), iterated maps of an interval and their fixed points, the quantile transform and monotone coupling, and one elementary calculus inequality. What is really being tested is whether you can turn a recursion on distributions into a recursion on a single number. Everything else in the problem is bookkeeping.

The first cue is that the operation is the same at every level and the inputs at every level are independent and identically distributed, so within thirty seconds you should have written the cdf recursion. If Y_1, Y_2, Y_3 are independent with common cdf F then their median is at most x exactly when at least two of the three are, so the median has cdf

$$3F^2(1-F) + F^3 = 3F^2 - 2F^3 = \phi(F), \qquad \phi(u) = 3u^2 - 2u^3.$$

Therefore the cdf after k rounds is $F_k = \phi^{\circ k}$, the k-fold iterate of one cubic, applied to $F_0(x) = x$.

The second cue is in the constants the question hands you, and this is the part almost nobody reads. $\frac{1}{4}$ is $E\left|U - \frac{1}{2}\right|$ for a uniform U, that is, μ_0. And ϕ fixes $\frac{1}{2}$ with $\phi'(\frac{1}{2}) = 6 \cdot \frac{1}{2} - 6 \cdot \frac{1}{4} = \frac{3}{2}$, so $\frac{2}{3} = 1/\phi'(\frac{1}{2})$. The inequality you are asked to prove is precisely

$$\mu_{2021} \;\geq\; \mu_0 \cdot \Big(\frac{1}{\phi'(1/2)}\Big)^{2021},$$

which announces both the method (one round at a time, losing at most the factor $1/\phi'(\frac{1}{2})$ each time) and the reason it is true (the multiplier of the iterated map at its unstable fixed point is the fastest possible rate of concentration). Read the constants; they are the statement of the lemma you must prove.

A caveat worth clarifying. Trimming concentrates: $\phi(u) < u$ on $(0, \frac{1}{2})$, so F_k decreases there and X_k moves towards $\frac{1}{2}$. The problem asks you to prove concentration is not too fast, which is a lower bound on a shrinking quantity, and lower bounds on shrinking quantities are where sloppy arguments die.

Approaches, ranked worst to best

1. **Compute F_k explicitly.** *Cue:* $F_k = \phi^{\circ k}$ is a polynomial. *Circuit:* iterate the cubic and estimate. (Why worst: $\phi^{\circ k}$ has degree 3^k, so for $k = 2021$ there is no expression to write down, and the coefficients carry no usable structure. This is zombie computation dressed as a plan.)

2. **Moment recursion.** *Cue:* bound $E\big[(X_k - \frac{1}{2})^2\big]$ and convert. *Circuit:* variance shrinks by a computable factor. (Why second worst: the moments of a median are not determined by the moments of the input, so there is no closed recursion; and even with a bound on the second moment you would need a reverse inequality such as Paley and Zygmund to descend to $E|X_k - \frac{1}{2}|$, because Cauchy and Schwarz points the wrong way.)
3. **Density comparison against a box.** *Cue:* $f_k(\frac{1}{2}) = (\frac{3}{2})^k$ and f_k is nondecreasing on $[0, \frac{1}{2}]$. *Circuit:* compare f_k with the density that is $(\frac{3}{2})^k$ on an interval of length $\frac{1}{2}(\frac{2}{3})^k$ and zero elsewhere, then integrate by parts. (Why third: correct, and it is the second official solution. But it needs a separate induction proving f_k nondecreasing on $[0, \frac{1}{2}]$, plus a rearrangement style comparison of two densities with the same total mass. Three moving parts where one suffices.)
4. **Cumulative distribution with the axes transposed.** *Cue:* $\mu_k = 2\int_0^{1/2} F_k$ by parts, and the area under a monotone curve equals the area to the left of its inverse. *Circuit:* turn μ_k into $2\int_0^{1/2}(\frac{1}{2} - F_k^{-1}(y))\,dy$ and iterate. (Why second: correct, and it is the first official solution. It contains the right idea, namely that the iteration must be moved into the argument, but it hides that idea inside an area transposition instead of naming it.)
5. **Quantile coupling.** *Cue:* a recursion on distributions with a monotone map. *Circuit:* realise every X_k on one probability space as $\psi^{\circ k}(U)$ with $\psi = \phi^{-1}$, so the distributional recursion becomes a pointwise one. (Why best: the distributional recursion becomes an identity between random variables, the required inequality becomes one calculus check on ψ, and taking expectations is free. Nothing needs to be interchanged, integrated by parts, or induced separately.)

The ideal solution

Write $\phi(u) = 3u^2 - 2u^3$ for $u \in [0,1]$.

Step 1: the model. For $k \geq 0$ let X_k be the number that survives when the trimming procedure is applied repeatedly to a list of 3^k independent uniform variables on $[0,1]$, so that $X = X_{2021}$, and put $\mu_k = E\big|X_k - \frac{1}{2}\big|$, so that $\mu = \mu_{2021}$. Let F_k be the cumulative distribution function of X_k; thus $F_0(x) = x$ on $[0,1]$.

If Y_1, Y_2, Y_3 are independent with common cdf F, their median is at most x if and only if at least two of them are, so its cdf is $3F(x)^2\big(1 - F(x)\big) + F(x)^3 = \phi\big(F(x)\big)$. After one round of trimming, the 3^{k-1} surviving numbers are medians of pairwise disjoint triples of independent variables, hence are themselves independent and identically distributed with cdf $\phi \circ F_0$. Applying this at every level,

$$F_k = \phi \circ F_{k-1}, \qquad \text{so} \qquad F_k = \phi^{\circ k} \text{ on } [0,1].$$

Step 2: properties of ϕ. On $[0,1]$ we have $\phi'(u) = 6u(1-u) \geq 0$, with strict positivity on $(0,1)$, and $\phi(0) = 0$, $\phi(1) = 1$. Hence $\phi : [0,1] \to [0,1]$ is a continuous, strictly increasing bijection. Also

$$\phi(1-u) = 3(1-u)^2 - 2(1-u)^3 = 1 - 3u^2 + 2u^3 = 1 - \phi(u),$$

so $\phi\big(\frac{1}{2}\big) = \frac{1}{2}$ and ϕ maps $[0, \frac{1}{2}]$ onto itself. Consequently each $F_k = \phi^{\circ k}$ is a continuous strictly increasing bijection of $[0,1]$ with $F_k(1-x) = 1 - F_k(x)$ and $F_k(\frac{1}{2}) = \frac{1}{2}$.

Let $\psi = \phi^{-1} : [0,1] \to [0,1]$, again a continuous strictly increasing bijection, with $\psi(\frac{1}{2}) = \frac{1}{2}$ and $\psi(1-u) = 1 - \psi(u)$ (apply ψ to the displayed symmetry of ϕ).

Step 3: the coupling. Let U be uniform on $[0,1]$ and set $Y_k = \psi^{\circ k}(U)$, so $Y_0 = U$ and $Y_k = \psi(Y_{k-1})$. Since F_k is a continuous strictly increasing bijection of $[0,1]$ and $\psi^{\circ k} = F_k^{-1}$,

$$P(Y_k \leq x) = P\big(U \leq F_k(x)\big) = F_k(x),$$

so Y_k has the same distribution as X_k, and in particular $\mu_k = E\big|Y_k - \frac{1}{2}\big|$. The point of this construction is that the recursion, which was a relation between distributions, is now an identity between random variables on one probability space.

Step 4: the key inequality. We claim that

$$\left|\psi(u)-\tfrac12\right| \;\ge\; \tfrac23\left|u-\tfrac12\right| \qquad \text{for all } u\in[0,1].$$

By the symmetry $\psi(1-u)=1-\psi(u)$ both sides are unchanged under $u\mapsto 1-u$, so it suffices to prove it for $u\in[0,\tfrac12]$, where $\psi(u)\le\tfrac12$ and the claim reads $\tfrac12-\psi(u)\ge\tfrac23\big(\tfrac12-u\big)$. Since ϕ maps $[0,\tfrac12]$ bijectively onto itself, write $u=\phi(x)$ with $x=\psi(u)\in[0,\tfrac12]$; the claim becomes

$$\tfrac12-x \;\ge\; \tfrac23\Big(\tfrac12-\phi(x)\Big), \qquad \text{that is} \qquad \tfrac12-\phi(x) \;\le\; \tfrac32\Big(\tfrac12-x\Big) \quad (x\in[0,\tfrac12]).$$

Put $g(x)=\tfrac32\big(\tfrac12-x\big)-\big(\tfrac12-\phi(x)\big)$. Then $g(\tfrac12)=0$ and

$$g'(x)=-\tfrac32+\phi'(x)=-\tfrac32+6x-6x^2=-\tfrac32\big(1-2x\big)^2 \;\le\; 0,$$

so g is nonincreasing on $[0,\tfrac12]$ and therefore $g(x)\ge g(\tfrac12)=0$ there. This proves the claim.

Step 5: iterate and take expectations. By Step 3 and Step 4, pointwise on the probability space,

$$\left|Y_k-\tfrac12\right| = \left|\psi(Y_{k-1})-\tfrac12\right| \;\ge\; \tfrac23\left|Y_{k-1}-\tfrac12\right|,$$

so by induction $\big|Y_k-\tfrac12\big|\ge\big(\tfrac23\big)^k\big|U-\tfrac12\big|$ for every $k\ge0$. Taking expectations and using $E\big|U-\tfrac12\big| = \int_0^1\big|u-\tfrac12\big|\,du=\tfrac14$,

$$\mu_k = E\left|Y_k-\tfrac12\right| \;\ge\; \left(\tfrac23\right)^k\cdot\tfrac14.$$

Taking $k=2021$ gives $\mu\ge\tfrac14\big(\tfrac23\big)^{2021}$, as required. ■

Remark on sharpness. The only loss is the inequality $\phi'\le\phi'(\tfrac12)$ on $[0,\tfrac12]$, which is an equality only at the fixed point, so the exponential rate is exactly right and only a bounded constant is given away: numerically $\mu_k/\big(\tfrac14(\tfrac23)^k\big)$ increases from 1 and settles near 1.28. For comparison, the exact median of the whole list of $n=3^{2021}$ numbers has $E\big|\mathrm{med}-\tfrac12\big|$ of order $n^{-1/2}=(1/\sqrt3)^{2021}\approx(0.577)^{2021}$, which is much smaller than $(2/3)^{2021}$. Local trimming is genuinely worse than global median taking, and the problem is asking you to quantify how much information the greedy procedure throws away.

Layer 1: WHAT

Block 1: read the process as a complete ternary tree, so that the numbers at each level are independent and identically distributed and the state is a distribution. Block 2: compute the one-round map on cumulative distribution functions, $F\mapsto\phi\circ F$ with $\phi(u)=3u^2-2u^3$, from the order statistics of three. Block 3: read the constants of the problem, $\tfrac14=\mu_0$ and $\tfrac23=1/\phi'(\tfrac12)$, and conclude that the target is $\mu_k\ge\tfrac23\mu_{k-1}$. Block 4: note that ϕ is an increasing bijection fixing $\tfrac12$ and symmetric about it, so $\psi=\phi^{-1}$ exists with the same properties. Block 5: couple, that is, realise every X_k as $\psi^{\circ k}(U)$ for a single uniform U, turning the distributional recursion into $Y_k=\psi(Y_{k-1})$. Block 6: prove $\big|\psi(u)-\tfrac12\big|\ge\tfrac23\big|u-\tfrac12\big|$ by one derivative computation. Block 7: iterate pointwise and take expectations.

Juxtaposition. The nominal route stops at Block 3 with $F_k=\phi\circ F_{k-1}$, writes $\mu_k=2\int_0^{1/2}F_k(x)\,dx$, and then tries to bound $\int_0^{1/2}\phi\big(F_{k-1}\big)$ from below by $\tfrac23\int_0^{1/2}F_{k-1}$. The pointwise sufficient condition for that would be $\phi(u)\ge\tfrac23u$ on $[0,\tfrac12]$, and that is simply false: near $u=0$ one has $\phi(u)\approx3u^2$, which is far below $\tfrac23u$. In fact $\phi(u)\ge\tfrac23u$ only for $u\ge\frac{3-\sqrt{11/3}}{4}\approx0.271$. So the nominal route does not merely cost more ink, it cannot work.

The bifurcation point is the sentence after $F_k=\phi\circ F_{k-1}$. The composition sits on the outside, acting on the values of the cdf, and an integral of a composed function is not controlled from below by the integral of the inner function. You must move the iteration into the argument. The device that does exactly that is the inverse function, since $\big(\phi\circ F\big)^{-1}=F^{-1}\circ\phi^{-1}$, and the probabilistic name of the inverse cdf is the quantile function.

Layer 2: HOW

Block 1. **Cue.** The same operation is applied at every stage to disjoint triples. **Why natural.** Functions of disjoint families of independent variables are independent, so at every level the surviving numbers are independent, and by symmetry identically distributed. That is the only reason a one-variable recursion exists at all; if the triples overlapped, the level would carry correlations and no scalar recursion would close. **Link to the next block.** The state of the process is one distribution, so find the map that advances it.

Block 2. **Cue.** "Median of three". **Why natural.** The distribution of an order statistic of independent identically distributed variables is a function of the common cdf alone. For the median of three, "median at most x" means "at least two of the three are at most x", giving $3F^2(1-F)+F^3 = 3F^2-2F^3$. Working with the cdf rather than the density is deliberate: the cdf turns a counting event into a polynomial and gives you a map ϕ that does not involve x at all. **Link to the next block.** The recursion is $F_k = \phi \circ F_{k-1}$, so F_k is the k-th iterate of one cubic.

Block 3. **Cue.** The two constants in the inequality you are asked to prove. **Why natural.** $\frac{1}{4}$ is $E\left|U-\frac{1}{2}\right|$, the value of the quantity at $k=0$. So the inequality is an iteration of a single step, and the single step must lose exactly the factor $\frac{2}{3}$. Now compute $\phi'(\frac{1}{2}) = \frac{3}{2}$: the factor is the reciprocal of the multiplier of ϕ at its interior fixed point. Nothing about this is a guess; a problem that hands you μ_0 and $1/\phi'(\text{fixed point})$ is telling you the lemma. **Link to the next block.** You must prove $\mu_k \geq \frac{2}{3}\mu_{k-1}$, and you must do it without integrating a composed cdf.

Block 4. **Cue.** ϕ is strictly increasing on $[0,1]$ with $\phi(1-u) = 1-\phi(u)$. **Why natural.** Monotonicity is what allows inversion, and the symmetry is what makes $\frac{1}{2}$ a fixed point and lets you reduce every statement to $[0,\frac{1}{2}]$. Both facts are one line each and both are used twice, so extract them before starting. **Link to the next block.** $\psi = \phi^{-1}$ exists and inherits both properties.

Block 5. **Cue.** A recursion between distributions that you need to iterate as an inequality. **Why natural.** Inequalities iterate cleanly between numbers, not between measures. The quantile transform realises every member of the family on one probability space: if F is a continuous strictly increasing cdf and U is uniform, then $F^{-1}(U)$ has cdf F. Applying it to every F_k with the same U gives a monotone coupling, and because $F_k^{-1} = \left(\phi^{\circ k}\right)^{-1} = \psi^{\circ k}$, the outer composition on cdfs has become an inner composition on quantiles. This is the whole solution in one move. **Link to the next block.** The recursion is now the pointwise identity $Y_k = \psi(Y_{k-1})$, and any pointwise bound on ψ will iterate.

Block 6. **Cue.** You need $\left|\psi(u)-\frac{1}{2}\right| \geq \frac{2}{3}\left|u-\frac{1}{2}\right|$, that is, ψ does not contract distance to $\frac{1}{2}$ by more than $\frac{2}{3}$. **Why natural.** Rewriting in terms of ϕ, this says ϕ does not expand distance to $\frac{1}{2}$ by more than $\frac{3}{2}$, which is exactly the mean value theorem statement $\phi' \leq \phi'(\frac{1}{2})$ on $[0,\frac{1}{2}]$. And that is true because $\phi'(x) = 6x(1-x)$ is increasing on $[0,\frac{1}{2}]$. The clean way to write it is to show $g(x) = \frac{3}{2}\left(\frac{1}{2}-x\right) - \left(\frac{1}{2}-\phi(x)\right)$ vanishes at $x=\frac{1}{2}$ and has $g' = -\frac{3}{2}(1-2x)^2 \leq 0$, which also shows where the loss is: only at $x=\frac{1}{2}$ is the inequality tight. **Link to the next block.** A pointwise inequality on a coupled family iterates by induction and survives taking expectations.

Block 7. **Cue.** A pointwise almost sure inequality. **Why natural.** Expectation is monotone, so no interchange, no convergence theorem and no integration by parts is required. The last ingredient is $E\left|U-\frac{1}{2}\right| = \frac{1}{4}$, a one line integral. **Link to the next block.** Set $k = 2021$.

Layer 3: WHY

The mathematical truth beneath the route is a statement about iterated maps. The cdf map $\phi(u) = 3u^2 - 2u^3$ has three fixed points on $[0,1]$: 0 and 1 with multiplier $\phi' = 0$, and $\frac{1}{2}$ with multiplier $\phi'(\frac{1}{2}) = \frac{3}{2} > 1$. So $\frac{1}{2}$ is repelling for ϕ and attracting for $\psi = \phi^{-1}$, and the iterates $F_k = \phi^{\circ k}$ converge to the step function at $\frac{1}{2}$. In probabilistic language, $X_k \to \frac{1}{2}$ in probability, and the natural length scale of the distribution around $\frac{1}{2}$ shrinks by the factor $1/\phi'(\frac{1}{2}) = \frac{2}{3}$ per round. The problem asks you to prove that the scale shrinks by no more than that, and the reason it is true is that the multiplier at the fixed point is the largest value of ϕ' on $[0, \frac{1}{2}]$. This is why the constant $\frac{2}{3}$ is exactly right and not merely sufficient.

The second truth is about the mechanics of iterating inequalities. A recursion $F_k = \phi \circ F_{k-1}$ places the iteration in the value slot; a recursion $q_k = \psi \circ q_{k-1}$ places it in the argument slot, where $q_k = F_k^{-1}$. Functionals like $\int F$ respond well to changes in the argument and badly to changes in the value, so the correct move is to invert. The probabilistic name of that inversion is the quantile transform, and the correct name of what it buys you is a monotone coupling: one probability space carrying every X_k at once, ordered by a deterministic increasing map. Once the family is coupled, distributional statements become pointwise statements and every inequality you prove about the map is inherited by every expectation you care about.

The discernment mechanism, in the form you can run in the arena. First, when a random object is built by repeating one operation on independent copies, write the recursion at the level of cumulative distribution functions and never at the level of densities, because order statistics are polynomial in the cdf. Second, read the constants in the target inequality: if one of them is the value of the quantity at step zero, the target is an iterated one step lemma, and if another is a derivative of the recursion map at a fixed point, the one step lemma is a mean value theorem statement. Third, if the recursion composes on the outside and you must iterate an inequality, invert.

How to train it. Take any problem in which a distribution evolves by a fixed rule and force yourself to write three objects before doing anything: the map on cdfs, its fixed points, and the derivative at each fixed point. Then compare those numbers with the constants in the question. On this problem that comparison finishes the analysis in under a minute.

What the examiners nudged with, and how. The exponent 2021 and the base 3^{2021} are there to make explicit computation absurd, which is a way of telling you the answer is one lemma iterated. The constant $\frac{1}{4}$ is μ_0 and is the starting value. The constant $\frac{2}{3}$ is $1/\phi'(\frac{1}{2})$ and is the loss per round. The word "median" with three elements is the smallest case in which the cdf map is nonlinear, so the problem is the minimal instance of its own idea. And the absolute value $\left|X - \frac{1}{2}\right|$ rather than a variance is chosen because $E\left|\cdot\right|$ respects pointwise inequalities directly, which is the only property the coupling proof needs.

Revolving concepts

Order statistics. For n independent variables with common cdf F, the j-th smallest has cdf $\sum_{i=j}^{n} \binom{n}{i} F^i (1-F)^{n-i}$. For the median of 3 this is $3F^2 - 2F^3$; for the median of $2m+1$ it is the regularised incomplete beta function $I_F(m+1, m+1)$, whose derivative in F is $\frac{(2m+1)!}{m!\,m!}\big(F(1-F)\big)^m$. See Book 1, field: Probability, topic: order statistics and the beta distribution.

Quantile function and the inverse transform. If F is a continuous strictly increasing cdf on an interval and U is uniform on $[0,1]$, then $F^{-1}(U)$ has cdf F. Consequently a whole family of distributions can be realised on one probability space, monotonically, by using the same U; this is the monotone coupling. Composition inverts: $\big(\phi \circ F\big)^{-1} = F^{-1} \circ \phi^{-1}$. See Book 1, field: Probability, topic: quantile transform and coupling.

Iterated maps and multipliers. For a C^1 map ϕ of an interval with fixed point p, the number $\phi'(p)$ is the multiplier; $|\phi'(p)| < 1$ makes p attracting, $|\phi'(p)| > 1$ repelling, and near a repelling fixed point the orbit of ϕ^{-1} approaches p at the geometric rate $1/\phi'(p)$. Here $\phi(u) = 3u^2 - 2u^3$ has fixed

points $0, \frac{1}{2}, 1$ with multipliers $0, \frac{3}{2}, 0$. See Book 1, field: Sequences and recurrences, topic: iterated maps and fixed point multipliers.

Symmetric distributions. If $F(1-x) = 1 - F(x)$ then the law is symmetric about $\frac{1}{2}$, $F(\frac{1}{2}) = \frac{1}{2}$, and $E|Z - \frac{1}{2}| = 2\int_0^{1/2} (\frac{1}{2} - x)\, dF(x) = 2\int_0^{1/2} F(x)\, dx$ after an integration by parts. The symmetry is preserved by ϕ because $\phi(1-u) = 1 - \phi(u)$.

Independence of blockwise functions. If $Z_1, \ldots, Z_n$ are independent and the index set is partitioned into blocks, then functions of the separate blocks are independent. This is why the surviving numbers at each level are independent and the whole reduction to a scalar recursion is legitimate; it is the single hypothesis that would fail if the triples overlapped.

The generalised recursion. Replace "median of three" by "median of $2m+1$" and repeat k times. The cdf map is $\phi_m = I_u(m+1, m+1)$, again an increasing bijection of $[0,1]$ with $\phi_m(1-u) = 1 - \phi_m(u)$ and $\phi_m(\frac{1}{2}) = \frac{1}{2}$, and its derivative $\frac{(2m+1)!}{m!\,m!}\big(u(1-u)\big)^m$ is maximised on $[0, \frac{1}{2}]$ at $u = \frac{1}{2}$, with value

$$c_m = \phi_m'\left(\tfrac{1}{2}\right) = \frac{(2m+1)!}{m!\,m!\,4^m}.$$

The identical argument then gives $\mu_k \geq \frac{1}{4}\, c_m^{-k}$, and $m = 1$ gives $c_1 = \frac{3}{2}$, which is this problem. More generally still: if ϕ is any C^1 increasing bijection of $[0,1]$ with $\phi(1-u) = 1 - \phi(u)$ and $\phi' \leq L$ on $[0, \frac{1}{2}]$, then iterating the associated median type operation k times gives $E\big|X_k - \frac{1}{2}\big| \geq L^{-k} E\big|X_0 - \frac{1}{2}\big|$. Store that statement, not the cubic.

Knowledge gaps, stated plainly. Four things here are past A-level Further Mathematics and must be installed, not improvised. First, the distribution of an order statistic, and specifically that it is a polynomial in the parent cdf. Second, the quantile transform and monotone coupling, which is the entire method. Third, the language of iterated maps: fixed point, multiplier, attracting and repelling, and the fact that the multiplier governs the rate. Fourth, the fact that functions of disjoint blocks of independent variables are independent, which is what makes the level-by-level recursion valid. None of these is difficult; all four are invisible if you have not met them, and the problem is unapproachable without the second.

Circuit Bank

- **WHEN** you see a random object built by repeating one operation on independent identically distributed copies **DO** write the recursion for the cumulative distribution function, not for the density and not for the variable **BECAUSE** order statistics are polynomials in the parent cdf, so the one round map is a fixed function ϕ with no dependence on the point x
- **WHEN** you have a recursion $F_k = \phi \circ F_{k-1}$ on distribution functions and you must iterate an inequality **DO** pass to quantile functions and couple: set $Y_k = \phi^{-1}$ applied k times to a single uniform U **BECAUSE** composition on the outside of a cdf becomes composition on the inside of its inverse, and inequalities iterate between numbers but not between integrals of composed functions
- **WHEN** the target inequality contains the value of the quantity at step zero and a derivative of the recursion map at a fixed point **DO** prove the one step lemma with that derivative as the loss factor and induct **BECAUSE** a constant equal to $1/\phi'(p)$ at a fixed point p is never a coincidence; it is the exact geometric rate at which the inverse map approaches p
- **WHEN** you need a lower bound on an expectation of an absolute value **DO** obtain a pointwise almost sure inequality first, then take expectations **BECAUSE** monotonicity of expectation is free, whereas lower bounds obtained from moment inequalities point the wrong way and need Paley and Zygmund style corrections
- **WHEN** a map ϕ of $[0,1]$ satisfies $\phi(1-u) = 1 - \phi(u)$ **DO** reduce every claim to $[0, \frac{1}{2}]$ and record that $\frac{1}{2}$ is a fixed point **BECAUSE** the symmetry is inherited by all iterates and by the

inverse, so it halves the work in every step of the argument

Backtesting

1. First useful cue: the same operation applied to disjoint triples at every level, which forces a recursion on cumulative distribution functions, $F \mapsto 3F^2 - 2F^3$.
2. Method the expression suggested: read $\frac{1}{4}$ as μ_0 and $\frac{2}{3}$ as $1/\phi'(\frac{1}{2})$, then prove the one step lemma $\mu_k \geq \frac{2}{3}\mu_{k-1}$ by coupling and iterate it.
3. Where you would hesitate, and the thought to reinforce: after obtaining $F_k = \phi \circ F_{k-1}$ you will want to integrate. Reinforce this: an outer composition is useless for lower bounds because $\phi(u) \geq \frac{2}{3}u$ is false near zero. Invert first, then integrate.
4. The trap the question sets: treating trimming as if it were the median of the whole list. The true median of 3^{2021} numbers sits at distance of order $(0.577)^{2021}$ from $\frac{1}{2}$, which is far smaller than the bound you are asked to prove, so any argument that silently replaces trimming by global median taking proves nothing.
5. What makes you recognise it faster next time: a deterministic map on distributions with a symmetric fixed point, and a target constant that equals the reciprocal of the derivative there. That pairing means coupling.
6. The reusable decision rule: distributional recursions become pointwise recursions under the quantile transform, and only pointwise inequalities iterate for free.

Mirror drills

1. Show that if Y_1, Y_2, Y_3 are independent with common cdf F, the median has cdf $3F^2 - 2F^3$, and that the density of the median of $2m+1$ such variables is $\frac{(2m+1)!}{m!\,m!}\big(F(1-F)\big)^m f$. *Answer:* the median is at most x exactly when at least $m+1$ of the variables are, so the cdf is $\sum_{i \geq m+1} \binom{2m+1}{i} F^i (1-F)^{2m+1-i}$; differentiating in F telescopes to the displayed beta density.
2. Let F be a continuous strictly increasing cdf on $[0,1]$ and U uniform. Show $F^{-1}(U)$ has cdf F, and deduce that if $G = \phi \circ F$ with ϕ an increasing bijection then $G^{-1} = F^{-1} \circ \phi^{-1}$. *Answer:* $P\big(F^{-1}(U) \leq x\big) = P\big(U \leq F(x)\big) = F(x)$; the second claim is the inverse of a composition, and it is the reason the iteration moves from the value slot to the argument slot.
3. Prove the generalisation: if each round keeps the median of $2m+1$ consecutive numbers and there are k rounds, then $\mu_k \geq \frac{1}{4}c_m^{-k}$ where $c_m = \frac{(2m+1)!}{m!\,m!\,4^m}$. *Answer:* the cdf map ϕ_m has derivative $\frac{(2m+1)!}{m!\,m!}(u(1-u))^m$, which on $[0, \frac{1}{2}]$ is maximised at $u = \frac{1}{2}$ with value c_m; run the same coupling and the same mean value argument. For $m = 1$, $c_1 = \frac{3}{2}$.

Chapter 6

Putnam 2020

6.1 A1. Repunits, the order of ten modulo 101

How many positive integers N satisfy all of the following three conditions?

(i) *N is divisible by* 2020.

(ii) *N has at most* 2020 *decimal digits.*

(iii) *The decimal digits of N are a string of consecutive ones followed by a string of consecutive zeros.*

Read it out loud

This is a counting question wearing a divisibility mask. Condition (iii) is not a condition at all, it is a parametrisation instruction: it hands you the shape of every candidate and asks you to name the two parameters. Say it out loud as "k ones then b zeros", and the object on the page is $N = \underbrace{11\ldots1}_{k}\underbrace{00\ldots0}_{b}$, which is $R_k \cdot 10^b$ where R_k is the repunit with k ones. Condition (ii) is $k + b \leq 2020$ and condition (i) is a divisibility test. The fields wired in are elementary number theory (factorisation, coprimality, multiplicative order) and a two variable count over a triangular region. Nothing else.

Within thirty seconds two lines should be on your page: $N = R_k \cdot 10^b$ with $k \geq 1$, $b \geq 0$, $k + b \leq 2020$, and $2020 = 2^2 \cdot 5 \cdot 101$. The second line is compulsory because you are being asked about divisibility by a composite, and a composite divisibility condition always splits into its prime power components. The moment those two lines sit next to each other the problem is already solved in outline, because R_k is odd and ends in the digit 1, so R_k is coprime to 10. Thus the factor $2^2 \cdot 5$ can only be supplied by 10^b, and the factor 101 can only be supplied by R_k. The two parameters separate completely and never speak to each other again.

What is really being tested is whether you take the number apart multiplicatively before you touch it, and whether you know that $10^2 \equiv -1 \pmod{101}$. That single congruence is the whole arithmetic content: it says the order of 10 modulo 101 is 4, which converts "101 divides N" into "4 divides k". The examiners chose 2020 precisely because 101 has that clean small order and because $2^2 \cdot 5$ forces the innocent looking condition $b \geq 2$ that most candidates get wrong by one.

Approaches, ranked worst to best

1. **Enumerate and hope.** *Cue:* "how many positive integers". *Circuit:* list candidates, look for a pattern. (There are more than two million candidate pairs (k, b) and no pattern is visible without the arithmetic, so this produces nothing at all.)

2. **Write $N = (10^a - 10^b)/9$ and clear the nine.** *Cue:* the repunit formula $R_k = (10^k - 1)/9$. *Circuit:* turn the divisibility into $9 \cdot 2020 \mid 10^b(10^{a-b} - 1)$. (Correct, and it is the official route, but you now carry a spurious factor 3^2 through every line and have to remark that it is automatic. Any fraction you introduce and then cancel is ink you paid for twice.)

3. **Factorise $N = R_k \cdot 10^b$ and split by prime.** *Cue:* R_k is coprime to 10. *Circuit:* each prime power of the modulus is supplied by exactly one factor. (Best on the arithmetic side. No fractions, no redundant primes, and the two conditions $b \geq 2$ and $4 \mid k$ appear one line apart.)

4. **Count by fixing the number of zeros b.** *Cue:* b is the parameter in the divisibility condition on 10^b. *Circuit:* for each b count the admissible a. (This is how the official solution counts, and it produces $\sum_b \lfloor (2020 - b)/4 \rfloor$, a sum with a floor function that then has to be regrouped into runs of four equal terms. Correct but it costs a paragraph.)

5. **Count by fixing the number of ones k.** *Cue:* the constraint on k is a congruence, the constraint on b is an interval. *Circuit:* substitute $k = 4j$ so the surviving count is an arithmetic progression. (Best. Once $k = 4j$ is substituted, b runs over $2 \leq b \leq 2020 - 4j$, so the inner count is $2019 - 4j$

with no floor function anywhere, and the outer sum is a single arithmetic series. Choose to fix the variable whose condition is a congruence, because a congruence is what creates floor functions when it is left in the inner loop.)

The ideal solution

Every N satisfying (ii) and (iii) is

$$N = R_k \cdot 10^b, \qquad R_k = \underbrace{11\ldots1}_{k} = \frac{10^k - 1}{9},$$

with integers $k \geq 1$ and $b \geq 0$ and $k + b \leq 2020$, and distinct pairs (k, b) give distinct N. Factor the modulus:

$$2020 = 2^2 \cdot 5 \cdot 101.$$

The repunit R_k has final digit 1, so it is odd and not divisible by 5; that is, $\gcd(R_k, 10) = 1$. Consequently

$$v_2(N) = v_2(10^b) = b, \qquad v_5(N) = v_5(10^b) = b,$$

so $2^2 \cdot 5 \mid N$ if and only if $b \geq 2$. Also $\gcd(10^b, 101) = 1$, so $101 \mid N$ if and only if $101 \mid R_k$, and since $\gcd(9, 101) = 1$ this holds if and only if $101 \mid 10^k - 1$.

Lemma 6.1.1. *The multiplicative order of* 10 *modulo* 101 *is* 4. *Hence* $101 \mid 10^k - 1$ *if and only if* $4 \mid k$.

Proof. $10^2 = 100 \equiv -1 \pmod{101}$, so $10^4 \equiv 1 \pmod{101}$ and the order divides 4. It is not 1 because $10 \not\equiv 1$, and not 2 because $-1 \not\equiv 1$ modulo 101. So the order is exactly 4, and $10^k \equiv 1$ if and only if the order divides k. □

So $2020 \mid N$ if and only if $b \geq 2$ and $4 \mid k$. Writing $k = 4j$ with $j \geq 1$, condition (ii) becomes $b \leq 2020 - 4j$, and b must satisfy $2 \leq b \leq 2020 - 4j$. The number of such b is $2019 - 4j$ when $2020 - 4j \geq 2$, that is when $j \leq 504$, and there are none for $j \geq 505$. Therefore the answer is

$$\sum_{j=1}^{504} (2019 - 4j) = 504 \cdot 2019 - 4 \cdot \frac{504 \cdot 505}{2} = 504(2019 - 1010) = 504 \cdot 1009.$$

Hence the count is

$$\boxed{508536}.$$

Layer 1: WHAT

Block 1: read (iii) as a parametrisation and write $N = R_k 10^b$ with $k + b \leq 2020$. Block 2: factor $2020 = 2^2 \cdot 5 \cdot 101$ and note $\gcd(R_k, 10) = 1$, so the modulus splits between the two factors with no overlap. Block 3: the $2^2 \cdot 5$ part is carried by 10^b alone, giving $b \geq 2$. Block 4: the 101 part is carried by R_k alone, and the order of 10 modulo 101 is 4, giving $4 \mid k$. Block 5: substitute $k = 4j$ and count lattice points, one arithmetic series.

Juxtaposition. The nominal route writes $N = (10^a - 10^b)/9$, multiplies up to $9N = 10^b(10^{a-b} - 1)$, and asks when 18180 divides that; it then has to dispose of the factor 3^2 as automatic, keep two variables a and b tangled by the inequality $b < a \leq 2020$, and finish with a floor function sum. The ideal route never introduces the nine and never uses a: it uses the two natural parameters, the count of ones and the count of zeros, because those are the parameters in which the arithmetic separates. The bifurcation point is the very first line you write down. If you write $(10^a - 10^b)/9$ you are describing the number; if you write $R_k \cdot 10^b$ you are factorising it, and factorising is what a divisibility question always wants.

Layer 2: HOW

Block 1. **Cue.** "The decimal digits are a string of ones followed by a string of zeros." **Why natural.** A description of digits is a description of a decimal expansion, and every decimal expansion of that shape is a repunit times a power of ten. You are not being clever here, you are reading the definition of the object out loud in symbols. The two counts, ones and zeros, are the only degrees of freedom, so they are the coordinates. **Link to the next block.** Once the object is a product, the divisibility condition can be tested factor by factor, which is exactly the next block.

Block 2. **Cue.** A divisibility condition by the composite 2020. **Why natural.** Divisibility by a composite is never one condition. It is one condition per prime power, and those conditions are independent by the Chinese remainder theorem. So factor first, always, before anything else. Here $2020 = 2^2 \cdot 5 \cdot 101$, and the presence of 101 is the reason the year was chosen. **Link to the next block.** The factorisation is only useful if you know which factor of N can supply each prime, and that is the coprimality observation.

Block 3. **Cue.** R_k ends in the digit 1. **Why natural.** A repunit is coprime to 10 by inspection of its last digit, so the entire 2 and 5 content of N sits in 10^b and the entire 101 content sits in R_k. In valuation language $v_2(N) = v_5(N) = b$. This is the structural reroute: the two parameters are decoupled, so the answer will be a product region, not a tangled one. **Link to the next block.** Decoupled means you may now treat the two conditions separately, and the harder one is the condition on R_k.

Block 4. **Cue.** $101 \mid R_k$, which is a statement about $10^k \bmod 101$. **Why natural.** The set of exponents k with $10^k \equiv 1 \pmod{101}$ is exactly the set of multiples of the multiplicative order, because the exponents form a subgroup of $\mathbb{Z}$ and every subgroup of $\mathbb{Z}$ is the multiples of one integer. So the only work is to compute that order, and $10^2 = 100 = 101 - 1$ makes it immediate. **Link to the next block.** A congruence condition on k and an interval condition on b: the count is now a lattice point count.

Block 5. **Cue.** One congruence condition, one interval condition, one inequality linking them. **Why natural.** Put the congruence in the outer loop. Substituting $k = 4j$ makes the constraint disappear into the index and leaves an interval of b values whose length is linear in j, so the sum is arithmetic. If instead you loop over b on the outside, the inner count is the number of multiples of 4 in an interval, which is a floor function, and floor functions must then be regrouped by residue class. **Link to the next block.** Nothing remains but one arithmetic series.

Layer 3: WHY

The mathematical truth beneath this problem is that divisibility is multiplicative and N has been handed to you as a product of two coprime pieces. When $N = AB$ with $\gcd(A, B) = 1$, the condition $m \mid N$ decomposes prime by prime, and each prime power of m must be found in whichever of A, B is not coprime to it. Here that decomposition is total: $2^2 \cdot 5$ lives only in 10^b and 101 lives only in R_k. That is why the answer is a clean lattice count and not a case analysis.

The second truth is the order. For $\gcd(a, m) = 1$, the set $\{k \in \mathbb{Z} : a^k \equiv 1 \pmod{m}\}$ is a subgroup of $\mathbb{Z}$, hence equal to $d\mathbb{Z}$ where $d = \mathrm{ord}_m(a)$, and $d \mid \varphi(m)$ by Lagrange. So any question of the form "for which k does m divide the repunit R_k" or "for which k does m divide $a^k - 1$" has the same shape of answer: the multiples of one number. The discernment mechanism is to notice that the unknown appears as an exponent, and an unknown in an exponent means order, never expansion.

Train the discernment with a habit: when a Putnam problem names a specific large year number as a modulus, factor it in the margin before reading the rest of the sentence. $2020 = 2^2 \cdot 5 \cdot 101$, and 101 is the prime whose reciprocal has period 4 because $10^2 \equiv -1$. The examiners nudged you twice: they chose 101 so that the order computation is a one liner, and they chose $2^2 \cdot 5$ rather than 10 so that the sloppy answer $b \geq 1$ is wrong. Every off by one in this problem lives at $b \geq 2$.

Revolving concepts

Repunits. $R_k = (10^k - 1)/9 = \sum_{i=0}^{k-1} 10^i$. They satisfy the recursion $R_{k+1} = 10R_k + 1$, and the general solution of $u_{k+1} = 10u_k + 1$ is $u_k = C \cdot 10^k - 1/9$, which is where the closed form comes from. Key divisibility fact: $R_d \mid R_k$ when $d \mid k$, because $\gcd(10^k - 1, 10^d - 1) = 10^{\gcd(k,d)} - 1$. See Book 1, field: Number theory, topic: repunits and $a^k - 1$.

Multiplicative order. For $\gcd(a, m) = 1$, $\operatorname{ord}_m(a)$ is the least $k \geq 1$ with $a^k \equiv 1$, the set of all such k is $\operatorname{ord}_m(a)\mathbb{Z}$, and $\operatorname{ord}_m(a) \mid \varphi(m)$. Here $\operatorname{ord}_{101}(10) = 4$, which is also the statement that $1/101 = 0.\overline{0099}$ has period 4. See Book 1, field: Number theory, topic: orders and primitive roots.

Chinese remainder theorem as a splitting device. If $m = \prod p_i^{e_i}$ then $m \mid N$ if and only if $p_i^{e_i} \mid N$ for every i, and these conditions are logically independent. Used here to break 2020 into three unrelated questions. See Book 1, field: Number theory, topic: CRT.

p-adic valuation of a product. $v_p(AB) = v_p(A) + v_p(B)$, so a coprime factor contributes nothing. Used to get $v_2(N) = v_5(N) = b$ in one line rather than by cases. See Book 1, field: Number theory, topic: valuations.

Lattice counting under a congruence. To count pairs with $k \equiv 0 \pmod{d}$ and $k + b \leq M$ and $b \geq b_0$: substitute $k = dj$ so the congruence vanishes, then the inner count is an arithmetic progression in j. The general sum is $\sum_{j=1}^{J} (M - dj - b_0 + 1)$ with $J = \lfloor (M - b_0)/d \rfloor$. See Book 1, field: Combinatorics, topic: counting lattice points in triangles.

Circuit Bank

- **WHEN** you see a condition on the decimal digits **DO** write the number as a sum or product of powers of ten and repunits **BECAUSE** a digit description is a decimal expansion, and only the algebraic form can be tested for divisibility
- **WHEN** you see divisibility by a composite **DO** factor the modulus into prime powers before anything else **BECAUSE** by the Chinese remainder theorem the condition splits into independent conditions, and each prime usually attaches to a different factor of the number
- **WHEN** the unknown sits in an exponent inside a congruence **DO** compute the multiplicative order of the base and convert to a divisibility condition on the exponent **BECAUSE** the exponents that give 1 form a subgroup of $\mathbb{Z}$, so they are exactly the multiples of the order
- **WHEN** you must count pairs with one congruence condition and one interval condition **DO** loop over the congruence variable by substituting $k = dj$ **BECAUSE** substituting kills the congruence, and the remaining count is an interval length, so no floor functions ever appear

Backtesting

1. First useful cue: condition (iii) is a parametrisation, giving $N = R_k \cdot 10^b$, and $2020 = 2^2 \cdot 5 \cdot 101$.
2. Method the expression suggested: split the divisibility prime by prime and use coprimality to attach each prime power to exactly one factor.
3. Where you would hesitate, and the thought to reinforce: at the condition on b. The thought is $v_2(N) = v_5(N) = b$, so $4 \cdot 5 \mid N$ needs $b \geq 2$, not $b \geq 1$. Write the valuation, not the sentence "N must end in enough zeros".

4. The trap the question sets: two off by one errors, $b \geq 2$ rather than $b \geq 1$, and the upper limit $j \leq 504$ rather than $j \leq 505$. Check the extreme case explicitly: $j = 504$ gives $k = 2016$ and $b \in \{2, 3, 4\}$, three values, and $2019 - 4 \cdot 504 = 3$ confirms the formula at the edge.
5. What makes you recognise it faster next time: any problem naming the year as a modulus wants its factorisation, and any problem about strings of repeated digits wants repunits and orders.
6. The reusable decision rule: factor the number, factor the modulus, match prime powers to coprime factors, then count with the congruence in the outer loop.

Mirror drills

1. For how many k with $1 \leq k \leq 100$ is R_k divisible by 41? *Answer:* $10^5 \equiv 1 \pmod{41}$ and no smaller exponent works, so the order is 5 and $41 \mid R_k$ if and only if $5 \mid k$; there are 20 such k.
2. How many positive integers with at most 30 decimal digits, whose digits are a block of ones followed by a block of zeros, are divisible by 1000? *Answer:* the condition is $b \geq 3$ with $k \geq 1$ and $k + b \leq 30$, giving $\sum_{k=1}^{27}(28 - k) = 378$.
3. Show that R_k is never divisible by 2, 5, or 3^3, and find all k with $27 \mid R_k \cdot 10^b$. *Answer:* the last digit rules out 2 and 5; $R_k \equiv k \pmod{9}$ shows $9 \mid R_k$ iff $9 \mid k$, and since $v_3(R_k) = v_3(k)$ by lifting the exponent, $27 \mid R_k$ iff $27 \mid k$; 10^b contributes no factor 3, so the answer is $27 \mid k$.

6.2 A2. A binomial sum that counts coin flip majorities

Let k be a nonnegative integer. Evaluate

$$\sum_{j=0}^{k} 2^{k-j} \binom{k+j}{j}.$$

Read it out loud

This is a single finite binomial sum with a weight that is a power of two, and the command term is "evaluate", which promises a closed form. Say the summand out loud: a binomial coefficient in which both indices move as j moves, multiplied by 2 to the power of the complementary index. Two structural features jump out. First, $\binom{k+j}{j}$ counts arrangements of k objects of one kind and j of another. Second, and this is the guiding light, the two "lengths" in the summand add to a constant:

$$(k+j) + (k-j) + 1 = 2k+1.$$

A summand built from a block of length $k+j$, a free block of length $k-j$, and one more slot, with the total independent of j, is the fingerprint of a decomposition of objects of fixed length $2k+1$ according to where something happens for the first time.

The fields wired in are combinatorics (counting binary strings, bijections, the complement symmetry) and, if you prefer the language, elementary probability (the negative binomial distribution and a race between two players). Nothing analytic is involved: the answer will be an integer.

Within thirty seconds you should have computed the first two or three values. $S_0 = 1$, $S_1 = 2 \cdot 1 + 1 \cdot \binom{2}{1} = 4$, $S_2 = 4 + 2\binom{3}{1} + \binom{4}{2} = 16$. So the answer is 4^k, and you now know the size of the set you must build. Guessing the target is legitimate reconnaissance; it is the proof that must never be guessed. A power of two as an answer is a loud instruction: find a set of size 2^{2k+1}, split it in half by a symmetry, and show the sum counts one half.

Approaches, ranked worst to best

1. **Compute values and assert the pattern.** *Cue:* "evaluate". *Circuit:* tabulate S_0, S_1, S_2 and write 4^k. (Zero marks. It identifies the target, which is useful, but a Putnam grader wants the reason a pattern continues.)

2. **Induction through Pascal's rule.** *Cue:* $\binom{k+j}{j}$ with both indices moving. *Circuit:* split $\binom{k+j}{j} = \binom{k-1+j}{j} + \binom{k-1+j}{j-1}$ and reassemble. (Correct, and it is the first official route: the two pieces reassemble into $2S_{k-1}$ and $\frac{1}{2}S_k$, giving $S_k = 2S_{k-1} + \frac{1}{2}S_k$, hence $S_k = 4S_{k-1}$. It works, but it needs two index shifts, a boundary convention $\binom{n}{-1} = 0$, and the nerve to recognise S_k itself on the right hand side. Under exam pressure that is three places to slip.)

3. **Generating functions.** *Cue:* a binomial with upper index $k+j$ is a coefficient of $(1+x)^{k+j}$. *Circuit:* write the sum as $[x^k] \sum_j 2^{k-j}(1+x)^{k+j}$, sum the geometric series. (Clean and mechanical, and it is the third official route, but it ends at $2^{k+1}\sum_{j\le k}\binom{k}{j} - \sum_{j\le k}\binom{2k+1}{j}$, and the second of those partial sums is evaluated by exactly the complement symmetry used in the best route. So the generating function is a longer path to the same idea.)

4. **Probabilistic race.** *Cue:* $\binom{n-1}{k}2^{-n}$ is the negative binomial law. *Circuit:* let X be the index of the $(k+1)$st head and compute $2^{2k+1}P[X \le 2k+1]$. (Very short and correct, and it makes the symmetry visible. Ranked below the next one only because it converts an integer identity into a probability and back again, which costs two sentences of translation and forces you to state the law of X carefully.)

5. **Direct bijection on binary strings.** *Cue:* the constant total length $2k+1$. *Circuit:* count strings of length $2k+1$ with a majority of heads by the position of the $(k+1)$st head, then halve by the complement symmetry. (Best. Everything is a finite count, the sum is produced rather than manipulated, and the answer 4^k appears as half of 2^{2k+1}. No conventions, no index shifts, no boundary cases.)

The ideal solution

Write $S_k = \sum_{j=0}^{k} 2^{k-j}\binom{k+j}{j}$. We claim

$$S_k = \boxed{4^k}.$$

Let Ω be the set of strings of length $2k+1$ over the alphabet $\{H, T\}$, so $|\Omega| = 2^{2k+1}$. Call a string *heavy* if it contains at least $k+1$ letters H, and *light* if it contains at least $k+1$ letters T.

Claim 6.2.1. *S_k is the number of heavy strings.*

Proof. Let w be heavy. Since w contains at least $k+1$ letters H, there is a well defined position p at which the $(k+1)$st H occurs. The first $p-1$ letters contain exactly k letters H, so $p-1 = k+j$ where $j \geq 0$ is the number of letters T before position p; and $p \leq 2k+1$ forces $j \leq k$. Thus w is determined by the triple: the value of j; the arrangement of the first $k+j$ letters, which consist of exactly k letters H and j letters T and may be arranged in $\binom{k+j}{j}$ ways; and the last $2k+1-p = k-j$ letters, which are arbitrary, giving 2^{k-j} ways. Position p itself is forced to be H.

Conversely, every such triple produces a heavy string whose $(k+1)$st H sits at position $k+j+1$, and different triples produce different strings, because j is recovered from the string as the number of letters T before the $(k+1)$st H. Hence the heavy strings are in bijection with the triples, and their number is $\sum_{j=0}^{k}\binom{k+j}{j}2^{k-j} = S_k$. □

Now exchange the two letters. The map σ that replaces every H by T and every T by H is an involution of Ω, and it maps heavy strings onto light strings and light strings onto heavy strings. Hence there are as many heavy strings as light ones. Moreover every string is exactly one of the two: a string of odd length $2k+1$ has $\#H + \#T = 2k+1$, so $\#H \geq k+1$ if and only if $\#T \leq k$, that is, if and only if the string is not light. So Ω is the disjoint union of the heavy and the light strings, and the two classes have equal size:

$$S_k = \#\{\text{heavy}\} = \tfrac{1}{2}|\Omega| = \tfrac{1}{2}\cdot 2^{2k+1} = 4^k.$$

For $k = 0$ this reads $S_0 = 1$, which matches the sum directly.

Layer 1: WHAT

Block 1: compute S_0, S_1, S_2 to learn the target 4^k, and read $4^k = \frac{1}{2}\cdot 2^{2k+1}$ as "half of all strings of length $2k+1$". Block 2: notice $(k+j)+(k-j)+1 = 2k+1$ is constant, so the summand describes objects of fixed length $2k+1$ cut at one distinguished position. Block 3: identify the cut as the position of the $(k+1)$st letter H, and verify the decomposition is a bijection. Block 4: apply the letter exchange involution and the parity of $2k+1$ to conclude that heavy strings are exactly half of all strings.

Juxtaposition. The nominal route treats the sum as an algebraic object: apply Pascal, shift indices, recognise a copy of S_k inside itself, solve the resulting equation for S_k, then induct. It is a valid route and it is short on paper, but every step is an index manipulation with a boundary convention attached. The ideal route never manipulates the sum at all; it builds the set the sum counts and then counts that set a second way. The bifurcation point is the moment you see 2^{k-j} next to $\binom{k+j}{j}$. The zombie reads 2^{k-j} as a coefficient to be absorbed; you read it as the number of ways to fill $k-j$ free slots, which forces the question "free slots in what object of total length $2k+1$".

Layer 2: HOW

Block 1. **Cue.** "Evaluate", a finite sum with a small parameter. **Why natural.** Three values cost fifteen seconds and remove all ambiguity about the target. Knowing the answer is 4^k changes the search: you are no longer looking for a manipulation, you are looking for a set of size 2^{2k+1} and a two to one reason. **Link to the next block.** A power of two answer points to a counting proof, so the next job is to identify what the summand counts.

Block 2. **Cue.** $(k+j)+(k-j)$ is independent of j. **Why natural.** Whenever a sum over j has one factor counting arrangements in a block of length $k+j$ and another factor counting free choices in a block of length $k-j$, the sum is counting objects of the constant total length by cutting them at a position that depends on the object. That is the only way a j dependent split can produce a j independent whole. So the sum equals the number of strings of length $2k+1$ in some family, and j records where the cut falls. **Link to the next block.** The cut position must be determined by the string itself, and the binomial $\binom{k+j}{j}$ tells you exactly which statistic is being fixed: k letters of one kind before the cut.

Block 3. **Cue.** $\binom{k+j}{j}$ with exactly k letters H and j letters T before a forced H. **Why natural.** The forced letter at the cut is what makes the decomposition a bijection rather than an overcount: the cut is the first time the count of H reaches $k+1$. Any first passage decomposition has this shape, one forced letter at the moment of passage, everything before it constrained, everything after it free. State the inverse map explicitly and the bijection is proved rather than asserted. **Link to the next block.** Having identified the family as "at least $k+1$ letters H in $2k+1$ letters", you need its size, and the family is defined by a majority condition.

Block 4. **Cue.** Odd total length, and a condition of the form "at least half". **Why natural.** In an odd number of trials there are no ties, so the majority condition splits the whole space into two classes, and the exchange of letters is an explicit bijection between them. Two classes, equal size, disjoint, covering everything: each is half. The oddness is not decoration, it is what makes the split clean, and it is why the problem was posed with $2k+1$ hidden inside the summand rather than $2k$. **Link to the next block.** The count is $2^{2k+1}/2 = 4^k$ and nothing remains.

Layer 3: WHY

The truth beneath this problem is that a binomial identity with a closed form as clean as 4^k is a statement that two ways of counting one set agree. The sum counts by conditioning on a first passage time; the closed form counts by a symmetry. Every proof of the identity is somewhere on the spectrum between those two, and the algebraic proofs (Pascal induction, generating functions) are the same argument with the combinatorial content compiled away. The generating function route makes this explicit: it terminates at $\sum_{j=0}^{k}\binom{2k+1}{j} = 2^{2k}$, which is precisely the complement symmetry $\binom{2k+1}{j} = \binom{2k+1}{2k+1-j}$ in disguise.

The discernment mechanism is the constant total. Before deciding how to attack a binomial sum, add up the lengths appearing in the summand. If they sum to a constant, the sum is a decomposition of a fixed size family and you should hunt for the family. If they do not, no such reading exists and you fall back on Pascal, generating functions, or creative telescoping. That is a one line diagnostic you can run on every binomial sum you ever meet.

Train it by rewriting powers as counts. The habit is to refuse to read 2^{k-j} as "a coefficient" and to read it as "the number of ways to fill $k-j$ binary slots". Once every factor in a summand is a count of something, the summand is a description of an object, and the sum is a family. The examiners nudged you toward this by choosing the weight 2^{k-j} rather than, say, 3^{k-j}: base two matches the two letters in the binomial, so the family is binary strings and the symmetry is available.

Revolving concepts

First passage decomposition. To count sequences in which a running statistic first reaches a threshold, condition on the position of that first passage: everything before it is constrained by the near threshold count, the position itself carries a forced letter, and everything after is free. In general, the number of binary strings of length $n+m+1$ with at least $n+1$ letters H is $\sum_{j=0}^{m}\binom{n+j}{j}2^{m-j}$, which is our identity when $m=n$. See Book 1, field: Combinatorics, topic: first passage and ballot type decompositions.

Negative binomial law. For fair coin flips, the index X of the $(k+1)$st head satisfies $P[X=n]=\binom{n-1}{k}2^{-n}$ for $n \geq k+1$. Writing $n=k+j+1$ turns our sum into $2^{2k+1}P[X \leq 2k+1]$, and $P[X \leq 2k+1]=\frac{1}{2}$ by the majority symmetry. See Book 1, field: Probability, topic: negative binomial and waiting times.

Complement symmetry. $\binom{n}{j}=\binom{n}{n-j}$, and for odd n the two halves of the row of Pascal's triangle each sum to 2^{n-1}: $\sum_{j=0}^{(n-1)/2}\binom{n}{j}=2^{n-1}$. This is the same involution as the letter exchange. See Book 1, field: Combinatorics, topic: binomial symmetry and partial row sums.

Pascal recursion and its solution. $\binom{n}{r}=\binom{n-1}{r}+\binom{n-1}{r-1}$ applied inside the sum yields the recursion $S_k=2S_{k-1}+\frac{1}{2}S_k$, that is, the first order linear recursion $S_k=4S_{k-1}$ with $S_0=1$, whose general solution is $S_k=S_0r^k$ with $r=4$. Any time a sum can be re expressed in terms of itself with shifted parameters you obtain such a recursion; the general template $u_k=\alpha u_{k-1}+\beta u_k$ solves to $u_k=\frac{\alpha}{1-\beta}u_{k-1}$, so always collect the copies of u_k before panicking. See Book 1, field: Sequences and recurrences, topic: first order linear recursions.

Mechanical proof of hypergeometric identities. Every identity of this shape, where the ratio of consecutive summands is a rational function of the index, is decidable by Zeilberger's creative telescoping (the WZ method), which outputs a recursion in k and a certificate. You do not need it here and you cannot run it by hand quickly, but it is the honest statement of why sums like this always have clean answers. This is a named knowledge gap: install the existence of the algorithm, not the algorithm. See Book 1, field: Generating functions, topic: hypergeometric summation.

Circuit Bank

- **WHEN** a binomial sum has lengths that add to a constant, such as $(k+j)+(k-j)$ **DO** read the summand as a description of one object of that constant length, cut at a position depending on j **BECAUSE** a j dependent split that produces a j independent total is exactly what conditioning on a first passage looks like
- **WHEN** a power such as 2^{k-j} sits next to a binomial coefficient **DO** read the power as the number of ways to fill $k-j$ free binary slots **BECAUSE** when every factor is a count, the summand describes an object and the sum describes a family
- **WHEN** a counting problem has odd total size and a condition of the form "at least half" **DO** apply the exchange involution and conclude the family is exactly half of everything **BECAUSE** oddness forbids ties, so the two complementary classes partition the space and the involution matches them
- **WHEN** a finite sum with a parameter asks you to evaluate **DO** compute the first three values before choosing a method **BECAUSE** knowing the closed form tells you which kind of proof to look for, and a power of two answer means look for a bijection rather than an algebraic identity
- **WHEN** a sum reappears inside its own transformation **DO** collect the copies and solve for the sum **BECAUSE** $S=\alpha T+\beta S$ is a linear equation, and $\beta \neq 1$ makes it a one line recursion

Backtesting

1. First useful cue: $(k+j)+(k-j)+1 = 2k+1$ is constant, and $S_0, S_1, S_2 = 1, 4, 16$.
2. Method the expression suggested: count binary strings of length $2k+1$ by the position of the $(k+1)$st head, then halve by the exchange symmetry.
3. Where you would hesitate, and the thought to reinforce: at "why is this a bijection". The thought to write is the inverse map: given a heavy string, j is the number of tails before the $(k+1)$st head. A decomposition without a stated inverse is an overcount waiting to happen.
4. The trap the question sets: the sum looks like something to manipulate. Pascal and generating functions both work and both cost more ink, and the generating function route ends up needing the same symmetry anyway.
5. What makes you recognise it faster next time: the pattern $\binom{a+b}{b}c^d$ with $a+b+d$ constant is the signature of a first passage count, and base two weight with a two letter binomial means the alphabet is $\{H, T\}$.
6. The reusable decision rule: if a binomial sum has constant total length, prove it by building the family; only if it does not, reach for Pascal, generating functions, or creative telescoping.

Mirror drills

1. Evaluate $\sum_{j=0}^{k} \binom{k+j}{j} 2^{-j}$. *Answer:* 2^k; divide the identity by 2^k, or repeat the argument with the free slots weighted by 2^{-1} each.
2. Show that $\sum_{j=0}^{k} \binom{2k+1}{j} = 4^k$. *Answer:* the involution $j \mapsto 2k+1-j$ pairs the terms with $j \le k$ against those with $j \ge k+1$, so the sum is half of $\sum_{j=0}^{2k+1} \binom{2k+1}{j} = 2^{2k+1}$.
3. Alice needs 3 more points and Bob needs 2 more to win a match decided by fair coin flips. Find the probability Alice wins. *Answer:* condition on the position of Alice's third point: $\sum_{j=0}^{1} \binom{2+j}{j} 2^{-(3+j)} = \frac{1}{8} + \frac{3}{16} = \frac{5}{16}$.

6.3 A3. Iterated sine and a neutral fixed point

Let $a_0 = \pi/2$, and let $a_n = \sin(a_{n-1})$ for $n \geq 1$. Determine whether

$$\sum_{n=1}^{\infty} a_n^2$$

converges.

Read it out loud

This is an iterated map feeding a series. The map is $f(x) = \sin x$, the orbit starts at $\pi/2$, and you are asked about the summability of the squares of the orbit. Say the structure out loud: $f(0) = 0$ and $f'(0) = 1$, so the origin is a fixed point at which the derivative is exactly 1. That is a neutral fixed point, and neutral fixed points are the whole subject of this problem. An attracting fixed point ($|f'| < 1$) would give geometric decay and every series in sight would converge; a neutral fixed point gives polynomial decay, and polynomial decay is exactly where convergence questions become interesting.

The fields wired in are real analysis (monotone sequences, Taylor bounds with a controlled sign, comparison tests) and discrete dynamics (asymptotics of orbits near a parabolic fixed point). The first cue is the mismatch between $\sin x$ and x: since $\sin x = x - x^3/6 + \cdots$, each step loses about $a_n^3/6$, so the decay of the orbit is governed by a cubic correction, and cubic correction to a neutral fixed point means the orbit decays like $n^{-1/2}$ and its square like n^{-1}. The harmonic series is the boundary case, which is why the problem is worth asking.

Within thirty seconds two things should be on your page: $a_1 = \sin(\pi/2) = 1$, so the orbit is really the orbit of 1 under repeated sine, and the heuristic $a_n \approx \sqrt{3/n}$, hence $a_n^2 \approx 3/n$, hence divergence. Now the only job is a proof, and the crucial observation is that divergence requires only a lower bound. You never need the sharp constant $\sqrt{3}$. That single realisation cuts the work by three quarters.

Approaches, ranked worst to best

1. **Note $a_n \to 0$ and guess.** *Cue:* the terms tend to zero. *Circuit:* hope that small terms sum. (Worthless: $a_n \to 0$ is necessary for convergence, never sufficient, and the harmonic series is the standing counterexample.)

2. **Ratio or root test.** *Cue:* a series with positive terms. *Circuit:* compute $\lim a_{n+1}^2/a_n^2$. (Silent by construction. The ratio tends to 1 because $a_{n+1}/a_n = \sin(a_n)/a_n \to 1$, and every test that compares against a geometric series returns no information for polynomially decaying terms. Recognising this in one line is worth more than attempting it.)

3. **Numerical evidence.** *Cue:* a concrete recursion. *Circuit:* compute partial sums. (Reconnaissance only. The partial sums grow like $3 \log n$, so after ten thousand terms you have about 28, which is suggestive and proves nothing.)

4. **Full asymptotic by Stolz and Cesaro.** *Cue:* the cubic correction $\sin x = x - x^3/6 + O(x^5)$. *Circuit:* set $b_n = a_n^{-2}$, show $b_{n+1} - b_n \to \frac{1}{3}$, conclude $a_n^2 \sim 3/n$. (Correct, sharp, and the right way to understand the problem, but it costs an expansion of $(1-t)^{-1}$ to second order, a Cesaro step, and careful error control. On the clock that is several places to lose a mark, and none of the sharpness is needed for the question actually asked.)

5. **One sided induction against $1/\sqrt{n}$.** *Cue:* you need divergence, so you need only a lower bound. *Circuit:* prove $\sin x \geq x - x^3/6$ once, then induct on $a_n \geq n^{-1/2}$. (Best. One inequality, one induction, one comparison with the harmonic series. The deliberate slack in the constant, 1 instead of the true $\sqrt{3}$, is what makes the induction step close with a factorisable quadratic.)

The ideal solution

The series diverges.

Lemma 6.3.1 (polynomial bounds for sine)**.** *For all $x \geq 0$: $\sin x \leq x$, $\cos x \geq 1 - \frac{x^2}{2}$, and $\sin x \geq x - \frac{x^3}{6}$.*

Proof. Let $u(x) = x - \sin x$. Then $u(0) = 0$ and $u'(x) = 1 - \cos x \geq 0$, so $u \geq 0$ on $[0, \infty)$, which is the first inequality. Let $v(x) = \cos x - 1 + \frac{x^2}{2}$. Then $v(0) = 0$ and $v'(x) = x - \sin x = u(x) \geq 0$, so $v \geq 0$, which is the second. Let $w(x) = \sin x - x + \frac{x^3}{6}$. Then $w(0) = 0$ and $w'(x) = \cos x - 1 + \frac{x^2}{2} = v(x) \geq 0$, so $w \geq 0$, which is the third. □

First, the orbit stays in $(0, 1]$. Indeed $a_1 = \sin(\pi/2) = 1$, and if $a_n \in (0, 1]$ then $a_{n+1} = \sin(a_n) \in (0, 1]$, because sin is positive on $(0, \pi)$ and $\sin x \leq x \leq 1$ there. In particular $a_n > 0$ for every $n \geq 1$, and sin is strictly increasing on $[0, 1]$ since $\cos > 0$ there.

Claim 6.3.2. *$a_n \geq n^{-1/2}$ for every $n \geq 1$.*

Proof. Induction on n. For $n = 1$, $a_1 = 1 = 1^{-1/2}$.

Assume $a_n \geq n^{-1/2}$ for some $n \geq 1$. Both a_n and $n^{-1/2}$ lie in $(0, 1]$ and sin is increasing there, so

$$a_{n+1} = \sin(a_n) \geq \sin\left(n^{-1/2}\right) \geq n^{-1/2} - \frac{1}{6}n^{-3/2} = \frac{6n - 1}{6n^{3/2}},$$

using the lemma. Since $n \geq 1$, the right hand side is positive, so it suffices to prove

$$\frac{6n - 1}{6n^{3/2}} \geq \frac{1}{\sqrt{n + 1}}.$$

Both sides are positive, so this is equivalent to the inequality obtained by squaring and clearing denominators:

$$(n + 1)(6n - 1)^2 \geq 36n^3.$$

Expanding the left side gives $36n^3 + 24n^2 - 11n + 1$, so the inequality is equivalent to

$$24n^2 - 11n + 1 \geq 0, \qquad \text{that is} \qquad (3n - 1)(8n - 1) \geq 0,$$

which holds for every $n \geq 1$. Hence $a_{n+1} \geq (n + 1)^{-1/2}$, completing the induction. □

Therefore $a_n^2 \geq 1/n$ for all $n \geq 1$, and since the harmonic series diverges, the comparison test for series with nonnegative terms gives

$$\sum_{n=1}^{\infty} a_n^2 \geq \sum_{n=1}^{\infty} \frac{1}{n} = \infty.$$

The series $\sum a_n^2$ **diverges**.

Layer 1: WHAT

Block 1: identify the fixed point structure, $\sin 0 = 0$ with derivative 1, so decay is polynomial rather than geometric. Block 2: estimate the decay rate from the cubic term, giving the heuristic $a_n \approx \sqrt{3/n}$ and $a_n^2 \approx 3/n$, so the answer is divergence. Block 3: notice that divergence needs only a lower bound, so discard the sharp constant and aim at $a_n \geq n^{-1/2}$. Block 4: prove the single inequality $\sin x \geq x - x^3/6$ by a three step derivative ladder. Block 5: run the induction, reducing the step to $(3n - 1)(8n - 1) \geq 0$. Block 6: compare with the harmonic series.

Juxtaposition. The nominal route sets $b_n = 1/a_n^2$, expands sin to fifth order, expands $(1 - t)^{-1}$, shows $b_{n+1} - b_n \to 1/3$, invokes Cesaro, deduces $a_n^2 \sim 3/n$, and finally compares. Every one of

those steps is correct and every one is optional. The ideal route uses the asymptotic only as a private prediction, never writing it down, and pays for a one sided bound instead. The bifurcation point is the question "what exactly do I need". The zombie answers "the asymptotic behaviour of a_n"; you answer "a lower bound whose square is not summable", and the entire second half of the work evaporates.

Layer 2: HOW

Block 1. **Cue.** An iteration $a_{n+1} = f(a_n)$ with $f(0) = 0$, $f'(0) = 1$, and $0 < f(x) < x$ near 0. **Why natural.** The orbit is positive and strictly decreasing, hence convergent, and its limit is a fixed point of the continuous map f, so the limit is 0. Because $f'(0) = 1$ the convergence is not geometric, so the decay is governed by the first nonlinear term of f at 0. Naming this before computing anything is what tells you the answer will sit near the harmonic boundary. **Link to the next block.** Knowing the decay is polynomial, you next need its exponent, and that comes from the cubic term.

Block 2. **Cue.** $\sin x = x - x^3/6 + O(x^5)$, so each step subtracts about $a_n^3/6$. **Why natural.** For a step law $x \mapsto x - cx^{p+1}$, the reciprocal power $b = x^{-p}$ increases by almost the constant cp each step, because $(x - cx^{p+1})^{-p} = x^{-p}(1 - cx^p)^{-p} \approx x^{-p} + cp$. Hence $b_n \approx cpn$ and $x_n \approx (cpn)^{-1/p}$. With $c = 1/6$ and $p = 2$ this predicts $a_n \approx \sqrt{3/n}$. This is the standard machine for neutral fixed points, and you should be able to run it in your head in fifteen seconds. **Link to the next block.** The prediction says $a_n^2 \approx 3/n$, which is not summable, so the target is a lower bound of order $n^{-1/2}$.

Block 3. **Cue.** The question is convergence or divergence, not the value. **Why natural.** Divergence of a series with nonnegative terms follows from a lower bound alone. So you may throw away the upper estimate, the error terms, and the sharp constant. Be lazy in the good sense: solve the question asked, not the question the structure suggests. **Link to the next block.** A lower bound of the form $a_n \geq cn^{-1/2}$ must be proved by induction, and induction needs a constant that leaves slack.

Block 4. **Cue.** You must compare sin against a polynomial, from below. **Why natural.** The truth is $a_n \sim \sqrt{3}\, n^{-1/2}$ and the inequality $a_n \geq \sqrt{3}\, n^{-1/2}$ is false for every n: the orbit approaches the sharp constant from below. So the induction can only close with a constant strictly smaller than $\sqrt{3}$, and 1 is the tidiest such constant. This is a general principle for asymptotic inductions: deliberately weaken the constant, because the slack is what the induction step spends. **Link to the next block.** With the target $a_n \geq n^{-1/2}$ fixed, you need exactly one analytic input, the lower Taylor bound for sin.

Block 5. **Cue.** A cubic lower bound for sin on $[0, 1]$. **Why natural.** Two standard justifications exist. Taylor with Lagrange remainder gives $\sin x = x - x^3/6 + \frac{\sin c}{24} x^4$ for some $c \in (0, x)$, and $\sin c \geq 0$ for $x \leq \pi$. Or, with no theorem quoted, a ladder of three derivative arguments: $x \geq \sin x$ implies $\cos x \geq 1 - x^2/2$ implies $\sin x \geq x - x^3/6$, each step being "value zero at zero, nonnegative derivative". Use the ladder in a write up: it is self contained and each line is checkable. **Link to the next block.** Now the induction step is an algebraic inequality between two positive quantities.

Block 6. **Cue.** An inequality between $\frac{6n-1}{6n^{3/2}}$ and $(n+1)^{-1/2}$, both positive. **Why natural.** Both sides positive means squaring is reversible, and squaring removes the square roots. What is left is a cubic inequality whose cubic terms cancel exactly, leaving the quadratic $24n^2 - 11n + 1 = (3n-1)(8n-1)$. The cancellation of the n^3 terms is not luck: it is the statement that the two sides agree to leading order, which is precisely the slack in the constant showing up as a lower order surplus. **Link to the next block.** Comparison with $\sum 1/n$ finishes.

Layer 3: WHY

The mathematical truth here is the classification of fixed points by the derivative. If $|f'(L)| < 1$ the orbit converges to L geometrically and every reasonable series built from it converges. If $f'(L) = 1$ the linear term gives no contraction and the first nonlinear term takes over: for $x_{n+1} = x_n - cx_n^{p+1} + O(x_n^{p+2})$ with $c > 0$ and $x_n \downarrow 0$, the substitution $b_n = x_n^{-p}$ converts the multiplicative iteration into an almost additive one, $b_{n+1} - b_n \to cp$, and the Cesaro theorem gives $b_n/n \to cp$, that is

$$x_n \sim (cpn)^{-1/p}.$$

Every sine, tangent, logarithm and arctangent iteration you will ever meet is an instance. For sin: $c = 1/6$, $p = 2$, so $a_n \sim \sqrt{3/n}$, and consequently $\sum a_n^q$ converges precisely when $q > 2$.

The discernment mechanism is a two question filter applied to any iteration problem. Question one: what is the limit and what is f' there? Question two: if $f' = 1$, what is the first nonlinear term? The answers give the decay exponent immediately, and the decay exponent decides every convergence question about the orbit. Train it by computing the exponent for $\sin x$, $\tan^{-1} x$, $\log(1 + x)$, $x - x^2$, and $x/(1 + x)$ until the substitution $b = x^{-p}$ is reflex.

The examiners nudged you twice. They started the orbit at $\pi/2$ rather than at 1 so that the first step, $a_1 = 1$, is free and puts the orbit inside $[0, 1]$ where all the estimates are comfortable. And they asked about $\sum a_n^2$ rather than $\sum a_n$ or $\sum a_n^3$: those two are decided by the crudest of bounds, whereas the square sits exactly at the harmonic boundary, so the answer depends on the constant in the decay being finite and positive rather than on any coarse estimate.

Revolving concepts

Neutral (parabolic) fixed point. For f smooth with $f(0) = 0$, $f'(0) = 1$ and $f(x) = x - cx^{p+1} + O(x^{p+2})$ with $c > 0$, any orbit starting small and positive decays like $(cpn)^{-1/p}$. Method: set $b_n = x_n^{-p}$, expand to get $b_{n+1} = b_n + cp + O(x_n^p)$, then apply the Cesaro theorem to the increments. See Book 1, field: Real analysis, topic: iteration near a neutral fixed point.

The generalised recursion. The orbit recursion $x_{n+1} = x_n - cx_n^{p+1}$ has no closed form, but its reciprocal power form $b_{n+1} = b_n + cp + o(1)$ is an additive recursion with the general solution $b_n = cpn + o(n)$. This is the standard method for every "slowly decaying" recursion: find the power of x that linearises the increment. Sharper versions add a $\log n$ correction: here $a_n^2 = \frac{3}{n} - \frac{27 \log n}{5n^2} + O(n^{-2})$, which is why $na_n^2 < 3$ for every n and approaches 3 from below. See Book 1, field: Sequences and recurrences, topic: asymptotics of slowly decaying recursions.

Stolz and Cesaro. If $b_{n+1} - b_n \to L$ then $b_n/n \to L$. This is the discrete analogue of l'Hopital, and it is the engine that converts an increment estimate into an asymptotic. See Book 1, field: Real analysis, topic: Cesaro means and Stolz.

Taylor bounds with a sign. For $x \geq 0$ the partial sums of the alternating series for sin and cos bracket the function: $x - \frac{x^3}{6} \leq \sin x \leq x$ and $1 - \frac{x^2}{2} \leq \cos x \leq 1$. Prove them by the derivative ladder rather than quoting a remainder theorem when the write up must be self contained. See Book 1, field: Calculus and integrals, topic: Taylor inequalities.

Comparison and p series. $\sum n^{-q}$ converges if and only if $q > 1$; for nonnegative terms, a lower bound by a divergent series forces divergence and an upper bound by a convergent series forces convergence. See Book 1, field: Real analysis, topic: comparison tests.

Circuit Bank

- **WHEN** a series is built from the orbit of an iteration **DO** find the limit, then the derivative of the map at the limit **BECAUSE** derivative less than one in modulus means geometric decay and instant convergence, derivative exactly one means polynomial decay and a real question

- **WHEN** the fixed point is neutral and $f(x) = x - cx^{p+1} + \cdots$ **DO** substitute $b_n = x_n^{-p}$ and read off $b_{n+1} - b_n \to cp$ **BECAUSE** the reciprocal power turns a multiplicative decay into an additive drift, and additive drift is linear growth
- **WHEN** you are asked only to decide convergence or divergence **DO** prove a one sided bound and throw away the other half of the analysis **BECAUSE** divergence of nonnegative series follows from a lower bound alone, so the sharp constant is wasted ink
- **WHEN** you must prove an asymptotic bound by induction **DO** use a constant strictly weaker than the true one **BECAUSE** the induction step spends the slack between your constant and the truth, and with the sharp constant the statement is usually false for every n
- **WHEN** an inequality compares two positive expressions with square roots **DO** square both sides, then check that the leading terms cancel **BECAUSE** cancellation of the leading terms is the visible form of the slack, and what remains factorises

Backtesting

1. First useful cue: $\sin 0 = 0$ with derivative 1, so the fixed point is neutral and decay is polynomial; and $a_1 = 1$.
2. Method the expression suggested: read the decay exponent off the cubic term ($a_n \approx \sqrt{3/n}$), then prove the weaker one sided bound $a_n \geq n^{-1/2}$ by induction.
3. Where you would hesitate, and the thought to reinforce: choosing the constant in the bound. The thought is that the true constant $\sqrt{3}$ is approached from below, so any induction must use a strictly smaller constant; take 1 and the algebra factorises.
4. The trap the question sets: computing the full asymptotic. It is the natural instinct, it is four times the work, and it answers a question that was not asked.
5. What makes you recognise it faster next time: any iteration by sin, $\tan^{-1}$, $\log(1+x)$ or $x - x^2$ is a neutral fixed point problem, and the exponent comes from the first nonlinear term.
6. The reusable decision rule: for convergence questions about orbits, get the decay exponent from the first nonlinear term, then prove only the inequality that the requested direction needs.

Mirror drills

1. With the same a_n, determine all real $q > 0$ for which $\sum a_n^q$ converges. *Answer:* $a_n \sim \sqrt{3/n}$, so $a_n^q \sim 3^{q/2} n^{-q/2}$ and the series converges exactly when $q > 2$.
2. Let $x_0 = 1/2$ and $x_{n+1} = x_n - x_n^2$. Show $\sum x_n$ diverges and $\sum x_n^2$ converges. *Answer:* here $p = 1$, $c = 1$, so $x_n \sim 1/n$; the first series is harmonic and the second is a convergent p series. For a written proof, induct on $x_n \geq \frac{1}{n+2}$.
3. Let $x_0 = 1$ and $x_{n+1} = \log(1 + x_n)$. Find the decay rate of x_n and decide whether $\sum x_n^2$ converges. *Answer:* $\log(1+x) = x - x^2/2 + \cdots$, so $p = 1$, $c = 1/2$ and $x_n \sim 2/n$; hence $\sum x_n^2$ converges while $\sum x_n$ diverges.

6.4 A4. Splitting a strip and a derangement limit

Consider a horizontal strip of $N+2$ squares in which the first and the last square are black and the remaining N squares are all white. Choose a white square uniformly at random, choose one of its two neighbours with equal probability, and colour this neighbouring square black if it is not already black. Repeat this process until all the remaining white squares have only black neighbours. Let $w(N)$ be the expected number of white squares remaining. Find

$$\lim_{N\to\infty} \frac{w(N)}{N}.$$

Read it out loud

This is a random process on a one dimensional lattice that stops when no two white squares are adjacent, and you are asked for the asymptotic density of survivors. Say the structure out loud: the state is a set of white squares inside a strip with black walls; each step picks a white square and one of its two neighbours; the step does something only if that neighbour is white. The stopping condition, "every remaining white square has only black neighbours", is exactly "the white squares form an independent set in the path". The fields wired in are probability (expectation, conditioning, linearity), self similar recursion (the strip splits), and finally the analysis of a first order recursion with a factorial solution.

Two features are planted for you. First, many steps do nothing: if the chosen neighbour is already black, the configuration is unchanged. Those null steps cannot possibly matter for the final answer, so the first structural move is to condition on the steps that do something. Second, the moment any interior square turns black, it becomes a wall, and the strip becomes two shorter strips of exactly the same type, each with black ends. That is a self similarity cue as loud as any you will meet: the object after one effective move is two smaller copies of the original object.

Within thirty seconds you should have written $w(0) = 0$, $w(1) = 1$, and the sentence "condition on the first square to change colour, then the strip splits". The requested limit $w(N)/N$ tells you that w is asymptotically linear, which is a hint about how to normalise later.

Approaches, ranked worst to best

1. **Simulate and guess.** *Cue:* a concrete random process. *Circuit:* estimate $w(N)/N$ numerically. (Gives about 0.37 and points at $1/e$, which is useful reconnaissance and no more. A Putnam answer of $1/e$ demands the exponential series.)
2. **Markov chain on configurations.** *Cue:* a random process with states. *Circuit:* write the transition matrix. (The state space is all subsets of the strip; nothing is computable and nothing simplifies.)
3. **Linearity of expectation over individual squares.** *Cue:* expectation of a count. *Circuit:* $w(N) = \sum_i \Pr[\text{square } i \text{ stays white}]$. (The right instinct in general, but here each of those probabilities depends on i and on N through the same self similar structure, so you must solve the recursion anyway. It postpones the work rather than doing it.)
4. **Condition on the first effective move, then guess the closed form and verify by induction.** *Cue:* the strip splits after one square changes colour. *Circuit:* recursion in N, then induction. (This is the official route and it is correct. Its weakness is the middle: after differencing you hold $w(N) = w(N-1) + w(N-2)/(N-1)$ and you must already know the answer $(N+1)\sum_{k\le N+1}(-1)^k/k!$ in order to verify it. A verification is not a derivation, and in the arena you may not have guessed the right closed form.)
5. **Condition on the first effective move, then solve the recursion by normalising.** *Cue:* the requested limit is $\lim w(N)/N$, so w is asymptotically linear. *Circuit:* substitute $w(N) =$

$(N+1)u_N$, difference, telescope. (Best. The substitution is chosen so that the only denominator cancels, the recursion collapses to $d_N = -d_{N-1}/(N+1)$ for the increments $d_N = u_N - u_{N-1}$, and telescoping produces the alternating factorial series with no guessing at all. The exponential appears as the limit of its own series, which is the only honest way to arrive at $1/e$.)

The ideal solution

The answer is $\boxed{1/e}$.

Number the squares 1 to $N+2$ from left to right, so squares 1 and $N+2$ are black and squares 2 to $N+1$ are white initially. Set $w(0) = 0$ and $w(1) = 1$, both immediate: with $N = 1$ the single white square already has two black neighbours.

Step 1: only effective moves matter. A move is the ordered pair (chosen white square, chosen neighbour). Call a move *effective* if the chosen neighbour is white. A move that is not effective leaves the configuration unchanged, so the final configuration is a function of the sequence of effective moves alone. If W white squares remain, every pair (white square, direction) has probability $\frac{1}{2W}$, so conditional on a move being effective it is uniformly distributed over the effective pairs available at that moment. As long as two white squares are adjacent there is at least one effective pair, so each move is effective with probability at least $\frac{1}{2N}$, and therefore effective moves occur almost surely; each one decreases the number of white squares by one, so the process terminates after at most N effective moves.

Step 2: the first square to change colour. Let $N \geq 2$. Initially the effective pairs are: square i with its left neighbour, for $3 \leq i \leq N+1$, colouring square $i-1$; and square i with its right neighbour, for $2 \leq i \leq N$, colouring square $i+1$. There are $2(N-1)$ of them, all equally likely. Square j is produced by exactly two of these pairs when $3 \leq j \leq N$, and by exactly one when $j = 2$ or $j = N+1$. Hence the first square to be coloured is j with probability

$$p_j = \frac{1}{N-1}\ (3 \leq j \leq N), \qquad p_2 = p_{N+1} = \frac{1}{2(N-1)}.$$

Step 3: the strip splits. Once square j is black, no future move involves a square on the left of j together with a square on the right of j, since every move acts on a pair of adjacent squares. So the configuration is a system on squares 1 to j (black at both ends, $j-2$ white inside) and a system on squares j to $N+2$ (black at both ends, $N+1-j$ white inside). By Step 1, the effective moves available at any later time are the disjoint union of those available in the two systems, and a uniform choice from a disjoint union restricts to a uniform choice within each part; hence, viewed only at its own effective moves, each system evolves exactly as a standalone system of its size. By linearity of expectation (independence of the two sides is not needed), the conditional expectation of the final number of white squares, given that square j was coloured first, is $w(j-2) + w(N+1-j)$.

Step 4: the recursion. For $N \geq 2$, using $w(0) = 0$ and the reversal $j \mapsto N+3-j$ inside the sum,

$$w(N) = \frac{w(N-1)+w(0)}{N-1} + \frac{1}{N-1}\sum_{j=3}^{N}\big(w(j-2)+w(N+1-j)\big),$$

so

$$(N-1)\,w(N) = w(N-1) + 2\sum_{m=1}^{N-2} w(m).$$

Step 5: remove the sum. Writing that identity with $N-1$ in place of N (valid for $N \geq 3$) and subtracting,

$$(N-1)w(N) - (N-2)w(N-1) = w(N-1) - w(N-2) + 2w(N-2),$$

that is $(N-1)w(N) = (N-1)w(N-1) + w(N-2)$, so

$$w(N) = w(N-1) + \frac{w(N-2)}{N-1} \qquad (N \geq 3),$$

and it also holds at $N = 2$, where both sides equal 1.

Step 6: solve it. Substitute $w(N) = (N+1)u_N$, the factor $N+1$ being chosen so that the coefficient $\frac{1}{N-1}$ cancels. Then the recursion becomes $(N+1)u_N = Nu_{N-1} + u_{N-2}$, and subtracting $(N+1)u_{N-1}$ from both sides,

$$(N+1)(u_N - u_{N-1}) = -(u_{N-1} - u_{N-2}).$$

So the increments $d_N = u_N - u_{N-1}$ satisfy $d_N = -\frac{d_{N-1}}{N+1}$ for $N \geq 2$, with $d_1 = u_1 - u_0 = \frac{1}{2} - 0 = \frac{1}{2}$. Telescoping the product,

$$d_N = (-1)^{N-1}\frac{1}{2}\prod_{i=2}^{N}\frac{1}{i+1} = (-1)^{N-1}\frac{1}{2}\cdot\frac{2}{(N+1)!} = \frac{(-1)^{N-1}}{(N+1)!},$$

and summing the increments from $u_0 = 0$,

$$u_N = \sum_{j=1}^{N}\frac{(-1)^{j-1}}{(j+1)!} = \sum_{k=2}^{N+1}\frac{(-1)^k}{k!} = \sum_{k=0}^{N+1}\frac{(-1)^k}{k!},$$

the last step because the terms $k = 0$ and $k = 1$ cancel. Hence

$$w(N) = (N+1)\sum_{k=0}^{N+1}\frac{(-1)^k}{k!} \qquad (N \geq 0).$$

Step 7: the limit. Since $\sum_{k\geq 0}(-1)^k/k! = e^{-1}$,

$$\lim_{N\to\infty}\frac{w(N)}{N} = \lim_{N\to\infty}\frac{N+1}{N}\sum_{k=0}^{N+1}\frac{(-1)^k}{k!} = 1\cdot e^{-1} = \frac{1}{e}.$$

Layer 1: WHAT

Block 1: discard null moves and work with the embedded sequence of effective moves. Block 2: compute the law of the first square to change colour, $2(N-1)$ equally likely pairs. Block 3: observe that a black interior square is a wall, so the strip becomes two strips of the same type, and apply linearity of expectation. Block 4: assemble the recursion $(N-1)w(N) = w(N-1) + 2\sum_{m\leq N-2} w(m)$. Block 5: difference two consecutive instances to kill the sum, giving $w(N) = w(N-1) + w(N-2)/(N-1)$. Block 6: substitute $w(N) = (N+1)u_N$, get $d_N = -d_{N-1}/(N+1)$ for the increments, telescope, recognise the alternating exponential series. Block 7: take the limit.

Juxtaposition. The nominal route conditions on the first move, including the moves that change nothing, and immediately has to describe the configuration after a null move, which is the same configuration; the recursion then refers to itself with no progress and the candidate abandons it for simulation. A second nominal route computes Pr[square i survives] for each i and drowns in boundary cases. The bifurcation point is the sentence "choose a white square and one of its neighbours". The zombie treats every choice as a step of the process; you separate the moves that alter the state from those that do not, and condition on the former. Everything downstream follows from that one sentence.

Layer 2: HOW

Block 1. **Cue.** "Colour this neighbouring square black *if it is not already black*." **Why natural.** The conditional clause is the examiners telling you that some moves are null. Null moves do not change the state, so they cannot change the final configuration; they only change how long the process takes, and you were not asked about the time. Conditioning on effectiveness is legitimate because all pairs are equally likely at any instant, so the conditional law of an effective move is uniform on the currently effective pairs. **Link to the next block.** With null moves removed, the process is a sequence of state changes and you may condition on the first one.

Block 2. **Cue.** A finite, explicitly listable set of possible first changes. **Why natural.** Count pairs, not squares. Each interior square j with $3 \le j \le N$ can be reached from the left or from the right, whereas squares 2 and $N+1$ can only be reached from one side, since square 1 and square $N+2$ are already black and are never chosen. That asymmetry at the two ends is exactly the factor $\frac{1}{2}$ in p_2 and p_{N+1}, and it is the standard place to lose the problem. **Link to the next block.** You now have a probability for each possible first wall, and the wall is what makes the recursion.

Block 3. **Cue.** Every move acts on two adjacent squares, and the newly black square sits between the two halves. **Why natural.** A black square is absorbing and is never chosen (only white squares are chosen), so it acts as a permanent wall identical to the walls at the two ends. The two halves are therefore instances of the same problem with smaller parameters. Note what you do *not* need: independence of the two halves. Expectation is linear, so the marginal law on each side is enough, and the marginal law is the standalone process by the uniform restriction argument. **Link to the next block.** Self similarity plus known probabilities gives a closed recursion.

Block 4. **Cue.** A conditional expectation summed against p_j. **Why natural.** The sum $\sum_{j=3}^{N}(w(j-2)+w(N+1-j))$ runs over the same list of values twice in opposite orders, so it is $2\sum_{m=1}^{N-2} w(m)$. Multiply through by $N-1$ so that no fractions survive. A recursion in which $w(N)$ depends on all earlier values is a signal, not an obstacle. **Link to the next block.** A recursion containing $\sum_{m<N} w(m)$ is always attacked the same way.

Block 5. **Cue.** The recursion contains a running sum with a coefficient linear in N. **Why natural.** Write the same identity for $N-1$ and subtract: the two running sums differ by exactly one term, so the sum disappears and a short recursion remains. This is the standard device for every recursion of quicksort type, and it is why such recursions have clean solutions. **Link to the next block.** You now hold a two term recursion with a variable coefficient, which needs a normalisation before it will telescope.

Block 6. **Cue.** The question asks for $\lim w(N)/N$, and the recursion has the single denominator $N-1$. **Why natural.** Since the answer is a limit of $w(N)/N$, the natural unknown is $w(N)$ divided by a linear factor. Choose the factor to kill the denominator: with $w(N) = (N+a)u_N$ the last term becomes $\frac{N-2+a}{N-1}u_{N-2}$, which is exactly u_{N-2} when $a = 1$. That is the whole reason for the substitution; it is a choice made to cancel, not a guess. The resulting relation is a first order recursion in the increments, and first order recursions with rational ratios telescope into factorials, which is where $\sum(-1)^k/k!$ and hence e^{-1} come from. **Link to the next block.** Summing the increments gives the closed form and the limit follows from the exponential series.

Layer 3: WHY

The truth beneath this problem is self similar fragmentation. A random process that cuts a structure into two independent smaller copies of itself produces a recursion of the form $E_N = \sum_j p_j(E_{L(j)} +$

$E_{R(j)}$), and when the cut position is close to uniform the recursion always has the same two features: a running sum, removable by differencing, and a variable coefficient, removable by a linear normalisation. Quicksort, random binary search trees, and the parking problems all live in this family. The only thing that changes from problem to problem is the law of the cut, and here it is uniform on $2(N-1)$ ordered pairs, which is uniform on the cut positions apart from a halving at the two extreme positions.

The second truth is the appearance of e^{-1}. The closed form $w(N) = (N+1)\sum_{k=0}^{N+1}(-1)^k/k!$ says exactly that

$$\frac{w(N)}{N+1} = \frac{D_{N+1}}{(N+1)!} = \Pr[\text{a uniform random permutation of } N+1 \text{ letters has no fixed point}],$$

where D_m is the number of derangements; indeed $w(N) = D_{N+1}/N!$ turns the recursion $w(N) = w(N-1) + \frac{w(N-2)}{N-1}$ into the classical $D_m = (m-1)(D_{m-1} + D_{m-2})$. That identity is proved here through the recursion, and a direct combinatorial explanation via random permutations is known and worth hunting for. Whenever a limit of $1/e$ appears in a discrete problem, look for an inclusion and exclusion or a derangement in the background; the alternating factorial series is its signature.

The discernment mechanism: when a random process is described procedurally, ask three questions in order. Which moves change the state? What does one state change do to the structure? Is the resulting structure a smaller copy of the original? If the answers are "some", "it splits it", and "yes", you write a recursion and stop thinking about probability. Train it on this problem by deliberately writing the recursion before computing a single probability, then filling the probabilities in.

Revolving concepts

Embedded (jump) process. If a Markov process has moves that leave the state unchanged, the sequence of states visited is unchanged by deleting them, and conditional on a move being a state change, its law is the original law restricted and renormalised to the state changing moves. Use this whenever a process description contains "if it is not already". See Book 1, field: Probability, topic: jump chains and uniformisation.

Linearity of expectation without independence. $E[X+Y] = E[X] + E[Y]$ always holds. In splitting arguments this means you need only each part's marginal law, never joint independence, which is usually the harder thing to justify. See Book 1, field: Probability, topic: linearity of expectation.

Fragmentation recursions and the differencing trick. A recursion of the form $c_N a_N = b_N + \sum_{m<N} \lambda_m a_m$ is solved by writing the same identity at $N-1$ and subtracting, which reduces the order to two or one. The general shape here is the quicksort recursion $Na_N = f(N) + 2\sum_{m<N} a_m$, giving $Na_N - (N-1)a_{N-1} = f(N) - f(N-1) + 2a_{N-1}$. See Book 1, field: Sequences and recurrences, topic: recursions with running sums.

First order recursions with rational ratios. $d_N = r(N)d_{N-1}$ has the solution $d_N = d_1 \prod_{i=2}^{N} r(i)$. When $r(N) = \pm\frac{1}{N+c}$ the product is a reciprocal factorial, so the increments are $\pm 1/(N+c)!$ and their sum is a truncated exponential series. This is the general mechanism by which e and e^{-1} enter recursion problems. See Book 1, field: Sequences and recurrences, topic: telescoping products.

Derangements. $D_m = m!\sum_{k=0}^{m}\frac{(-1)^k}{k!}$, $D_m = mD_{m-1} + (-1)^m$, $D_m = (m-1)(D_{m-1} + D_{m-2})$, and $D_m/m! \to e^{-1}$. Here $w(N) = D_{N+1}/N!$. See Book 1, field: Combinatorics, topic: inclusion and exclusion, derangements.

Independent sets in a path as a stopping condition. "Every white square has only black neighbours" means the white set is independent in the path graph. The maximum such set has size $\lceil N/2 \rceil$, so $w(N) \le \lceil N/2 \rceil$ and the limit is at most $1/2$; the answer $1/e \approx 0.368$ sits comfortably below. Use such crude bounds as a sanity check on any answer you produce. See Book 1, field: Discrete structures and graphs, topic: independent sets in paths.

Circuit Bank

- **WHEN** a process description contains "if it is not already" **DO** condition on the moves that actually change the state and ignore the rest **BECAUSE** null moves cannot affect the final configuration, and conditioning on effectiveness keeps the uniform law over the moves that matter
- **WHEN** one move turns a structure into two smaller copies of itself **DO** write a recursion by conditioning on where the split happens, using linearity of expectation **BECAUSE** expectation is additive over the two parts, so only the marginal law on each part is needed and independence never has to be proved
- **WHEN** a recursion contains a sum of all earlier terms **DO** write the identity at $N-1$ and subtract **BECAUSE** the two running sums differ by one term, so differencing lowers the order and leaves a short recursion
- **WHEN** you must solve $a_N = a_{N-1} + \frac{a_{N-2}}{N-1}$ or similar **DO** substitute $a_N = (N+c)u_N$ with c chosen so the fractional coefficient becomes 1 **BECAUSE** the substitution is engineered to cancel the denominator, after which the increments obey a first order recursion that telescopes
- **WHEN** a discrete limit turns out to be $1/e$ **DO** look for derangements, inclusion and exclusion, or a truncated alternating factorial series **BECAUSE** the alternating series $\sum(-1)^k/k!$ is the only common source of e^{-1} in a counting problem

Backtesting

1. First useful cue: "if it is not already black" announces null moves, and a newly blackened interior square is a wall that splits the strip.
2. Method the expression suggested: condition on the first effective move, use self similarity and linearity of expectation, then solve the recursion.
3. Where you would hesitate, and the thought to reinforce: the endpoints $j = 2$ and $j = N+1$ have half the probability of the interior positions, because they can be reached from only one side. Count ordered pairs (square, direction), never squares, and the halving appears automatically.
4. The trap the question sets: trying to compute the survival probability of each individual square, or trying to track the process in real time including null moves. Both are correct in principle and neither terminates.
5. What makes you recognise it faster next time: a random process on an interval where one event creates a permanent wall is always a fragmentation recursion, and fragmentation recursions are always attacked by differencing then normalising.
6. The reusable decision rule: delete null moves, condition on the first real move, exploit self similarity with linearity of expectation, difference away any running sum, normalise by a linear factor chosen to cancel the denominator.

Mirror drills

1. From $(N-1)w(N) = w(N-1) + 2\sum_{m=1}^{N-2} w(m)$, derive $w(N) = w(N-1) + \frac{w(N-2)}{N-1}$. *Answer:* write the identity at $N-1$, subtract, and note the two running sums differ by the single term $2w(N-2)$.
2. Solve $d_N = -\frac{d_{N-1}}{N+1}$ for $N \geq 2$ with $d_1 = \frac{1}{2}$. *Answer:* $d_N = \frac{1}{2}(-1)^{N-1}\prod_{i=2}^{N}(i+1)^{-1} = \frac{(-1)^{N-1}}{(N+1)!}$.

3. Show that $D_m = (m-1)(D_{m-1} + D_{m-2})$ with $D_1 = 0$, $D_2 = 1$ implies $D_m = mD_{m-1} + (-1)^m$, and hence $D_m/m! = \sum_{k=0}^{m} (-1)^k/k!$. *Answer:* set $e_m = D_m - mD_{m-1}$; the first recursion gives $e_m = -e_{m-1}$ with $e_2 = 1$, so $e_m = (-1)^m$; dividing $D_m = mD_{m-1} + (-1)^m$ by $m!$ telescopes.

6.5 A5. Counting Fibonacci representations by complementation

Let a_n be the number of sets S of positive integers for which

$$\sum_{k\in S} F_k = n,$$

where the Fibonacci sequence $(F_k)_{k\geq 1}$ satisfies $F_{k+2} = F_{k+1} + F_k$ and begins $F_1 = 1$, $F_2 = 1$, $F_3 = 2$, $F_4 = 3$. Find the largest integer n such that $a_n = 2020$.

Read it out loud

This is a representation counting function. The sets S are sets of *indices*, not of values, so F_1 and F_2 are two different summands that happen both to equal 1; that is why $a_1 = 2$ and not 1. The command term is "find the largest n with $a_n = 2020$", which carries two hidden assertions: that a is not monotone (otherwise you would say "the" n), and that $\{n : a_n \leq 2020\}$ is finite, so that some last n exists. Your solution must supply both an n with $a_n = 2020$ and a proof that everything beyond it is strictly larger.

The fields wired in are Fibonacci arithmetic, representation counting in a numeration system, and one involution. The structural cue is the identity

$$F_1 + F_2 + \cdots + F_{m-1} = F_{m+1} - 1.$$

Read that out loud: the total of all the summands available below index m is one less than a Fibonacci number. Whenever the total of your available weights is a known number T, the map "take the complementary subset" is an involution turning a representation of n into a representation of $T - n$. That is the entire engine of this problem: it converts the case "the top index is not used" into another instance of the same counting function.

Within thirty seconds you should have $a_0 = 1$ (empty set), $a_1 = a_2 = 2$, $a_3 = a_4 = 3$, and the observation that Fibonacci numbers cut the integers into blocks $[F_m, F_{m+1})$. Answers of the form $F_{4040} - 1$ live at block boundaries, so the whole game will be to evaluate a at the two landmarks F_m and $F_{m+1} - 1$ and to bound it from below in between.

Approaches, ranked worst to best

1. **Tabulate a_n and look for a pattern.** *Cue:* a concrete counting function. *Circuit:* compute by dynamic programming and stare. (Essential reconnaissance and worthless as a proof: the answer involves F_{4040}, a number with over eight hundred digits.)

2. **Generating function $\prod_{k\geq 1}(1 + x^{F_k})$.** *Cue:* counting subsets with a prescribed sum. *Circuit:* coefficients of a product. (Correct as a definition, useless as a tool: the product has no closed form and no functional equation you can exploit here.)

3. **Zeckendorf plus local rewriting.** *Cue:* every representation is reachable from the greedy one. *Circuit:* repeatedly replace F_k by $F_{k-1} + F_{k-2}$ and count reachable states. (This is the official second route. It genuinely works and even gives a product formula over the blocks of the Zeckendorf bitstring, but the bookkeeping of the strings $(10)^k 0^\ell$ and their rewritings is long, and the final inequality needs a separate argument.)

4. **Split on the largest usable index, then complement.** *Cue:* the top index is either used or not, and the total below it is $F_{m+1} - 1$. *Circuit:* $a_n = a_{n-F_m} + a_{F_{m+1}-1-n}$ for $F_m \leq n < F_{m+1}$. (Best. Two cases, one line each, and the second case is handled by an involution rather than by a new idea. The recursion evaluates the landmarks immediately and drives the lower bound by induction.)

The ideal solution

The answer is $\boxed{n = F_{4040} - 1}$.

Throughout, $a_0 = 1$, counting the empty set. Two elementary facts:

Lemma 6.5.1 (partial sums, and existence of a representation). $\sum_{k=1}^{m-1} F_k = F_{m+1} - 1$ *for every* $m \geq 1$, *and* $a_n \geq 1$ *for every* $n \geq 0$.

Proof. For the identity, $F_k = F_{k+2} - F_{k+1}$ makes the sum telescope to $F_{m+1} - F_2 = F_{m+1} - 1$; for $m = 1$ the empty sum is $0 = F_2 - 1$. For the second statement, induct strongly on n: for $n \geq 1$ choose the largest m with $F_m \leq n$; then $n - F_m < F_{m+1} - F_m = F_{m-1} \leq F_m$, so by induction $n - F_m$ has a representation, and every index k occurring in it satisfies $F_k \leq n - F_m < F_m$, hence $k < m$; adjoining m gives a representation of n. □

Lemma 6.5.2 (top index recursion). *Let* $m \geq 2$ *and* $F_m \leq n < F_{m+1}$. *Then*

$$a_n = a_{n-F_m} + a_{F_{m+1}-1-n}.$$

Proof. Every S counted by a_n satisfies $\max S \leq m$, since $F_k \geq F_{m+1} > n$ for $k \geq m+1$. Split on whether $m \in S$.

Suppose $m \in S$. Then $S \setminus \{m\} \subseteq \{1, \ldots, m-1\}$ has sum $n - F_m$. Conversely, let T be *any* set with sum $n - F_m$. Since $n - F_m < F_{m+1} - F_m = F_{m-1} \leq F_m$, every index $k \in T$ has $F_k \leq n - F_m < F_m$, so $k < m$ and $T \cup \{m\}$ is counted by a_n. These two maps are mutually inverse, so this case contributes a_{n-F_m}.

Suppose $m \notin S$. Then $S \subseteq \{1, \ldots, m-1\}$, and by the partial sums lemma the complementary set $\{1, \ldots, m-1\} \setminus S$ has sum $(F_{m+1} - 1) - n$. Conversely, let U be *any* set with sum $F_{m+1} - 1 - n$. Since $n \geq F_m$ we have $F_{m+1} - 1 - n \leq F_{m-1} - 1 < F_m$, so as before $U \subseteq \{1, \ldots, m-1\}$, and $\{1, \ldots, m-1\} \setminus U$ is counted by a_n and omits m. Complementation inside $\{1, \ldots, m-1\}$ is an involution, so this case contributes $a_{F_{m+1}-1-n}$. □

Write $c_m = a_{F_m - 1}$ for $m \geq 2$, so $c_2 = a_0 = 1$ and $c_3 = a_1 = 2$.

Lemma 6.5.3 (the two landmarks). *For* $m \geq 2$,

$$a_{F_m} = a_{F_{m+1}-1} = 1 + c_{m-1} \quad (m \geq 3), \qquad \text{and} \qquad c_m = \left\lfloor \frac{m+1}{2} \right\rfloor, \qquad a_{F_m} = \left\lfloor \frac{m+2}{2} \right\rfloor.$$

Proof. Apply the top index recursion at the two ends of the block $[F_m, F_{m+1})$. At $n = F_m$ it gives $a_{F_m} = a_0 + a_{F_{m-1}-1} = 1 + c_{m-1}$. At $n = F_{m+1} - 1$, which lies in the block because $F_{m+1} - 1 \geq F_m$, it gives $a_{F_{m+1}-1} = a_{F_{m-1}-1} + a_0 = 1 + c_{m-1}$. The second of these says $c_{m+1} = c_{m-1} + 1$ for $m \geq 3$, and one checks $c_4 = a_2 = 2 = c_2 + 1$ directly, so $c_{m+1} = c_{m-1} + 1$ for all $m \geq 3$. With $c_2 = 1$ and $c_3 = 2$, the even and odd subsequences are arithmetic with common difference 1, giving $c_m = \lfloor (m+1)/2 \rfloor$. Hence $a_{F_m} = 1 + \lfloor m/2 \rfloor = \lfloor (m+2)/2 \rfloor$ for $m \geq 3$, and also for $m = 2$ since $a_{F_2} = a_1 = 2$. □

Lemma 6.5.4 (block minimum). *For* $m \geq 2$ *and* $F_m \leq n < F_{m+1}$ *we have* $a_n \geq \lfloor (m+2)/2 \rfloor$.

Proof. Strong induction on m. For $m = 2, 3, 4$ the blocks are $\{1\}$, $\{2\}$, $\{3, 4\}$ and the values $a_1 = a_2 = 2$, $a_3 = a_4 = 3$ meet the bounds $2, 2, 3$.

Let $m \geq 5$ and put $j = n - F_m$ and $j' = F_{m+1} - 1 - n$, so that $j, j' \geq 0$, $j + j' = F_{m-1} - 1$, and $a_n = a_j + a_{j'}$ by the top index recursion. The expression is symmetric in j and j', so assume $j \leq j'$.

If $j = 0$, then $j' = F_{m-1} - 1$, and $F_{m-2} \leq F_{m-1} - 1 < F_{m-1}$ because $F_{m-3} \geq 1$. So j' lies in block $m - 2$ and the induction hypothesis gives $a_{j'} \geq \lfloor m/2 \rfloor$, whence $a_n = 1 + a_{j'} \geq 1 + \lfloor m/2 \rfloor = \lfloor (m+2)/2 \rfloor$.

If $j \geq 1$, then $a_j \geq 2$: indeed j lies in some block, so the top index recursion writes a_j as a sum of two values of a, each at least 1 by the partial sums lemma. For j', note $j' \geq \frac{1}{2}(F_{m-1} - 1) \geq F_{m-3}$, the

last inequality being equivalent to $F_{m-3}+1 \le F_{m-2}$, which holds since $m \ge 5$. Also $j' \le F_{m-1}-1 < F_{m-1}$. So j' lies in a block with index q satisfying $m-3 \le q \le m-2$, and the induction hypothesis gives $a_{j'} \ge \lfloor (m-1)/2 \rfloor$. Therefore

$$a_n \ge 2 + \left\lfloor \frac{m-1}{2} \right\rfloor \ge \left\lfloor \frac{m+2}{2} \right\rfloor,$$

with equality when m is even and strict inequality when m is odd. □

Now finish. By the landmark lemma, $a_{F_{4040}-1} = c_{4040} = \lfloor 4041/2 \rfloor = 2020$. If $n > F_{4040}-1$, then $n \ge F_{4040}$, so n lies in a block $[F_m, F_{m+1})$ with $m \ge 4040$, and the block minimum lemma gives

$$a_n \ge \left\lfloor \frac{m+2}{2} \right\rfloor \ge \left\lfloor \frac{4042}{2} \right\rfloor = 2021 > 2020.$$

Hence no n larger than $F_{4040}-1$ has $a_n = 2020$, and $n = F_{4040}-1$ is the largest such integer.

Layer 1: WHAT

Block 1: fix the convention $a_0 = 1$ and compute the first few values, noticing the equal pairs $a_1 = a_2$, $a_3 = a_4$. Block 2: prove $\sum_{k \le m-1} F_k = F_{m+1} - 1$, the identity that makes complementation available. Block 3: split a representation on whether it uses the largest usable index m, and convert the "not used" case by complementing inside $\{1, \dots, m-1\}$; this gives $a_n = a_{n-F_m} + a_{F_{m+1}-1-n}$. Block 4: evaluate at the two ends of the block to get $a_{F_m} = a_{F_{m+1}-1} = 1 + a_{F_{m-1}-1}$, a lag two recursion, hence $\lfloor (m+1)/2 \rfloor$ and $\lfloor (m+2)/2 \rfloor$. Block 5: prove that the block minimum is attained at the ends, by induction using the same recursion. Block 6: read off the last block where the value 2020 can occur.

Juxtaposition. The nominal route computes a_n for n up to a few hundred, spots that the small values of a occur at $n = F_m$ and $n = F_m - 1$, guesses the answer $F_{4040}-1$, and then has no mechanism to prove that a_n never returns to 2020 later. The gap is not the formula, it is the monotone lower envelope. The ideal route builds one recursion that serves both purposes: evaluating the landmarks and bounding the interior. The bifurcation point is the sentence "suppose $m \notin S$". The zombie treats that case as a new, harder counting problem over $\{1, \dots, m-1\}$; you complement it and land back inside the same function a.

Layer 2: HOW

Block 1. **Cue.** Sets of indices, with $F_1 = F_2 = 1$ both available. **Why natural.** The problem says "sets S of positive integers" and the sum runs over $k \in S$, so the objects are index sets. Computing $a_1 = 2$ immediately confirms it and stops you from silently deduplicating the two ones. Small values are also what tell you the answer will be phrased at Fibonacci landmarks. **Link to the next block.** To say anything about a_n you must control which indices can appear, and that is decided by the block containing n.

Block 2. **Cue.** $F_m \le n < F_{m+1}$ bounds the largest usable index. **Why natural.** If $k \ge m+1$ then $F_k > n$, so index k cannot appear at all. The Fibonacci blocks are therefore the natural coordinates for this function, exactly as powers of ten are the natural coordinates for a digit problem. Every statement you prove should be indexed by the block. **Link to the next block.** Inside a block, the only structural question left is whether the top index m is used.

Block 3. **Cue.** A binary choice: is m in S or not. **Why natural.** This is the standard first move for counting representations in any numeration system, because removing the largest weight reduces the problem to the same problem with a smaller target. The "used" branch is immediate. The "not used" branch would normally be a different problem (subsets of a restricted index range), and the

reason it is not is the identity $\sum_{k\le m-1} F_k = F_{m+1} - 1$: complementation inside $\{1,\dots,m-1\}$ is a bijection onto representations of $F_{m+1}-1-n$, and, crucially, every representation of that number automatically lives inside $\{1,\dots,m-1\}$, so the count is the unrestricted $a_{F_{m+1}-1-n}$. **Link to the next block.** You now have a self referential recursion whose two arguments add up to $F_{m-1}-1$.

Block 4. **Cue.** The two arguments j and j' satisfy $j + j' = F_{m-1} - 1$, so at the ends of the block one of them is 0. **Why natural.** Evaluating a recursion at the extreme cases is free information, and here both ends give the same value, which explains the observed pairs $a_1 = a_2$ and $a_3 = a_4$. The resulting relation $c_{m+1} = c_{m-1} + 1$ has lag two, so it splits by parity into two arithmetic progressions; that parity split is where the floor function in the answer is born. **Link to the next block.** The landmarks give candidates for $a_n = 2020$; to know they are the last ones you must bound the interior of every later block.

Block 5. **Cue.** A recursion that expresses a_n as a sum of two values at smaller arguments. **Why natural.** Any such recursion converts a lower bound on all earlier blocks into a lower bound on the current one, provided you can locate the blocks of j and j'. With $j \le j'$ you always have $j' \ge \frac{1}{2}(F_{m-1}-1)$, and since F_{m-3} is less than half of F_{m-1} (the ratio tends to $\varphi^{-2} \approx 0.382$), j' sits in block $m-3$ or later. The other term is at least 2 whenever $j \ge 1$, and at least 1 always. Those two crude facts are exactly enough. **Link to the next block.** The block minimum is $\lfloor (m+2)/2 \rfloor$, an increasing function of m, so the set of n with $a_n \le 2020$ is finite and its last element is at the end of block 4039.

Block 6. **Cue.** $\lfloor (m+2)/2 \rfloor = 2021$ first happens at $m = 4040$. **Why natural.** $c_m = 2020$ has the two solutions $m = 4039$ and $m = 4040$, so $a_n = 2020$ at $n = F_{4039} - 1$ and at $n = F_{4040} - 1$; the larger is the answer. Everything from F_{4040} onwards is at least 2021 by the block minimum. State both halves: the value is attained, and nothing later attains it. **Link to the next block.** Nothing remains.

Layer 3: WHY

The truth beneath this problem is that a representation counting function in a numeration system is governed by a recursion on the leading digit, and that Fibonacci weights have one extra gift: the partial sums of the weights are again (nearly) weights. In base ten, the analogue of the identity $\sum_{k\le m-1} F_k = F_{m+1} - 1$ is $\sum_{k\le m-1} 9 \cdot 10^k = 10^m - 1$, which is exactly what makes "nines complement" arithmetic work. Complementation is available whenever the total weight is a landmark, and it converts an "omitted" case into an "included" case at a reflected target. That is why the second branch of the recursion costs nothing.

The second truth is about extremal questions for non monotone functions. To find the last n with $a_n = c$, you need a monotone lower envelope: a function $\mu(m)$, increasing, with $a_n \ge \mu(m)$ throughout block m, and equality somewhere. Here $\mu(m) = \lfloor (m+2)/2 \rfloor$, and equality holds at both ends of each block. The general shape of such an argument is: recursion, then induction on the block index, then the observation that the minimum of a sum is attained when the split is as lopsided as possible. Lopsided splits give one term equal to $a_0 = 1$, so representations of F_m and of $F_{m+1} - 1$ are the scarcest, and that scarcity grows by one every two blocks because the recursion has lag two.

The discernment mechanism: whenever a problem counts representations, ask what the largest usable weight is, split on it, and then look for an identity that lets you reflect the omitted case. Train it by proving the same recursion for base b digits and for the Zeckendorf system, and by computing the first twenty values of a_n by hand so that the landmark pattern is familiar rather than surprising. The examiners nudged you by choosing $2020 = \lfloor 4041/2 \rfloor$, a value that lands exactly on a landmark, and by starting the Fibonacci indexing at $F_1 = F_2 = 1$, which doubles every count at the bottom and forces you to read the definition carefully.

Revolving concepts

Zeckendorf representation. Every positive integer is a sum of Fibonacci numbers with indices at least 2, no two consecutive, and this representation is unique; it is produced by the greedy algorithm. The count a_n is the number of *all* representations, of which the Zeckendorf one is a single member, and every other representation is obtained from it by repeatedly rewriting $F_k \to F_{k-1} + F_{k-2}$. See Book 1, field: Number theory, topic: numeration systems and Zeckendorf.

Fibonacci partial sums. $\sum_{k=1}^{m} F_k = F_{m+2} - 1$, proved by telescoping $F_k = F_{k+2} - F_{k+1}$. Companions worth banking: $\sum F_{2k-1} = F_{2m}$, $\sum F_{2k} = F_{2m+1} - 1$, $\sum F_k^2 = F_m F_{m+1}$. See Book 1, field: Sequences and recurrences, topic: Fibonacci identities.

Complementation involution. If the available weights have total T, then $S \mapsto S^c$ is an involution on subsets carrying sum n to sum $T - n$, so the two counts are equal. This is the only content of the second branch of the recursion, and it is a general tool: any subset sum count is symmetric about $T/2$. See Book 1, field: Combinatorics, topic: involutions and symmetric subset sums.

Leading weight recursion (the general form). Let $u_1 \le u_2 \le \cdots$ be weights with partial sums $U_m = u_1 + \cdots + u_m$, and let $r(n)$ be the number of subsets of indices with weight sum n. If $u_m \le n$ and every representation of n omits all indices above m, then

$$r(n) = r(n - u_m) + \#\{\text{subsets of } \{1, \ldots, m-1\} \text{ of sum } n\} = r(n - u_m) + r(U_{m-1} - n),$$

the last equality when every representation of $U_{m-1} - n$ automatically avoids indices above $m - 1$. This is the general digit dynamic programme; the Fibonacci case is special only because $U_{m-1} = F_{m+1} - 1$ is itself a landmark. See Book 1, field: Combinatorics, topic: counting representations in numeration systems.

Lag two recursions. $c_{m+1} = c_{m-1} + d$ splits into two independent arithmetic progressions along the even and odd indices, giving $c_m = c_{m_0} + d\lfloor (m - m_0)/2 \rfloor$ on each parity class, which is why floor functions of the form $\lfloor (m+1)/2 \rfloor$ appear in the answer. The same split handles $u_{m+2} = u_m + f(m)$ in general: sum f over the arithmetic progression of the appropriate parity. See Book 1, field: Sequences and recurrences, topic: recursions with lag greater than one.

Circuit Bank

- **WHEN** you must count representations of n as a sum of distinct weights **DO** split on whether the largest usable weight is used **BECAUSE** removing the largest weight reduces to the same problem at a smaller target, and everything above it is excluded by size
- **WHEN** the total of all weights below the top equals a landmark such as $F_{m+1} - 1$ or $10^m - 1$ **DO** complement the subset instead of treating the omitted case separately **BECAUSE** complementation is an involution sending sum n to sum (total minus n), so the omitted case is the same counting function at a reflected argument
- **WHEN** a recursion relates a value to two earlier values whose arguments sum to a constant **DO** evaluate at the extreme splits first **BECAUSE** extreme splits force one argument to zero, which gives the landmark values and usually the extremal behaviour
- **WHEN** a recursion has lag two **DO** split by parity and solve two arithmetic progressions **BECAUSE** even and odd indices never interact, and the floor function in the answer is exactly this parity split
- **WHEN** you are asked for the largest n with $f(n) = c$ and f is not monotone **DO** prove an increasing lower envelope for f on each block, then locate the last block where c is reachable **BECAUSE** without a lower envelope you can never exclude a later return to the value c, which is where most attempts fail

Backtesting

1. First useful cue: the sets are index sets, so $a_1 = 2$; and $\sum_{k \le m-1} F_k = F_{m+1} - 1$ makes complementation available.
2. Method the expression suggested: split on the top index, complement the other branch, get $a_n = a_{n-F_m} + a_{F_{m+1}-1-n}$.
3. Where you would hesitate, and the thought to reinforce: after complementing, do you count subsets of $\{1, \dots, m-1\}$ or all subsets. The thought is a size check: $F_{m+1} - 1 - n \le F_{m-1} - 1 < F_m$, so no index above $m-1$ can occur anyway, and the count is the unrestricted a.
4. The trap the question sets: producing the value $F_{4040} - 1$ and stopping. Half the marks are in the proof that $a_n \ge 2021$ for every larger n, and that needs the block minimum.
5. What makes you recognise it faster next time: any counting question about Fibonacci or base b representations is a leading weight recursion, and any answer of the form $F_M - 1$ says the extremal cases sit at block boundaries.
6. The reusable decision rule: for representation counts, recurse on the top weight, complement the omitted branch, evaluate the recursion at extreme splits, then induct for the envelope.

Mirror drills

1. Compute a_{12} with the recursion. *Answer:* $F_6 = 8 \le 12 < 13 = F_7$, so $a_{12} = a_{12-8} + a_{13-1-12} = a_4 + a_0 = 3 + 1 = 4$.
2. Prove $\sum_{k=1}^{m-1} F_k = F_{m+1} - 1$. *Answer:* write $F_k = F_{k+2} - F_{k+1}$ and telescope to $F_{m+1} - F_2$.
3. Let b_n count the sets of indices $S \subseteq \{2, 3, 4, \dots\}$ with $\sum_{k \in S} F_k = n$. Show $a_n = b_n + b_{n-1}$ and check it at $n = 4$. *Answer:* split on whether $1 \in S$; since $F_1 = 1$, the sets containing 1 correspond to representations of $n-1$ using indices at least 2. At $n = 4$: $b_4 = 1$, $b_3 = 2$, and $a_4 = 3$.

6.6 A6. A Fejer mean of the square wave in disguise

For a positive integer N, let f_N be the function defined by

$$f_N(x) = \sum_{n=0}^{N} \frac{N + 1/2 - n}{(N+1)(2n+1)} \sin\big((2n+1)x\big).$$

Determine the smallest constant M such that $f_N(x) \le M$ for all N and all real x.

Read it out loud

This is a trigonometric polynomial containing only odd harmonics and only sines, so it is odd and 2π periodic, and it vanishes at every multiple of π. The coefficient is the interesting object. Say it out loud: a numerator linear in n, over a product of $(N+1)$ and $(2n+1)$. A linear numerator over a product of two linear factors is a partial fractions cue, and here the split is forced:

$$\frac{N + \frac{1}{2} - n}{(N+1)(2n+1)} = \frac{\frac{1}{2}\big[2(N+1) - (2n+1)\big]}{(N+1)(2n+1)} = \frac{1}{2n+1} - \frac{1}{2(N+1)}.$$

So f_N is the partial sum $\sum_{n \le N} \frac{\sin((2n+1)x)}{2n+1}$ minus $\frac{1}{2(N+1)} \sum_{n \le N} \sin((2n+1)x)$. The first of those is the classical Fourier partial sum of the square wave, whose sum on $(0, \pi)$ is $\pi/4$. The second is a plain trigonometric sum with a closed form. The answer is going to be $\pi/4$, and the whole problem is the word "smallest": you must show the family never exceeds $\pi/4$ and gets arbitrarily close to it.

The fields wired in are Fourier analysis (the odd sine series of the square wave, Cesaro summation, the Gibbs phenomenon), trigonometric telescoping, and one alternating series evaluation. What is really being tested is whether you know that the plain partial sums $\sum_{n \le N} \frac{\sin((2n+1)x)}{2n+1}$ do *not* obey the bound $\pi/4$: their maxima decrease to $\frac{1}{2}\,\mathrm{Si}(\pi) \approx 0.926$ and never come near $\pi/4 \approx 0.785$. That is the Gibbs phenomenon. The subtracted term is exactly the correction that removes the overshoot, and the problem is asking you to prove that it does.

Within thirty seconds you should have the partial fractions split on the page, plus the two evaluations $f_1(\pi/2) = 1 - \frac{1}{3} = \frac{2}{3}$ and $f_2(\pi/2) = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{6} = 0.7$, which sit below $\pi/4$ and climb towards it.

Approaches, ranked worst to best

1. **Numerical maximisation.** *Cue:* a concrete family of functions. *Circuit:* plot f_N and read off the peak. (Reveals that the maximum always sits at $x = \pi/2$ and climbs to 0.7854, which is priceless reconnaissance and no proof at all.)

2. **Bound each term.** *Cue:* a finite sum of sines. *Circuit:* triangle inequality. (Gives $\sum 1/(2n+1)$, a logarithmically divergent bound. Useless, but worth ten seconds to notice that the cancellation between terms is the entire content, so no term by term estimate can ever work.)

3. **Monotonicity in N plus Fourier convergence.** *Cue:* the correction term is $O(1/N)$. *Circuit:* show $f_{N+1} \ge f_N$ on $(0, \pi)$, then pass to the limit. (This is the official route and it is correct. It costs a two case argument, because the sign of the newly added harmonic $\sin((2N+3)x)$ is not controlled, and it finishes by quoting pointwise convergence of the square wave Fourier series. Two named theorems and a case split.)

4. **Recognise the Fejer mean.** *Cue:* coefficients tapered linearly in n. *Circuit:* f_N is the Cesaro mean of order $2N+1$ of the square wave series, and the Fejer kernel is nonnegative. (Conceptually the best: a Cesaro mean of a bounded function is an average of its values, so it is trapped between $\inf g$ and $\sup g$, and Fejer's theorem gives convergence to g at points of continuity. Three lines if you are allowed the machinery. It is ranked below the next route

only because it quotes a theorem most candidates cannot state precisely under pressure, and because the write up must still identify f_N with the Cesaro mean, which is a computation.)

5. **Differentiate and watch the collapse.** *Cue:* a finite trigonometric sum whose derivative is a kernel. *Circuit:* $f_N'(x) = \dfrac{\cos x \sin^2((N+1)x)}{2(N+1)\sin^2 x}$, so the maximum is at $x = \pi/2$ for every N. (Best. Self contained, no Fourier theorem quoted, and it localises the problem to a single point, after which the value is an alternating series whose distance from $\pi/4$ is controlled exactly. The collapse of the derivative is not luck: the correction term was built to cancel the oscillating kernel, which is the same statement as the Fejer identification.)

The ideal solution

The answer is $M = \boxed{\dfrac{\pi}{4}}$.

Step 1: split the coefficient. Since $N + \frac{1}{2} - n = \frac{1}{2}[2(N+1) - (2n+1)]$,

$$\frac{N+\frac{1}{2}-n}{(N+1)(2n+1)} = \frac{1}{2n+1} - \frac{1}{2(N+1)},$$

so, writing $S_N(x) = \sum_{n=0}^{N} \frac{\sin((2n+1)x)}{2n+1}$ and $T_N(x) = \sum_{n=0}^{N} \sin((2n+1)x)$,

$$f_N(x) = S_N(x) - \frac{T_N(x)}{2(N+1)}.$$

Step 2: close the second sum. Using $2\sin x \sin((2n+1)x) = \cos(2nx) - \cos((2n+2)x)$ and telescoping,

$$2\sin x \; T_N(x) = 1 - \cos((2N+2)x) = 2\sin^2((N+1)x),$$

so for $\sin x \neq 0$,

$$T_N(x) = \frac{\sin^2((N+1)x)}{\sin x} = \frac{1-\cos((2N+2)x)}{2\sin x}.$$

The same trick with $2\sin x \cos((2n+1)x) = \sin((2n+2)x) - \sin(2nx)$ gives

$$S_N'(x) = \sum_{n=0}^{N} \cos((2n+1)x) = \frac{\sin((2N+2)x)}{2\sin x} \qquad (\sin x \neq 0).$$

Step 3: reduce to $(0,\pi)$. Each f_N is 2π periodic and odd, and $f_N(0) = f_N(\pi) = 0$ because $\sin((2n+1)k\pi) = 0$. Oddness together with periodicity gives $f_N(2\pi - x) = f_N(-x) = -f_N(x)$, so the values on $(\pi, 2\pi)$ are the negatives of those on $(0,\pi)$. Hence

$$\sup_{x\in\mathbb{R}} f_N(x) = \max\Big(0, \max_{x\in(0,\pi)} f_N(x)\Big).$$

Step 4: differentiate. Fix $x \in (0,\pi)$, so $\sin x > 0$. By the coefficient split and the closed form for T_N,

$$f_N(x) = S_N(x) - \frac{1-\cos((2N+2)x)}{4(N+1)\sin x},$$

and differentiating the quotient,

$$\frac{d}{dx}\left[\frac{1-\cos((2N+2)x)}{\sin x}\right] = \frac{(2N+2)\sin((2N+2)x)\sin x - \big(1-\cos((2N+2)x)\big)\cos x}{\sin^2 x}.$$

Together with the closed form for S_N', the first pieces cancel exactly:

$$f_N'(x) = \frac{\sin((2N+2)x)}{2\sin x} - \frac{\sin((2N+2)x)}{2\sin x} + \frac{\big(1-\cos((2N+2)x)\big)\cos x}{4(N+1)\sin^2 x},$$

that is,

$$f_N'(x) = \frac{\cos x \, \sin^2((N+1)x)}{2(N+1)\sin^2 x} \qquad (0 < x < \pi).$$

Step 5: locate the maximum. By the derivative formula the sign of f_N' on $(0,\pi)$ is the sign of $\cos x$: nonnegative on $(0,\pi/2]$ and nonpositive on $[\pi/2,\pi)$. Since f_N is continuous on $[0,\pi]$, it increases on $[0,\pi/2]$ and decreases on $[\pi/2,\pi]$, so

$$\max_{x\in[0,\pi]} f_N(x) = f_N(\pi/2) \geq f_N(0) = 0.$$

Combining with Step 3, $\sup_{x\in\mathbb{R}} f_N(x) = f_N(\pi/2)$ for every N.

Step 6: evaluate at $\pi/2$. Since $\sin((2n+1)\pi/2) = (-1)^n$ and $\sin^2((N+1)\pi/2)$ equals 1 for N even and 0 for N odd,

$$f_N(\pi/2) = A_N - \frac{\varepsilon_N}{2(N+1)}, \qquad A_N = \sum_{n=0}^{N} \frac{(-1)^n}{2n+1}, \qquad \varepsilon_N = \begin{cases} 1 & N \text{ even}, \\ 0 & N \text{ odd}. \end{cases}$$

Step 7: bracket the alternating series. For $t \in [0,1]$, summing the finite geometric series with ratio $-t^2$,

$$\sum_{n=0}^{N} (-1)^n t^{2n} = \frac{1-(-1)^{N+1}t^{2N+2}}{1+t^2},$$

and integrating over $[0,1]$ gives, since $\int_0^1 \frac{dt}{1+t^2} = \frac{\pi}{4}$,

$$A_N = \frac{\pi}{4} + (-1)^N E_N, \qquad E_N = \int_0^1 \frac{t^{2N+2}}{1+t^2}\,dt \in \left(0,\ \frac{1}{2N+3}\right),$$

the bound on E_N coming from $0 < \frac{1}{1+t^2} \leq 1$ on $[0,1]$.

If N is odd then $f_N(\pi/2) = A_N = \frac{\pi}{4} - E_N < \frac{\pi}{4}$.

If N is even then

$$f_N(\pi/2) = \frac{\pi}{4} + E_N - \frac{1}{2N+2} < \frac{\pi}{4} + \frac{1}{2N+3} - \frac{1}{2N+2} < \frac{\pi}{4}.$$

Hence $f_N(x) \leq f_N(\pi/2) < \frac{\pi}{4}$ for every N and every real x, so $M = \pi/4$ is admissible.

Step 8: minimality. Along odd N, $f_N(\pi/2) = \frac{\pi}{4} - E_N$ and $0 < E_N < \frac{1}{2N+3} \to 0$, so $f_N(\pi/2) \to \pi/4$. Therefore no constant smaller than $\pi/4$ bounds the whole family, and $\pi/4$ is the smallest such constant. It is a supremum and not a maximum: the bound is strict for every individual N and x.

Layer 1: WHAT

Block 1: partial fraction the coefficient, exposing $f_N = S_N - \frac{1}{2(N+1)}T_N$, a Fourier partial sum minus a tapering correction. Block 2: close T_N in one line by multiplying by $2\sin x$ and telescoping, and get S_N' the same way. Block 3: use oddness and periodicity to reduce the supremum to the interval $(0,\pi)$. Block 4: differentiate; the oscillatory kernel cancels and $f_N'(x) = \frac{\cos x \sin^2((N+1)x)}{2(N+1)\sin^2 x}$. Block 5: conclude the maximum sits at $x = \pi/2$ for every N. Block 6: evaluate there, getting the Leibniz partial sum minus a parity dependent correction. Block 7: bracket the Leibniz partial sum with an integral remainder and check both parities. Block 8: let N run through odd values for minimality.

Juxtaposition. The nominal route recognises the Fourier series of the square wave, asserts that the sum is $\pi/4$ on $(0,\pi)$, and concludes that $\pi/4$ is the bound because "the partial sums converge to $\pi/4$". That is false reasoning and it fails on exactly this family's more famous cousin: the plain partial sums S_N converge to $\pi/4$ pointwise and yet their maxima tend to $\frac{1}{2}\,\mathrm{Si}(\pi) \approx 0.926$. Pointwise convergence never bounds a family uniformly. The bifurcation point is the moment you realise that the subtracted term is not an error term to be discarded but the entire point of the problem. The zombie throws away $\frac{T_N}{2(N+1)}$ because it is $O(1/N)$; you keep it, because it is the term that kills the Gibbs overshoot, and the fact that it is small pointwise is irrelevant near the peak, where T_N is of size N.

Layer 2: HOW

Block 1. **Cue.** A coefficient that is linear in n over a product of linear factors. **Why natural.** Partial fractions in the summation index is the standard reflex, and here the numerator is visibly a combination of the two denominators: $2(N+1)-(2n+1)=2N+1-2n$. Splitting is not a manipulation for its own sake; it separates a universal object (the square wave partial sum, independent of the taper) from an N dependent correction. Once separated, each piece can be recognised. **Link to the next block.** The correction is a bare trigonometric sum, and bare trigonometric sums with angles in arithmetic progression always close.

Block 2. **Cue.** $\sum \sin((2n+1)x)$, angles in arithmetic progression with common difference $2x$. **Why natural.** Multiply by $2\sin$ of half the common difference. The product to sum identity then turns each term into a difference of consecutive cosines and the sum telescopes. This is the real reason such sums have closed forms, and it is worth more than memorising the formula: the same move gives $\sum \cos((2n+1)x)$, which you will need in the next block for S_N'. **Link to the next block.** With T_N in closed form, f_N is an explicit elementary function plus S_N, and you can differentiate.

Block 3. **Cue.** Only odd harmonics and only sines, and the question says "all real x". **Why natural.** Odd plus 2π periodic means the graph on $(\pi, 2\pi)$ is the reflection of the graph on $(0,\pi)$ through the origin, so the supremum over the line equals the supremum over $(0,\pi)$, provided you also check the two boundary points where $\sin x = 0$ and every term vanishes. Doing this reduction first is what allows you to divide by $\sin x$ freely afterwards. **Link to the next block.** On $(0,\pi)$ the function is smooth and you may look for critical points.

Block 4. **Cue.** f_N is now S_N minus an explicit quotient, and S_N' is a known kernel. **Why natural.** Differentiating a sum of sines with coefficients $1/(2n+1)$ removes the coefficients entirely and produces the kernel $\frac{\sin((2N+2)x)}{2\sin x}$. The derivative of the correction contains the same kernel with coefficient $\frac{2N+2}{4(N+1)}=\frac{1}{2}$, so the two cancel identically. That cancellation is the fingerprint of the design: the coefficient $\frac{1}{2(N+1)}$ in the problem was chosen to make it happen. What survives is nonnegative apart from the factor $\cos x$. **Link to the next block.** A derivative whose sign is the sign of $\cos x$ pins the maximum at $\pi/2$ for every N simultaneously.

Block 5. **Cue.** f_N' has the sign of $\cos x$ on $(0,\pi)$. **Why natural.** Sign of the derivative is all you need; the zeros of $\sin^2((N+1)x)$ are isolated points where the derivative vanishes without changing sign, so monotonicity on each half is unaffected. The uniformity in N is the gift: the supremum over x has become the value at one fixed point, and the problem has collapsed from two variables to one. **Link to the next block.** At $x=\pi/2$ the sines take the values $(-1)^n$, so the value is an alternating series.

Block 6. **Cue.** $\sin((2n+1)\pi/2)=(-1)^n$. **Why natural.** This is why $\pi/2$ is where the answer lives: the odd harmonics all attain modulus one there and the series becomes the Madhava, Gregory and Leibniz series for $\pi/4$. The correction contributes only for even N, because $\sin^2((N+1)\pi/2)$ vanishes when N is odd, and that parity split is what makes the two cases of the final estimate. **Link to the next block.** An alternating series needs a sharp two sided bound, not just convergence.

Block 7. **Cue.** A partial sum of an alternating series compared with its limit. **Why natural.** The integral form is better than the alternating series test here because it gives the error with a sign and a bound in one line: expand $\frac{1}{1+t^2}$ as a finite geometric series with an exact remainder, integrate, and read off $A_N=\frac{\pi}{4}+(-1)^N E_N$ with $0<E_N<\frac{1}{2N+3}$. For even N the overshoot E_N must be beaten by

the correction $\frac{1}{2N+2}$, and $\frac{1}{2N+3} < \frac{1}{2N+2}$ settles it with room to spare. **Link to the next block.** Both parities give a strict inequality, and the odd case shows the bound is approached.

Layer 3: WHY

The structural truth is this. Let g be the square wave, equal to $\pi/4$ on $(0,\pi)$, to $-\pi/4$ on $(-\pi,0)$, and to 0 at 0 and π, extended with period 2π. Its Fourier series is $\sum_{n\geq 0} \frac{\sin((2n+1)x)}{2n+1}$, whose partial sums of order m are $T_m^{\mathrm{F}} = \sum_{n \text{ odd}, n\leq m} \frac{\sin(nx)}{n}$, so $T_{2k+1}^{\mathrm{F}} = T_{2k+2}^{\mathrm{F}} = S_k$. Now average:

$$\frac{1}{2N+2}\sum_{m=0}^{2N+1} T_m^{\mathrm{F}} = \frac{1}{2N+2}\left(2\sum_{k=0}^{N-1} S_k + S_N\right),$$

and the coefficient of $\frac{\sin((2n+1)x)}{2n+1}$ on the right is $\frac{2(N-n)+1}{2N+2} = \frac{2N+1-2n}{2N+2}$, which is exactly the coefficient in f_N after multiplying the coefficient split out. In other words

$$f_N = \sigma_{2N+1}(g), \qquad \sigma_m(g) = \frac{1}{m+1}\sum_{j=0}^{m} T_j^{\mathrm{F}},$$

the Fejer (Cesaro) mean of order $2N+1$ of the square wave. Fejer means are convolutions with the Fejer kernel $K_m(t) = \frac{1}{m+1}\left(\frac{\sin((m+1)t/2)}{\sin(t/2)}\right)^2 \geq 0$, of total mass 1, so $\sigma_m(g)(x)$ is a weighted average of the values of g and therefore lies between $-\pi/4$ and $\pi/4$ everywhere; and Fejer's theorem gives $\sigma_m(g)(x) \to g(x)$ at every point of continuity, in particular $\sigma_m(g)(\pi/2) \to \pi/4$. That is the whole problem in two sentences, and it is why the answer is the supremum of g rather than anything larger.

Contrast this with the plain partial sums, which are convolutions with the Dirichlet kernel; that kernel changes sign, its mass is not bounded, and the partial sums overshoot: $\max_x S_N(x) \to \frac{1}{2}\operatorname{Si}(\pi) = \frac{1}{2}\int_0^\pi \frac{\sin t}{t}\,dt \approx 0.926$, about nine per cent of the jump above the limiting value. The examiners took the classical Gibbs example and applied the classical cure, then asked you to prove the cure works without naming it. That is the design of the problem, and recognising the linear taper $1 - \frac{n}{N+1}$ style coefficient as a Cesaro weight is the single cue that unlocks it.

Knowledge gaps, named without disguise. To meet this problem at full speed you must have installed: the Fourier series of the square wave and its sum $\pi/4$ on $(0,\pi)$; the Dirichlet kernel and the fact that pointwise convergence gives no uniform bound; the Fejer kernel, its nonnegativity, and the Cesaro mean bound $\inf g \leq \sigma_m(g) \leq \sup g$; the Gibbs phenomenon and the constant $\frac{1}{2}\operatorname{Si}(\pi)$; and the integral remainder form of the Madhava, Gregory and Leibniz series. None of these is in A level Further Mathematics. The good news is that the ideal solution above uses none of them: it needs only the product to sum identities, one quotient derivative, and a finite geometric series under an integral. Install the Fourier theory because it explains the problem; solve the problem with calculus because that is what you can execute under time pressure.

The discernment mechanism: when a family of trigonometric polynomials carries coefficients that taper linearly to zero at the top, suspect a Cesaro mean and expect a bound by the supremum of the underlying function. When you are asked for a uniform bound over a family, never argue from pointwise convergence; either bound each member directly or find the location of the maximum. Train it by computing the maximum of the plain partial sums numerically for a few N so that the Gibbs overshoot is a fact you have seen, not a story you have heard.

Revolving concepts

Telescoping trigonometric sums. For angles in arithmetic progression, multiply by $2\sin(\frac{d}{2})$ where d is the common difference and use $2\sin A\sin B = \cos(A-B) - \cos(A+B)$ or $2\sin A\cos B = \sin(A+B) - \sin(A-B)$. Results worth banking: $\sum_{n=0}^{N}\sin((2n+1)x) = \frac{\sin^2((N+1)x)}{\sin x}$, $\sum_{n=0}^{N}\cos((2n+1)x) =$

$\frac{\sin((2N+2)x)}{2\sin x}$, and the Dirichlet kernel $\frac{1}{2}+\sum_{n=1}^{N}\cos(nx)=\frac{\sin((N+\frac{1}{2})x)}{2\sin(x/2)}$. See Book 1, field: Complex numbers, topic: sums of sines and cosines in arithmetic progression.

Fourier series of the square wave. $\sum_{n\geq 0}\frac{\sin((2n+1)x)}{2n+1}=\frac{\pi}{4}$ for $x\in(0,\pi)$, $-\frac{\pi}{4}$ for $x\in(-\pi,0)$, and 0 at $x=0,\pi$. At $x=\pi/2$ it is the Madhava, Gregory and Leibniz series. See Book 1, field: Real analysis, topic: Fourier series of elementary waveforms.

Fejer means and kernel positivity. $\sigma_m(g)=\frac{1}{m+1}\sum_{j=0}^{m}T_j^{\mathrm{F}}(g)$ equals the convolution of g with $K_m(t)=\frac{1}{m+1}\left(\frac{\sin((m+1)t/2)}{\sin(t/2)}\right)^2\geq 0$, whose integral is 1. Hence $\inf g\leq\sigma_m(g)\leq\sup g$ everywhere, and $\sigma_m(g)\to g$ at points of continuity, uniformly on compact sets of continuity. See Book 1, field: Real analysis, topic: Cesaro summability and Fejer's theorem.

Gibbs phenomenon. The Fourier partial sums of a function with a jump overshoot near the jump by about 8.95 per cent of the jump, and the overshoot does not decay with N; for the square wave, $\max_x S_N(x)\to\frac{1}{2}\,\mathrm{Si}(\pi)\approx 0.926>\frac{\pi}{4}$. Cesaro averaging removes it. See Book 1, field: Real analysis, topic: Gibbs phenomenon.

Alternating series with an integral remainder. $\sum_{n=0}^{N}(-1)^n t^{2n}=\frac{1-(-1)^{N+1}t^{2N+2}}{1+t^2}$ integrated over $[0,1]$ gives $\sum_{n=0}^{N}\frac{(-1)^n}{2n+1}=\frac{\pi}{4}+(-1)^N\int_0^1\frac{t^{2N+2}}{1+t^2}dt$, with the remainder in $\left(\frac{1}{2(2N+3)},\frac{1}{2N+3}\right)$. The same device with $\frac{1}{1+t}$ gives the partial sums of $\log 2$. This is the general recursion generalisation of "truncate a geometric series exactly, then integrate": always keep the exact remainder rather than an asymptotic one, because you usually need its sign. See Book 1, field: Calculus and integrals, topic: geometric series with exact remainder.

Uniform bounds versus pointwise limits. $f_N\to f$ pointwise says nothing about $\sup_N\sup_x f_N$. To bound a family you must either locate the maxima or bound each member by a kernel argument. See Book 1, field: Real analysis, topic: modes of convergence.

Circuit Bank

- **WHEN** a coefficient is linear in the summation index over a product of linear factors **DO** partial fraction it in that index **BECAUSE** the split separates a universal series from an N dependent correction, and each half is then recognisable
- **WHEN** you meet a trigonometric sum with angles in arithmetic progression **DO** multiply by $2\sin$ of half the common difference and telescope **BECAUSE** the product to sum identities turn each term into a difference of consecutive terms, which is why such sums always close
- **WHEN** a family of trigonometric polynomials has coefficients tapering linearly to zero **DO** suspect a Cesaro or Fejer mean and expect the bound $\sup g$ **BECAUSE** Fejer kernels are nonnegative with unit mass, so a Cesaro mean is an average of values of the function and cannot overshoot
- **WHEN** you must bound a whole family uniformly **DO** locate the maximum of each member, never argue from a pointwise limit **BECAUSE** Gibbs is the standing counterexample: partial sums converge pointwise to a function of supremum $\pi/4$ while their own maxima tend to 0.926
- **WHEN** a derivative of a designed expression looks like it might cancel **DO** compute it and expect the oscillatory kernel to vanish **BECAUSE** problem setters build such families so that the derivative has constant sign, which is the only way the maximum can sit at the same point for every N
- **WHEN** the value at the critical point is an alternating series **DO** expand the underlying geometric series with an exact remainder and integrate **BECAUSE** this gives the error with a sign and a sharp bound, which is what a strict inequality needs

Backtesting

1. First useful cue: the coefficient splits as $\frac{1}{2n+1} - \frac{1}{2(N+1)}$, exposing a square wave partial sum minus a taper.
2. Method the expression suggested: close the taper by telescoping, differentiate, watch the kernel cancel, evaluate at $x = \pi/2$.
3. Where you would hesitate, and the thought to reinforce: after seeing that the correction is $O(1/N)$, the instinct is to discard it. The thought to reinforce is that near the peak T_N has size of order N, so the correction is of order one exactly where it matters; that is the whole problem.
4. The trap the question sets: concluding $M = \pi/4$ from pointwise convergence alone. The same argument applied to S_N gives the wrong answer, since $\max_x S_N(x) \to \frac{1}{2}\,\mathrm{Si}(\pi) \approx 0.926$, not $\pi/4$.
5. What makes you recognise it faster next time: linear tapers in n mean Cesaro means, and Cesaro means never overshoot; the answer to such a problem is the supremum of the limiting waveform.
6. The reusable decision rule: for a supremum over a family of trigonometric polynomials, differentiate first and hope for a constant sign factor; if the derivative collapses, the two variable problem becomes a one variable series estimate.

Mirror drills

1. Prove $\sum_{n=0}^{N} \sin((2n+1)x) = \frac{\sin^2((N+1)x)}{\sin x}$ for $\sin x \neq 0$. *Answer:* multiply by $2\sin x$, use $2\sin x \sin((2n+1)x) = \cos(2nx) - \cos((2n+2)x)$, telescope to $1 - \cos((2N+2)x) = 2\sin^2((N+1)x)$.
2. Verify the derivative formula by hand at $N = 1$. *Answer:* $f_1(x) = \frac{3}{4}\sin x + \frac{1}{12}\sin 3x$, so $f_1'(x) = \frac{3}{4}\cos x + \frac{1}{4}\cos 3x = \frac{3}{4}\cos x + \frac{1}{4}(4\cos^3 x - 3\cos x) = \cos^3 x$, which is $\frac{\cos x \sin^2(2x)}{4\sin^2 x}$.
3. Show $\left|\sum_{n=0}^{N} \frac{(-1)^n}{2n+1} - \frac{\pi}{4}\right| < \frac{1}{2N+3}$ and identify the sign of the error. *Answer:* the error is $(-1)^N \int_0^1 \frac{t^{2N+2}}{1+t^2}dt$, positive for even N and negative for odd N, and bounded by $\int_0^1 t^{2N+2}dt$.

6.7 B1. Binary digit signs annihilate low degree polynomials

For a positive integer n, define $d(n)$ to be the sum of the digits of n when written in binary (for example, $d(13) = 1+1+0+1 = 3$). Let

$$S = \sum_{k=1}^{2020} (-1)^{d(k)} k^3.$$

Determine S modulo 2020.

Read it out loud

This is a signed power sum. The weight is a cubic, k^3, and the sign is $(-1)^{d(k)}$, the parity of the number of ones in the binary expansion of k. Say that sentence slowly, because it already contains the entire problem: the weight is a *polynomial of degree three*, and the sign is a *function of the binary digits*. Two objects from two different worlds have been multiplied together, and the question is asking whether the sign world can eat the polynomial world.

The fields wired in are: binary expansions and the Thue Morse sequence; finite difference calculus (equivalently, generating functions and multiplicities of roots at $x = 1$); and elementary modular arithmetic to finish. Nothing else. There is no number theory of 2020 beyond the last three lines.

What is really being tested is one structural observation, and it is the observation that $(-1)^{d(k)}$ is *multiplicative across disjoint binary blocks*. If c is a multiple of 2^m and $0 \le r < 2^m$, then the binary expansions of c and r never collide, so $d(c+r) = d(c) + d(r)$, and therefore $(-1)^{d(c+r)} = (-1)^{d(c)}(-1)^{d(r)}$. That single line is the guiding light. Once you have it, the sign over a block of 2^m consecutive integers starting at a multiple of 2^m is a fixed constant times the pattern $(-1)^{d(0)}, (-1)^{d(1)}, \ldots, (-1)^{d(2^m-1)}$, and that pattern is precisely the sign pattern $\prod_i (-1)^{\varepsilon_i}$ attached to the m independent binary choices $\varepsilon_0, \ldots, \varepsilon_{m-1}$.

Within thirty seconds you should have written three things: $(-1)^{d(2^m j + r)} = (-1)^{d(j)}(-1)^{d(r)}$ for $0 \le r < 2^m$; the word "difference" next to it, because summing a function against all 2^m sign patterns of m independent binary choices is by definition an m-fold finite difference; and $2016 = 16 \cdot 126$, because 2016 is the largest multiple of 16 below 2020 and $16 = 2^4$ is the first power of two whose exponent exceeds the degree 3. That last line is the whole solution compressed into an arithmetic fact.

Approaches, ranked worst to best

1. **Term by term evaluation.** *Cue:* no cue at all, just panic. *Circuit:* none. Two thousand and twenty cubes, each with a binary digit count. This is zombie maths in its purest form. It cannot be done in the arena and it teaches nothing, so it ranks last even though it would in principle succeed.

2. **Consecutive pairing.** *Cue:* $d(2k+1) = d(2k) + 1$, so adjacent terms carry opposite signs. *Circuit:* pair up terms whose signs are forced to be opposite. Grouping $k = 2j$ with $k = 2j+1$ turns the sum into $\sum_j (-1)^{d(j)} \left((2j)^3 - (2j+1)^3\right)$, which is a Thue Morse sum against a quadratic. Repeat and you get a linear one, then a constant one. It works, but every pass costs a full expansion and a re-indexing, and you must track the boundary terms three times. It costs more ink than it should, and each expansion is a fresh opportunity for a skipped-calculation error.

3. **Blocks of eight with an explicit constant.** *Cue:* blocks of length 2^m have a clean sign pattern. *Circuit:* tile the range by aligned power of two blocks. Compute $\sum_{r=0}^{7} (-1)^{d(r)} r^3 = -48$ by hand, deduce that the block starting at $8j$ contributes $(-1)^{d(j)} \cdot (-48)$, then note $2016 = 8 \cdot 252$

and finish by showing $\sum_{j=0}^{251}(-1)^{d(j)} = 0$ from consecutive pairing. This is a correct and honest route. It ranks here because it needs two separate arguments and one numerical evaluation that you must get right.

4. **Generating function with $x\,d/dx$.** *Cue:* a product $\prod(1-x^{2^i})$ generates exactly these signs. *Circuit:* convert a signed digit sum into a polynomial identity. Use $\prod_{i=0}^{m-1}(1-x^{2^i}) = \sum_{k=0}^{2^m-1}(-1)^{d(k)}x^k$, apply the operator $x\frac{d}{dx}$ three times, set $x=1$, and note the left side still vanishes because $x=1$ was a root of multiplicity m. Correct, and it is the same fact as the winner, only wearing a coat. It ranks just below because you must argue that three applications of $x\,d/dx$ cannot destroy a root of multiplicity $m>3$, which is a sentence of extra work.

5. **Finite difference annihilation.** *Cue:* the sign is a product of independent digit signs, and a cubic has vanishing fourth difference. *Circuit:* when a sign is a product over independent binary choices, the sum is an iterated difference operator. Blocks of length 16 aligned at multiples of 16, each contributing exactly zero because four difference operators annihilate a cubic. One lemma, one tiling, one five term tail. This is the ideal route: it is the shortest, it generalises immediately to any degree and any base, and it never asks you to compute a single cube until the final line.

The ideal solution

For $h \neq 0$ write $(\Delta_h P)(x) = P(x+h) - P(x)$ and $(S_h P)(x) = P(x+h)$, so $\Delta_h = S_h - I$.

Lemma 6.7.1. *If P is a polynomial of degree $D \geq 1$ then $\Delta_h P$ has degree exactly $D-1$; if P is constant then $\Delta_h P = 0$. Consequently, if $\deg P < m$ then $\Delta_{h_1}\Delta_{h_2}\cdots\Delta_{h_m}P = 0$ for any nonzero $h_1,\ldots,h_m$.*

Proof. Write $P(x) = a_D x^D + \cdots$ with $a_D \neq 0$. Then $P(x+h) - P(x) = a_D D h x^{D-1} + (\text{lower order})$, and $a_D D h \neq 0$, so the degree drops by exactly one. Each application therefore drops the degree by one until the polynomial is constant, and one further application returns zero. Applying m operators to a polynomial of degree at most $m-1$ produces zero. □

Lemma 6.7.2. *Let $m \geq 1$, let c be a multiple of 2^m, and let P be any polynomial of degree less than m. Then*

$$\sum_{r=0}^{2^m-1}(-1)^{d(c+r)}P(c+r) = 0.$$

Proof. Since $2^m \mid c$ and $0 \leq r < 2^m$, the binary expansions of c and of r use disjoint digit positions, so $c+r$ has the digits of c above position $m-1$ and the digits of r below it. Hence $d(c+r) = d(c)+d(r)$ and $(-1)^{d(c+r)} = (-1)^{d(c)}(-1)^{d(r)}$.

Set $Q(x) = P(c+x)$, a polynomial of degree less than m. Every r with $0 \leq r < 2^m$ has a unique expansion $r = \sum_{i=0}^{m-1}\varepsilon_i 2^i$ with $\varepsilon_i \in \{0,1\}$, and then $(-1)^{d(r)} = \prod_{i=0}^{m-1}(-1)^{\varepsilon_i}$. Expanding the operator product,

$$\prod_{i=0}^{m-1}\Delta_{2^i} \;=\; \prod_{i=0}^{m-1}(S_{2^i} - I) \;=\; \sum_{T\subseteq\{0,\ldots,m-1\}}(-1)^{m-|T|}\,S_{r_T}, \qquad r_T = \sum_{i\in T}2^i,$$

because the shift operators commute and $S_h S_{h'} = S_{h+h'}$. Evaluating at $x=0$ and noting that $T \mapsto r_T$ is a bijection from subsets onto $\{0,1,\ldots,2^m-1\}$ with $|T| = d(r_T)$,

$$\Big(\prod_{i=0}^{m-1}\Delta_{2^i}Q\Big)(0) \;=\; (-1)^m\sum_{r=0}^{2^m-1}(-1)^{d(r)}Q(r).$$

The left side is zero by Lemma 1, since $\deg Q < m$. Multiplying by $(-1)^m(-1)^{d(c)}$ gives the claim. □

Now take $m = 4$, so $2^m = 16$, and $P(x) = x^3$, of degree $3 < 4$. Since $2016 = 16 \cdot 126$, the interval $\{0, 1, \ldots, 2015\}$ is the disjoint union of the 126 blocks $\{16j, 16j+1, \ldots, 16j+15\}$ for $j = 0, 1, \ldots, 125$, and every one of these blocks starts at a multiple of 16. By Lemma 2 each block contributes zero, so

$$\sum_{k=0}^{2015} (-1)^{d(k)} k^3 = 0, \qquad \text{hence} \qquad \sum_{k=1}^{2015} (-1)^{d(k)} k^3 = 0$$

(the term $k = 0$ is zero anyway). Therefore

$$S = \sum_{k=2016}^{2020} (-1)^{d(k)} k^3.$$

It remains to evaluate five terms. Now $2016 = 11111100000_2$, so $d(2016) = 6$ and 2016 is a multiple of 32. For $0 \le r \le 4$ the same disjointness argument gives $d(2016 + r) = 6 + d(r)$, so the signs of $k = 2016, 2017, 2018, 2019, 2020$ are the signs of $d(0), d(1), d(2), d(3), d(4)$, namely

$$+, \ -, \ -, \ +, \ -.$$

Hence

$$S = 2016^3 - 2017^3 - 2018^3 + 2019^3 - 2020^3.$$

Reduce modulo 2020 by writing each base as a small negative number: $2016 \equiv -4$, $2017 \equiv -3$, $2018 \equiv -2$, $2019 \equiv -1$, $2020 \equiv 0 \pmod{2020}$. Then

$$S \equiv (-4)^3 - (-3)^3 - (-2)^3 + (-1)^3 - 0 = -64 + 27 + 8 - 1 = -30 \pmod{2020},$$

and $-30 \equiv 1990 \pmod{2020}$. Therefore

$$\boxed{S \equiv 1990 \pmod{2020}}.$$

Layer 1: WHAT

Block 1. Read the sign as a function of binary digits and record $d(2^m j + r) = d(j) + d(r)$ for $0 \le r < 2^m$.

Block 2. Recognise that summing over one aligned block of length 2^m means summing over all 2^m sign patterns of m independent binary choices, which is an m-fold finite difference.

Block 3. State the difference lemma: m difference operators annihilate any polynomial of degree less than m.

Block 4. Choose the smallest legal m: the degree is 3, so $m = 4$ and the block length is 16.

Block 5. Check the arithmetic that makes the tiling work: $16 \mid 2016$, with $2016 = 16 \cdot 126$. Conclude that everything below 2016 cancels.

Block 6. Evaluate the five leftover terms, reading their signs off $d(2016) = 6$ and $d(r)$ for $r \le 4$.

Block 7. Reduce modulo 2020 by replacing $2016, \ldots, 2020$ with $-4, \ldots, 0$, so that the cubes are tiny.

The nominal route runs: "the sum has 2020 terms, so I need the value of $(-1)^{d(k)}$ for each k; let me find a pattern in the Thue Morse sequence." That route spends its energy on the sequence itself and eventually reaches consecutive pairing, then a second pairing, then a third, and arrives at the answer exhausted.

The bifurcation point is the sentence you write immediately after reading the problem. The zombie writes "what is $(-1)^{d(k)}$?". The ideal solver writes "over which ranges does $(-1)^{d(k)}$ integrate a cubic to zero?". One question is about individual values; the other is about an annihilation property. The whole problem is decided there.

Layer 2: HOW

Block 1. **Cue.** The definition of d is given in terms of binary digits, and binary digits of a number below 2^m never interact with the digits of a multiple of 2^m. **Why natural.** You are not being asked to understand $(-1)^{d(k)}$ as a sequence; you are being asked to use it as a weight. A weight is only useful if it factorises, and the only factorisation available for a digit sum is across disjoint digit positions. So the first move is forced: split k at a power of two boundary. **Link to the next block.** Once the sign factorises across a block, the block sum is a fixed constant times a universal pattern, so all blocks look alike and you only need to understand one.

Block 2. **Cue.** The universal pattern is $(-1)^{d(r)} = \prod_i (-1)^{\varepsilon_i}$, a product over m independent choices. **Why natural.** Summing f over all choices with the sign $\prod(-1)^{\varepsilon_i}$ is, by definition, the alternating sum $\sum_T (-1)^{|T|} f(r_T)$, and an alternating sum over subsets of shifts is exactly an iterated difference operator. This is not a leap. It is the standard dictionary between "alternating over independent binary choices" and "iterated difference". If you have ever written $\Delta^n f(0) = \sum_j (-1)^{n-j} \binom{n}{j} f(j)$, you already know it. **Link to the next block.** Difference operators have one famous property, and it is exactly the property you need.

Block 3. **Cue.** A difference operator lowers the degree of a polynomial by one, with no exceptions when $h \neq 0$. **Why natural.** The leading terms cancel and the next term $a_D D h x^{D-1}$ survives with a nonzero coefficient. That is a one line proof, and it is the definition-level reason: differencing is a discrete derivative, and m derivatives kill degree less than m. **Link to the next block.** You now have a free parameter, m, and the smaller you take it the finer the tiling, so take it as small as the degree permits.

Block 4. **Cue.** Degree three, so you need $m \geq 4$. **Why natural.** Be lazy. A larger m means longer blocks, which means the leftover tail after tiling is longer and you compute more cubes by hand. Minimal m minimises ink. **Link to the next block.** The choice $m = 4$ is only useful if 16 divides something close to 2020.

Block 5. **Cue.** $2020 = 16 \cdot 126 + 4$. **Why natural.** This is the arithmetic check that decides whether the plan survives. It does: 2016 is a multiple of 16, so the tiling is exact and the tail has only five terms. **Link to the next block.** Five terms is a finite computation, and you now need their signs.

Block 6. **Cue.** 2016 is not just a multiple of 16; it is a multiple of 32, and $2020 - 2016 = 4 < 32$. **Why natural.** This means the same factorisation applies again on the tail: $d(2016 + r) = d(2016) + d(r)$ for $r \leq 4$. You never have to count binary digits of 2017, 2018, 2019 or 2020 separately. You count $d(2016) = 6$ once, then read $d(0), d(1), d(2), d(3), d(4) = 0, 1, 1, 2, 1$. **Link to the next block.** The five signed cubes are still large numbers, but the question only wants a residue.

Block 7. **Cue.** The modulus is 2020 and the terms sit at 2016 to 2020. **Why natural.** The bases are within 4 of the modulus, so replacing k by $k - 2020$ turns each cube into a single digit cube. Never cube a four digit number when the question hands you a modulus that makes it a one digit number. **Link to the next block.** The arithmetic collapses to $-64 + 27 + 8 - 1 = -30$, and normalising into $[0, 2020)$ gives 1990.

Layer 3: WHY

The mathematical truth beneath this route is that $(-1)^{d(\cdot)}$ is a character. On the block $\{c, c+1, \ldots, c+2^m-1\}$ with $2^m \mid c$, the map $r \mapsto (-1)^{d(r)}$ is the product of the m coordinate characters of the

group $(\mathbb{Z}/2)^m$ acting on the binary digits $\varepsilon_0, \ldots, \varepsilon_{m-1}$. Pairing a function against the full product of coordinate characters is the classical way of writing an m-fold difference, and an m-fold difference is a discrete m-th derivative. Polynomials of degree less than m have vanishing m-th derivative. That is the entire content of the problem, and everything else is arithmetic.

The same truth in generating function language is that

$$\prod_{i=0}^{m-1} \left(1 - x^{2^i}\right) = \sum_{k=0}^{2^m-1} (-1)^{d(k)} x^k$$

has a zero of order exactly m at $x = 1$, one order from each factor. Moments of order less than m read off derivatives of order less than m at $x = 1$, so they vanish. The two languages are the same lemma; the difference operator version is shorter because it never asks you to think about what $x \frac{d}{dx}$ does to a root of high multiplicity.

The discernment mechanism is a two part question that you should ask of every signed sum. First: does the sign factorise over some decomposition of the index? Second: over the block on which it factorises, what does the sign annihilate? Here the answers are "yes, over binary blocks" and "every polynomial of degree less than the block exponent". If the sign had been $(-1)^k$ the block length would be 2 and the annihilated class would be constants, which is why $\sum(-1)^k$ telescopes. If the sign had been a b-adic digit character in base b you would get $\prod_{i<m}(1 - x^{b^i}\zeta)$ style products and the same annihilation of low degrees. The general shape is always: character times polynomial, block length controls degree killed.

To train the discernment, do this. Every time you meet a weight that is defined by digits, immediately ask what happens over a block whose length is the relevant power of the base. Every time you meet an alternating sum over subsets, immediately write it as an iterated difference. These are two of the cheapest circuits on the Putnam and they fire together here.

The examiners nudged you with three planted signals. The modulus 2020 and the upper limit 2020 are the same number, which is the nudge to reduce k modulo 2020 at the end and turn the cubes into single digits. The exponent 3 is small and fixed, which is the nudge that a bounded number of difference operators will suffice. And the upper limit is four above $2016 = 16 \cdot 126$, which is the nudge that a power of two tiling is meant to be exact except for a very short tail. If the limit had been, say, 2019, the tail would have been four terms; if it had been a prime, you would have suspected a different structure entirely.

Revolving concepts

Binary digit sum and the Thue Morse sequence. Define $t_k = (-1)^{d(k)}$. The defining recursion is $t_0 = 1$, $t_{2k} = t_k$, $t_{2k+1} = -t_k$. This is a 2-automatic sequence: its value is a finite state function of the binary expansion. The generalised recursion, which you should install once and reuse, is: for a base b and a digit function g, the sequence $u_{bk+r} = \chi(r)u_k$ is determined by the multiplicative rule across digit blocks, and every sum of u against a function over an aligned block of length b^m becomes an m-fold operator applied to that function. Pointer: see Book 1, field: Number theory, topic: automatic sequences and digit characters.

Finite difference calculus. $\Delta_h P(x) = P(x + h) - P(x)$; $\deg \Delta_h P = \deg P - 1$ for nonconstant P; $\Delta_h^m P = 0$ if and only if $\deg P < m$; Newton's forward difference formula $P(x) = \sum_j \binom{x}{j} (\Delta_1^j P)(0)$ for the step one case. The composite $\Delta_{h_1} \cdots \Delta_{h_m}$ applied to x^m equals $m!\, h_1 h_2 \cdots h_m$, which is the exact analogue of the m-th derivative of x^m being $m!$. Pointer: see Book 1, field: Polynomials, topic: finite differences.

The exact first nonvanishing moment. From the composite formula with $h_i = 2^i$,

$$\sum_{k=0}^{2^m-1} (-1)^{d(k)} k^m = (-1)^m\, m! \prod_{i=0}^{m-1} 2^i = (-1)^m\, m!\, 2^{m(m-1)/2}.$$

For $m = 3$ this reads $-6 \cdot 8 = -48$, which is exactly the constant that route three in the ranking has to compute by hand. Knowing the general formula means you never compute such a constant again. Pointer: see Book 1, field: Number theory, topic: digit sums against polynomial weights.

Generating function for a digit character. $\prod_{i=0}^{m-1}(1 - x^{2^i}) = \sum_{k<2^m}(-1)^{d(k)}x^k$, with a zero of order m at $x = 1$. More generally $\prod_{i\geq 0}(1 - x^{2^i})$ is the Thue Morse generating series. The multiplicity of the root at $x = 1$ is exactly the number of factors, and multiplicity at $x = 1$ is the generating function encoding of moment vanishing. Pointer: see Book 1, field: Generating functions, topic: root multiplicity and moment vanishing.

Reduction of a residue tail. If a sum modulo M has its surviving terms in $[M - c, M]$ for small c, replace k by $k - M$ before doing any arithmetic. Pointer: see Book 1, field: Number theory, topic: modular normalisation.

Circuit Bank

- **WHEN** a sign of the form $(-1)^{\text{digit sum in base } b}$ multiplying a polynomial **DO** split the range into blocks of length b^m starting at multiples of b^m, with m greater than the degree **BECAUSE** the sign factorises across disjoint digit positions, so each block sum is an m-fold difference and m differences annihilate degree less than m
- **WHEN** an alternating sum over all subsets of a fixed finite set of shifts **DO** write it as the composite difference operator $\prod_i(S_{h_i} - I)$ evaluated at a point **BECAUSE** shift operators commute and expanding the product reproduces the subset sum with the same signs, and each factor lowers polynomial degree by exactly one
- **WHEN** a summation limit that is a small amount above a multiple of a power of two **DO** tile up to that multiple and treat the short tail by hand **BECAUSE** the structural cancellation is exact only on aligned blocks, so the tail is where all the actual arithmetic lives, and it should be as short as possible
- **WHEN** a sum to be evaluated modulo M whose surviving terms sit just below M **DO** replace each k by $k - M$ before raising to any power **BECAUSE** cubing -4 costs one line and cubing 2016 costs four, and the extra digits carry no information modulo M

Backtesting

1. First useful cue: the sign is a binary digit parity, which means it factorises across power of two blocks, so the very first thing written down is $d(2^m j + r) = d(j) + d(r)$ for $0 \leq r < 2^m$.
2. Method the expression suggested: a polynomial weight against a digit character means iterated finite differences; choose the block exponent to exceed the degree and tile the range.
3. Where you would hesitate, and the thought to reinforce: the hesitation is at the step "an alternating sum over binary patterns is a difference operator". Reinforce it by writing $\Delta_{h_1}\Delta_{h_2} = S_{h_1+h_2} - S_{h_1} - S_{h_2} + I$ once by hand and seeing the four subsets with their signs. After that the general case is bookkeeping, not insight.
4. The trap the question sets: the number 2020 is dressed to look like a number theory problem about $2020 = 2^2 \cdot 5 \cdot 101$. It is not. The only role of 2020 is that 2016 is a multiple of 16 and that the tail sits within four of the modulus. Chasing the factorisation of 2020 wastes the whole session.
5. What makes you recognise it faster next time: the pairing "digit character times polynomial". Whenever those two appear multiplied, the answer is always "block of length base to the power (degree plus one), everything cancels, compute the tail".

6. The reusable decision rule: a weight that is a product over independent digit choices turns any sum over an aligned block into an iterated difference, and iterated differences annihilate polynomials of low degree. Choose the block length minimal, tile, and do arithmetic only on the remainder.

Mirror drills

1. Evaluate $\sum_{k=0}^{63}(-1)^{d(k)}k^5$. *Answer:* zero. The range is one aligned block of length 2^6, and six difference operators annihilate a polynomial of degree 5.
2. Evaluate $\sum_{k=0}^{2^m-1}(-1)^{d(k)}k^m$ in closed form. *Answer:* $(-1)^m m!\,2^{m(m-1)/2}$. The composite $\Delta_1\Delta_2\cdots\Delta_{2^{m-1}}$ applied to x^m equals $m!$ times the product of the steps, and the sign $(-1)^m$ comes from the operator expansion. Check $m=3$: $-6\cdot 8=-48$.
3. Determine $\sum_{k=1}^{2020}(-1)^{d(k)}k$ modulo 2020. *Answer:* zero. The degree is 1, so take blocks of length $2^2=4$; since $2020=4\cdot 505$, the range $\{0,1,\ldots,2019\}$ tiles exactly and contributes nothing, leaving only $k=2020$, whose contribution is $\pm 2020\equiv 0$.

6.8 B2. Adjacent pairing decides the peg sliding game

Let k and n be integers with $1 \leq k < n$. Alice and Bob play a game with k pegs in a line of n holes. At the beginning of the game, the pegs occupy the k leftmost holes. A legal move consists of moving a single peg to any vacant hole that is further to the right. The players alternate moves, with Alice playing first. The game ends when the pegs are in the k rightmost holes, so whoever is next to play cannot move and therefore loses. For what values of n and k does Alice have a winning strategy?

Read it out loud

This is an impartial game under the normal play convention: both players have the same moves available, and the player who cannot move loses. Positions are k-element subsets of $\{1, \ldots, n\}$, a move slides one peg rightwards to any vacant hole, and the unique position with no legal move is the block of k rightmost holes. The fields wired in are combinatorial game theory (normal play, winning and losing positions, pairing strategies) and nothing else; there is no arithmetic here beyond parity.

What is really being tested is whether you reach for a strategy instead of a computation. The answer to "for what n and k" is going to be a congruence condition, and the moment you accept that, you are being told that some parity object is conserved. The naive candidate is the number of moves in the game. Kill that candidate immediately: a peg may slide one hole or ten, so different lines of play from the same start can take different numbers of moves. Play $n = 4$, $k = 2$ once and you will see a two move game and a three move game from the identical start. So the parity is not in the move count; it must be in the *shape of the position*.

Once you know the parity lives in the position, the only cheap objects on a line of n holes that carry parity are pairings of the holes. And there is exactly one canonical pairing of a line: cut it into adjacent blocks $\{1,2\}, \{3,4\}, \ldots$. That pairing exists only when n is even, and the starting configuration respects it only when k is even. Two evenness conditions have appeared without any calculation, and the answer is already visible: Bob wins when n and k are both even, Alice wins otherwise.

Within thirty seconds you should have written: "normal play, so I want a pairing or a mirroring strategy"; "pair adjacent holes"; and "if n or k is odd, Alice's first move should destroy the obstruction and hand Bob an even by even board". The rest is verification.

Approaches, ranked worst to best

1. **Total move count parity.** *Cue:* normal play games are often decided by whether the total number of moves is fixed and odd. *Circuit:* count the moves, take the parity. This is the trap, and it is a good trap because the game does have a conserved quantity of exactly this flavour. It is false here: from $\{1,2\}$ on four holes, the line $1 \to 3$, $2 \to 4$ takes two moves while $2 \to 3$, $1 \to 2$, $2 \to 4$ takes three. Ranks last because it produces a confident wrong answer.

2. **Full Sprague Grundy tabulation.** *Cue:* impartial game under normal play. *Circuit:* compute the Grundy value of every position by the mex recursion. Correct in principle and it is what a machine would do, but the state space is all $\binom{n}{k}$ subsets, the game does not decompose into independent components, and you only need to know who wins the single starting position, not a Grundy value that could be added to other games. It costs enormous ink for information you do not need.

3. **Induction on n and k with a case analysis of Alice's first move.** *Cue:* the answer looks like a congruence in n and k. *Circuit:* strong induction on board size. This can be pushed through, but Alice has up to $k(n-k)$ first moves and you must handle all of them in the losing cases. You end up rediscovering the pairing anyway, in a disguised and longer form.

4. **Small case tabulation, then conjecture.** *Cue:* a two parameter family with a congruence answer. *Circuit:* compute the small table, read the pattern. Necessary reconnaissance and you should always do it. It is not a proof, so it cannot rank above a method that produces one, but it tells you which theorem to prove and it costs almost nothing.
5. **Adjacent pairing strategy with a one move trim.** *Cue:* normal play, a line of holes, an answer that is a parity condition. *Circuit:* when the loser is the player who runs out of moves, look for an involution of the board under which the second player can always mirror. Bob keeps every adjacent pair either full or empty; Alice's move always breaks one full pair and half fills a strictly later empty pair, and Bob completes it. When a parity obstruction exists, Alice spends one move retiring an end hole to remove it. Two short arguments, no case explosion, and both halves are checkable in the arena.

The ideal solution

Number the holes 1 to n from left to right. A position is a set $P \subseteq \{1, \dots, n\}$ with $|P| = k$; a move replaces P by $(P \setminus \{p\}) \cup \{v\}$ for some $p \in P$ and some vacant $v > p$. The initial position is $P_0 = \{1, \dots, k\}$ and the player who cannot move loses.

Lemma 6.8.1. *The game terminates, and the unique position with no legal move is* $\{n-k+1, \dots, n\}$.

Proof. The potential $\Phi(P) = \sum_{p \in P} p$ strictly increases with every move and is bounded above by $\sum_{i=n-k+1}^{n} i$, so only finitely many moves are possible. A position has no legal move exactly when no vacant hole lies to the right of any peg, that is, when every vacant hole precedes every peg, which for a set of size k means $P = \{n-k+1, \dots, n\}$. □

Theorem 6.8.2. *Alice has a winning strategy if and only if at least one of n and k is odd. If n and k are both even, Bob has a winning strategy.*

Step 1: both even, so the player to move loses.
Let n and k both be even, with $0 \le k \le n$. Split the holes into the $n/2$ adjacent pairs

$$Q_i = \{2i-1,\, 2i\}, \qquad i = 1, \dots, n/2.$$

Call a position P *balanced* if for every i either $Q_i \subseteq P$ or $Q_i \cap P = \emptyset$. Since k is even, $P_0 = \{1, \dots, k\}$ is balanced.

Claim 6.8.3. *If P is balanced and the player to move makes any legal move, the opponent has a legal reply after which the position is again balanced.*

Proof. Say the mover takes the peg at p to the vacant hole $v > p$. Let $Q_i \ni p$ and $Q_j \ni v$. Since P is balanced and $p \in P$, we have $Q_i \subseteq P$; since $v \notin P$, we have $Q_j \cap P = \emptyset$, so $Q_j \neq Q_i$ and hence $j \neq i$. If $j < i$ then $v \le 2j \le 2i-2 < 2i-1 \le p$, contradicting $v > p$. Therefore $j > i$, and consequently every element of Q_j is larger than every element of Q_i.

Let p' be the other hole of Q_i and v' the other hole of Q_j. After the mover's move, Q_i contains exactly the peg at p' and Q_j contains exactly the peg at v, while every other pair is untouched and hence still full or empty. The opponent moves the peg at p' to v': this is legal because $v' > p'$ (as Q_j lies entirely to the right of Q_i) and v' is vacant. Now Q_i is empty, Q_j is full, and every other pair is unchanged, so the position is balanced. □

Bob's strategy is: always restore balance. By the claim this is always available to him, so he never runs out of moves. By Lemma 1 the game terminates, and it can only terminate on a turn where the player to move has no move; that player is Alice. Hence when n and k are both even, the second player wins.

Step 2: two retirement facts.

(R1) If hole 1 is vacant, no peg can ever occupy it, because every move goes rightwards. The remaining play is therefore identical to the game on holes $2, \dots, n$ with the same k pegs, and the terminal position of the original game restricts to the terminal position of that game.

(R2) If hole n is occupied, that peg can never move, and no other peg can move into hole n. The remaining play is therefore identical to the game on holes $1, \dots, n-1$ with the other $k-1$ pegs, and again the terminal positions correspond.

Step 3: at least one of n, k odd, so Alice wins.

In each case Alice makes one move and hands Bob a game which, after retiring end holes, is an even by even game with Bob to move; Step 1 then says Bob loses.

Case A: n odd and k odd. Since $k < n$, hole n is vacant. Alice moves the peg at hole k to hole n, reaching $\{1, \dots, k-1\} \cup \{n\}$. By (R2) the remaining game is the game on the $n-1$ holes $1, \dots, n-1$ with the $k-1$ pegs in the leftmost $k-1$ holes. Both $n-1$ and $k-1$ are even, and Bob is to move, so Bob loses.

Case B: n odd and k even. Since $k < n$, hole $k+1$ exists and is vacant. Alice moves the peg at hole 1 to hole $k+1$, reaching $\{2, \dots, k+1\}$. By (R1) the remaining game is the game on the $n-1$ holes $2, \dots, n$ with the k pegs in the leftmost k of them. Both $n-1$ and k are even, and Bob is to move, so Bob loses.

Case C: n even and k odd. Alice moves the peg at hole 1 to hole n, reaching $\{2, \dots, k\} \cup \{n\}$. By (R1) and (R2) the remaining game is the game on the $n-2$ holes $2, \dots, n-1$ with the $k-1$ pegs in the leftmost $k-1$ of them. Both $n-2$ and $k-1$ are even, and Bob is to move, so Bob loses.

In Cases A and C with $k = 1$ the reduced game has no pegs at all, so Bob is immediately unable to move, which is the same conclusion. This proves the theorem, and the answer is:

$$\boxed{\text{Alice wins exactly when } n \text{ is odd or } k \text{ is odd}}.$$

Layer 1: WHAT

Block 1. Formalise: positions are k-subsets, a move slides one peg right into a vacancy, the terminal position is the right block, and the game is finite because $\sum_{p \in P} p$ strictly increases.

Block 2. Test the move count parity hypothesis on a small board and watch it fail. Conclude the parity lives in the position, not the length of the game.

Block 3. Look for a pairing of the board that the initial position respects. On a line there is only one natural one, adjacent blocks of two, and it exists exactly when n is even and is respected by $\{1, \dots, k\}$ exactly when k is even.

Block 4. Prove the mirroring claim: Alice must break a full pair and half fill a strictly later empty pair, so Bob can complete that pair.

Block 5. Record the two retirement facts: a vacant hole 1 is dead forever, and an occupied hole n is frozen forever.

Block 6. In each of the three odd cases, find a single Alice move that trims the board to even by even.

The nominal route runs: "impartial game, so compute Grundy values". That route builds a table of $\binom{n}{k}$ positions, finds no product structure to exploit, and never terminates by hand.

The bifurcation point is Block 2. The zombie asks "how many moves does this game take?" and, on seeing a plausible answer for the first small case, commits. The ideal solver asks "is the number of moves even determined by the start?", finds one three move line and one two move line on the four hole board, and immediately abandons counting for structure. Everything downstream follows from refusing to count.

Layer 2: HOW

Block 1. Cue. "The game ends when the pegs are in the k rightmost holes, so whoever is next to play cannot move and therefore loses." That is the normal play convention stated in words.

Why natural. Before anything else, confirm the game is finite and identify the unique terminal position, because every argument about who runs out of moves is vacuous if play could go on forever. The potential $\sum p$ is the obvious monotone quantity because every move increases exactly one coordinate. **Link to the next block.** A finite normal play game is decided by structure, and the two structural tools are Grundy values and pairing strategies.

Block 2. Cue. The question asks for which n and k, not for a Grundy value, so the answer is a congruence. **Why natural.** Congruence answers come from conserved parities. There are only two candidates: the parity of the number of moves, and the parity of some feature of the position. Test the cheap one first, on the smallest board where a choice exists. It fails, which is information, not a setback. **Link to the next block.** Having eliminated the move count, you are forced to look at the position itself.

Block 3. Cue. A line of n holes, and a losing condition of the form "you run out of moves". **Why natural.** In a normal play game the second player wins whenever the board admits an involution such that every move of the first player can be answered by the image move. On a line, the involution that respects the "rightwards only" constraint must map each hole to a neighbour, because the reply has to be legal in the same direction. Pairing $\{1,2\},\{3,4\},\ldots$ is the unique such involution. This is not a guess, it is the only candidate the geometry allows. **Link to the next block.** The pairing exists only for even n, and the start respects it only for even k, which is exactly the answer the small table predicted.

Block 4. Cue. The mirroring reply must be legal, which means it must go rightwards. **Why natural.** This is the one place where the proof could fail, so it is the one place that deserves a careful sentence. Alice takes a peg out of a full pair and puts it into an empty pair. A full pair cannot be the same as an empty pair, and the target must be to the right, which forces the target pair to lie entirely to the right of the source pair. That is what makes Bob's completing move legal. **Link to the next block.** Bob's strategy is now well defined and always available, so the game cannot end on his turn.

Block 5. Cue. Moves only go right, so extreme holes can become permanently irrelevant. **Why natural.** A vacant leftmost hole can never be filled, and an occupied rightmost hole can never be emptied. Each fact removes one hole from the board without changing the structure of the remaining game. This is the only way to change the parity of n inside the game, so it is what Alice must use. **Link to the next block.** Alice now needs one move that removes the right number of holes and pegs.

Block 6. Cue. Three parity cases, each needing a different trim: (n,k) odd odd needs one hole and one peg removed; odd even needs one hole and no peg; even odd needs two holes and one peg. **Why natural.** Match the trim to the deficit. Moving the rightmost peg to hole n freezes a peg and retires the right end. Moving the leftmost peg away from hole 1 retires the left end. Moving the leftmost peg all the way to hole n does both at once. There are exactly three trims and exactly three cases, and they line up because retiring the left end changes n only, while retiring the right end changes both n and k. **Link to the next block.** Each case lands on an even by even board with Bob to move, which Step 1 has already settled.

Layer 3: WHY

The mathematical truth beneath this route is that a pairing strategy is a homomorphism from the board to a quotient in which every position is already "done". Formally, when n and k are both even, the balanced positions form a set closed under "Alice moves then Bob restores", and the

terminal position is balanced. The second player therefore never faces a position from which he cannot answer, so the length of the game, whatever it is, ends on the first player's turn. No Grundy value is ever computed, because Grundy values carry information about sums of games and this game is never summed with another.

There is also a genuine conserved quantity in this game, and knowing it is what lets you kill the move count hypothesis without guessing. For a position P define

$$I(P) = \#\{(v, p) : v \text{ vacant},\ p \in P,\ v > p\}.$$

A move that carries a peg from p to v decreases I by exactly $v - p$. To see this, note that the pairs not involving p or v are untouched; the pair (v, p) is destroyed; each vacancy strictly between p and v loses its partner p and gains no new one; each peg strictly between p and v loses the vacancy v; and every hole outside $[p, v]$ exchanges one partner for another. Counting, the loss is $1 + (\text{holes strictly between}) = v - p$. Since $I(P_0) = k(n-k)$ and I is zero exactly at the terminal position, the total distance travelled by all pegs over the whole game is always $k(n-k)$, no matter how the game is played. What is *not* conserved is how that total is split into moves, which is precisely why the move count parity argument fails and why a genuine strategy is needed.

The discernment mechanism is a three question filter for any impartial game. First, is the game finite, and what is the unique terminal position? Second, is the total number of moves forced, and if so is its parity the answer? Third, if not, does the board carry an involution under which the second player can mirror, and does the starting position respect it? Only when all three fail do you reach for Sprague Grundy. On this problem the filter answers "yes, unique right block", "no, and here is a counterexample", "yes, adjacent pairing", and you are done.

To train it, take any normal play game you meet and immediately look for the involution before anything else. Mirroring beats computation whenever the board has a symmetry compatible with the move rule. The compatibility requirement is the part people forget: on this board a reflection through the centre is a perfectly good involution of the holes but it is useless, because the reply to a rightward move would have to be a leftward move.

The examiners nudged you deliberately. They wrote "a line of n holes", which is a board with an obvious block structure. They allowed a peg to move to *any* vacant hole further right, not just the adjacent one, which is exactly the modification that destroys the move count invariant and forces you to think. And they asked "for what values of n and k", which promises a congruence and therefore promises a parity object.

Revolving concepts

Impartial games under normal play. Both players have the same legal moves from any position and the player unable to move loses. Every position is either an $\mathcal{N}$-position (the player to move wins) or a $\mathcal{P}$-position (the previous player wins). The defining recursion is: P is a $\mathcal{P}$-position if and only if every move from P leads to an $\mathcal{N}$-position, and P is an $\mathcal{N}$-position if and only if some move leads to a $\mathcal{P}$-position. Generalised, this is the Sprague Grundy function $G(P) = \operatorname{mex}\{G(P') : P \to P'\}$ where mex of a set of nonnegative integers is the least nonnegative integer not in it; $\mathcal{P}$-positions are exactly those with $G = 0$, and for a disjoint sum of games $G(P \oplus Q) = G(P) \oplus G(Q)$ with $\oplus$ the bitwise exclusive or. Here the balanced positions are exactly a family of $\mathcal{P}$-positions and you never need the numerical values. Pointer: see Book 1, field: Games and invariants, topic: Sprague Grundy theory.

Pairing and mirroring strategies. If the board admits an involution σ with no fixed points, the starting position is σ-symmetric, and for every legal move m the "image" move is legal immediately afterwards, then the second player wins by always playing the image. The engineering content is always the legality of the reply, not the existence of σ. Pointer: see Book 1, field: Games and invariants, topic: pairing strategies and strategy stealing.

Monotone potentials and termination. A strictly monotone bounded integer functional on positions proves a game is finite. Here $\Phi(P) = \sum_{p \in P} p$ works. Pointer: see Book 1, field: Games and invariants, topic: termination arguments.

The inversion count and its recursion. $I(P) = \#\{(v, p) : v \text{ vacant}, p \text{ peg}, v > p\}$ satisfies $I(P') = I(P) - (v - p)$ for a move from p to v, with $I(P_0) = k(n-k)$ and $I = 0$ at the end. Written as a recursion, $I_{t+1} = I_t - d_t$ where d_t is the distance of the t-th move, so $\sum_t d_t = k(n-k)$ for every play. The general lesson is that when a game has a conserved total but a free decomposition of that total into moves, the move count carries no invariant and a strategy is required. Pointer: see Book 1, field: Combinatorics, topic: inversions of a binary word.

Related classical games. Sliding coins rightwards along a strip is the family containing the Silver Dollar Game and Mock Turtles; when jumping over occupied cells is forbidden, the game becomes staircase Nim on the gaps. The present rule permits jumping, which is exactly why the gap structure is not preserved and the pairing argument replaces the Nim analysis. Pointer: see Book 1, field: Games and invariants, topic: coin sliding games.

Circuit Bank

- **WHEN** an impartial normal play game whose answer is asked as a condition on parameters **DO** look for a pairing or mirroring strategy for the second player before computing any Grundy value **BECAUSE** a congruence answer signals a conserved parity, and the cheapest carrier of parity on a structured board is an involution the second player can imitate
- **WHEN** a game where you suspect the number of moves is fixed **DO** find two lines of play from the same start with different lengths, or prove the total is forced **BECAUSE** a move count argument is worthless unless the count is determined by the position, and one explicit pair of unequal lines settles it in ten seconds
- **WHEN** moves that go only in one direction along a line **DO** ask which cells become permanently dead, namely a vacancy with nothing to its left that can fill it and an occupied cell with nothing to its right **BECAUSE** dead cells can be deleted from the board without changing the game, and deleting cells is the only way a player can change the parity of the board size
- **WHEN** a mirroring strategy whose reply must obey a direction constraint **DO** check that the target block lies entirely on the correct side of the source block **BECAUSE** the existence of the involution is never the difficulty; the legality of the mirrored reply is, and it is the only step that can fail

Backtesting

1. First useful cue: normal play, plus an answer requested as a condition on n and k, which together say "find the parity object" and, on a line, "pair adjacent holes".
2. Method the expression suggested: a second player pairing strategy for the symmetric case, plus a single trimming move by the first player to remove any parity obstruction.
3. Where you would hesitate, and the thought to reinforce: the hesitation is whether Bob's reply is always legal. Reinforce with the sentence "a full pair and an empty pair are distinct, and a rightward move forces the empty one to lie entirely to the right". That single observation is the load bearing step of the whole proof.
4. The trap the question sets: allowing a peg to move to *any* vacant hole to the right, which looks like generosity but is there to destroy the move count invariant. If the rule were "move to the adjacent vacant hole", the total number of moves would be forced to $k(n-k)$ and the answer would be a different, simpler parity condition.

5. What makes you recognise it faster next time: the shape "line of cells, one directional moves, last player to move wins" should fire the adjacent pairing circuit instantly, and the shape "answer is a condition on parameters" should fire "conserved parity".
6. The reusable decision rule: in a finite normal play game, before computing anything, ask whether the board has a fixed point free involution compatible with the direction of play under which the starting position is symmetric; if it does, the second player wins, and the first player's only hope is a move that destroys the symmetry defect.

Mirror drills

1. Same game, but a legal move is to slide a peg into the vacant hole immediately to its right (no jumping). Who wins? *Answer:* pegs can no longer pass one another, so the i-th peg must travel from hole i to hole $n-k+i$, and the game always lasts exactly $k(n-k)$ moves. Alice wins if and only if $k(n-k)$ is odd, that is, if and only if k is odd and n is even.
2. Prove that in the original game the total distance travelled by all pegs is the same for every line of play. *Answer:* the inversion count $I(P) = \#\{(v,p) : v \text{ vacant}, p \text{ peg}, v > p\}$ drops by exactly $v-p$ on a move from p to v, starts at $k(n-k)$ and ends at 0.
3. Why must the pairs be adjacent? Show that pairing hole i with hole $n+1-i$ cannot support Bob's strategy. *Answer:* the starting position $\{1,\dots,k\}$ is not even symmetric under that pairing, since hole 1 is occupied while hole n is not; and even if it were, Bob's completing move could be forced to go leftwards, which is illegal.

6.9 B3. Take logarithms and count exponential arrivals

Let $x_0 = 1$, and let δ be some constant satisfying $0 < \delta < 1$. Iteratively, for $n = 0, 1, 2, \ldots$, a point x_{n+1} is chosen uniformly from the interval $[0, x_n]$. Let Z be the smallest value of n for which $x_n < \delta$. Find the expected value of Z, as a function of δ.

Read it out loud

This is a first passage time for a *multiplicative* random walk. Read the recursion literally: x_{n+1} is uniform on $[0, x_n]$, which is the same sentence as $x_{n+1} = x_n U_{n+1}$ with U_{n+1} uniform on $[0, 1]$ and independent of everything before. So $x_n = U_1 U_2 \cdots U_n$, a product of independent uniforms, and Z is the first index at which that product drops below a fixed level.

The fields wired in are: transformations of random variables, sums of independent exponentials and the Gamma distribution, the tail sum formula for the expectation of a nonnegative integer variable, and (as the one line reading of the whole thing) the Poisson process. There is no calculus of variations, no differential equation, and nothing that needs the word "martingale".

What is really being tested is one reflex: a product of independent factors becomes a sum of independent increments the moment you take logarithms. The problem has been engineered so that the resulting increments are the nicest possible ones. If U is uniform on $[0, 1]$ then $\mathbb{P}(-\log U > t) = \mathbb{P}(U < e^{-t}) = e^{-t}$, so $-\log U$ is exponential with rate one. The walk $-\log x_n$ is therefore a sum of independent rate one exponentials, which is by definition the sequence of arrival times of a rate one Poisson process, and the question "when does the walk first exceed the level $\log(1/\delta)$?" is the question "how many arrivals happen in an interval of length $\log(1/\delta)$?".

Within thirty seconds you should have written three lines: $x_n = U_1 \cdots U_n$; $-\log U_i \sim \mathrm{Exp}(1)$; $L := \log(1/\delta)$ and $Z = \min\{n : T_n > L\}$ where $T_n = -\log x_n$. At that point the answer $1 + L$ is already visible, because the expected number of rate one arrivals in a window of length L is L and Z is one more than that count.

Approaches, ranked worst to best

1. **Convolve the densities of products of uniforms.** *Cue:* a product of n independent uniforms has a computable density. *Circuit:* find the law of x_n, then sum $\mathbb{P}(x_n \geq \delta)$. Doable, since the density of the product is $(-\log x)^{n-1}/(n-1)!$ on $(0, 1)$, but you are deriving that by an integral recursion that is nothing other than the logarithm in disguise, and you are doing it without admitting it. It ranks last because it is the ideal method performed blindfolded.

2. **Condition on x_1 and solve an integral equation.** *Cue:* the problem is scale invariant, so conditioning on the first step reproduces the same problem with a rescaled δ. *Circuit:* self-similarity of the process. Write $f(\delta) = \mathbb{E}[Z]$ and $f(\delta) = 1 + \int_\delta^1 f(\delta/c)\, dc$, then substitute $h(x) = f(1/x)$ to get $xh(x) - x = \int_1^x h$, differentiate and solve $h'(x) = 1/x$. This is correct and it is the route the official solution takes, but it silently uses that h is continuous before differentiating an integral, and it asks you to solve a functional equation rather than to recognise a distribution you already know.

3. **Renewal reward with Wald's identity.** *Cue:* Z is a stopping time for a sum of independent identically distributed increments. *Circuit:* Wald plus memorylessness. After taking logarithms, Wald's identity gives $\mathbb{E}[T_Z] = \mathbb{E}[Z]\,\mathbb{E}[E_1] = \mathbb{E}[Z]$, and $T_Z = L + R$ where the overshoot R is again exponential with mean one by memorylessness. Hence $\mathbb{E}[Z] = L + 1$. Short and beautiful, and it explains where the "+1" comes from, but it quotes two theorems and needs $\mathbb{E}[Z] < \infty$ established first.

4. **Logarithms plus the Poisson process.** *Cue:* the increments are exactly rate one exponentials. *Circuit:* arrival times of a Poisson process. $Z = N(L) + 1$ where $N(L)$ is the number of arrivals

in $[0, L]$, and $N(L)$ is Poisson with mean L, so $\mathbb{E}[Z] = L + 1$. This is the correct mental picture and it is two lines. It ranks just below the winner only because it imports a named process.

5. **Logarithms plus the tail sum formula.** *Cue:* expectation of a nonnegative integer variable, and $\{Z > n\}$ is exactly $\{T_n \le L\}$. *Circuit:* sum the survival probabilities, swap by positivity. $\mathbb{E}[Z] = \sum_{n\ge 0} \mathbb{P}(T_n \le L)$, each term is the Gamma cumulative distribution, and swapping sum and integral collapses the exponential series against e^{-t} to give $1 + L$. Nothing is imported beyond the Gamma density, every interchange is justified by nonnegativity, and the finiteness of $\mathbb{E}[Z]$ comes out of the computation rather than being assumed. This is the ideal write up.

The ideal solution

Write $L = \log(1/\delta)$, so $L > 0$ because $0 < \delta < 1$.

Step 1: realise the process as a product. Saying that x_{n+1} is uniform on $[0, x_n]$ is exactly saying $x_{n+1} = x_n U_{n+1}$ where $U_1, U_2, \dots$ are independent and uniform on $[0, 1]$, independent of the past: if $x_n = t > 0$ then tU_{n+1} is uniform on $[0, t]$. Hence

$$x_n = U_1 U_2 \cdots U_n \qquad (n \ge 0),$$

with the empty product equal to $x_0 = 1$. Each $U_i > 0$ almost surely, so $x_n > 0$ almost surely and the logarithms below are defined.

Step 2: take logarithms. Put $E_i = -\log U_i$. For $t \ge 0$,

$$\mathbb{P}(E_i > t) = \mathbb{P}(U_i < e^{-t}) = e^{-t},$$

so the E_i are independent exponential random variables of rate one. Setting $T_0 = 0$ and $T_n = E_1 + \cdots + E_n = -\log x_n$, the stopping condition transforms as

$$x_n < \delta \iff -\log x_n > -\log \delta \iff T_n > L,$$

so

$$Z = \min\{n \ge 0 : T_n > L\}.$$

Since $T_0 = 0 \le L$ we have $Z \ge 1$, which matches $x_0 = 1 \ge \delta$.

Step 3: the survival events. The sequence T_n is nondecreasing, so $\{Z > n\} = \{T_n \le L\}$ for every $n \ge 0$. For a random variable Z taking values in $\{0, 1, 2, \dots\} \cup \{\infty\}$,

$$\mathbb{E}[Z] = \sum_{n\ge 0} \mathbb{P}(Z > n),$$

with both sides simultaneously finite or infinite; this is Tonelli applied to $\sum_{n\ge 0} \mathbb{E}[\mathbf{1}_{\{Z>n\}}]$.

Step 4: the law of T_n. For $n \ge 1$, T_n has density $g_n(t) = t^{n-1}e^{-t}/(n-1)!$ on $t > 0$. Indeed $g_1(t) = e^{-t}$, and if g_{n-1} has this form then

$$g_n(t) = \int_0^t g_{n-1}(s)\, e^{-(t-s)}\, ds = e^{-t} \int_0^t \frac{s^{n-2}}{(n-2)!}\, ds = \frac{t^{n-1}e^{-t}}{(n-1)!},$$

which is the induction step.

Step 5: sum. Using $\mathbb{P}(Z > 0) = 1$ and $\mathbb{P}(Z > n) = \mathbb{P}(T_n \le L) = \int_0^L \frac{t^{n-1}e^{-t}}{(n-1)!}\, dt$ for $n \ge 1$,

$$\mathbb{E}[Z] = 1 + \sum_{n=1}^{\infty} \int_0^L \frac{t^{n-1}e^{-t}}{(n-1)!}\, dt = 1 + \int_0^L e^{-t} \sum_{n=1}^{\infty} \frac{t^{n-1}}{(n-1)!}\, dt = 1 + \int_0^L e^{-t}e^{t}\, dt = 1 + L.$$

Every term of the double sum is nonnegative, so the interchange of $\sum$ and $\int$ is justified by Tonelli's theorem. In particular $\mathbb{E}[Z]$ is finite, so $Z < \infty$ almost surely.

Therefore

$$\boxed{\mathbb{E}[Z] = 1 + \log(1/\delta) = 1 - \log \delta}$$

with log the natural logarithm.

Remark (the same computation in one line). The points $T_1 < T_2 < \cdots$ are the arrival times of a rate one Poisson process, so $N(L) := \#\{n \geq 1 : T_n \leq L\}$ is Poisson with mean L, and $Z = N(L) + 1$. Hence $\mathbb{E}[Z] = L + 1$, and moreover $Z - 1$ is Poisson, so $\mathrm{Var}(Z) = L$ as well.

Check. As $\delta \to 1^-$, $L \to 0$ and $\mathbb{E}[Z] \to 1$: with δ near 1 the very first point falls below δ with probability near one. As $\delta \to 0^+$, $\mathbb{E}[Z] \to \infty$ logarithmically, which is right because the walk descends by a constant factor per step on average.

Layer 1: WHAT

Block 1. Rewrite "uniform on $[0, x_n]$" as "x_n times an independent uniform on $[0, 1]$", so x_n is a product of independent identically distributed factors.

Block 2. Take logarithms; the product becomes a sum, and the summands are rate one exponentials because $\mathbb{P}(-\log U > t) = e^{-t}$ directly from the definition.

Block 3. Translate the stopping rule: $x_n < \delta$ becomes $T_n > L$ with $L = \log(1/\delta)$, so Z is a first passage index above a fixed level.

Block 4. Use monotonicity of T_n to identify the survival events $\{Z > n\} = \{T_n \leq L\}$, and use the tail sum formula for $\mathbb{E}[Z]$.

Block 5. Write down the Gamma density of T_n and hence each survival probability as an integral over the fixed window $[0, L]$.

Block 6. Swap sum and integral, recognise $\sum t^{n-1}/(n-1)! = e^t$, and watch $e^{-t}e^t = 1$ collapse the integral to L.

The nominal route runs: "let $f(\delta)$ be the answer; condition on the first point; this gives $f(\delta) = 1 + \int_\delta^1 f(\delta/c)\, dc$; now solve the functional equation." It arrives at the same place after a substitution, a differentiation under an integral sign, and a first order differential equation.

The bifurcation point is the first line you write. The zombie writes "let $f(\delta) = \mathbb{E}[Z]$", that is, it starts from the *answer* and tries to characterise it. The ideal solver writes "$x_{n+1} = x_n U_{n+1}$", that is, it starts from the *process* and changes coordinates until the process is one it already knows. Naming the unknown is the reflex that costs you the elegant solution here, because the unknown is not the object with structure; the walk is.

Layer 2: HOW

Block 1. Cue. "Chosen uniformly from the interval $[0, x_n]$" has the previous value in the range of the uniform, not in the answer. **Why natural.** A uniform law on $[0, t]$ is the scaling by t of the uniform law on $[0, 1]$. That is the definition of the uniform distribution, not an insight. So the recursion is multiplication by an independent factor with a fixed law, and the process is a multiplicative random walk with independent increments. **Link to the next block.** A walk with independent multiplicative increments is a walk with independent additive increments after one change of coordinates.

Block 2. Cue. The state space is $(0, 1]$ under multiplication. **Why natural.** The logarithm is the isomorphism from the multiplicative group of positive reals to the additive reals. Whenever a recursion multiplies, the coordinate in which it is linear is the logarithm. The bonus is that the specific law here is the nicest one there is: $-\log U$ for U uniform is exponential, which you verify in one line from the definition of the distribution function. **Link to the next block.** Additive walks with independent increments are first passage problems, and first passage above a level is what the question asks.

Block 3. **Cue.** "The smallest value of n for which $x_n < \delta$." **Why natural.** A threshold in the original coordinate becomes a threshold in the logarithmic coordinate, because log is increasing. The parameter δ enters only through $L = \log(1/\delta)$, which is the first sign that the answer will be a function of L alone and probably an affine one. **Link to the next block.** You now need the distribution of the first passage index, and the cheapest handle on any stopping index is its tail.

Block 4. **Cue.** The quantity requested is an expectation of a nonnegative integer variable. **Why natural.** For such a variable the tail sum formula turns an expectation into a sum of probabilities of "not yet stopped" events. Here that event is $\{T_n \le L\}$, which is a statement about a sum of n known independent variables, and therefore computable. Computing the law of Z itself would require the joint statement $T_n \le L < T_{n+1}$, which is strictly harder for no benefit. **Link to the next block.** Each survival probability is a Gamma cumulative distribution over the same window.

Block 5. **Cue.** A sum of n independent rate one exponentials. **Why natural.** This is the Gamma distribution, and the density is obtained by one convolution induction that takes two lines. You should never look this up in the arena; the induction is faster than remembering. **Link to the next block.** You now have a sum of integrals over one fixed interval, all sharing the factor e^{-t}.

Block 6. **Cue.** A sum over n of $t^{n-1}/(n-1)!$. **Why natural.** That is the exponential series, and it is sitting next to e^{-t}. Be lazy: swap the order, let the series do the work, and the integrand becomes the constant 1. The swap needs no delicate justification because every term is nonnegative, so Tonelli applies with no hypotheses to check. **Link to the next block.** The integral of 1 over $[0, L]$ is L, so the answer is $1 + L$.

Layer 3: WHY

The mathematical truth beneath this route is the identification of two symmetries. The problem is *scale invariant*: conditioned on $x_1 = c$, the remaining process is a copy of the original with δ replaced by δ/c. That is what the official integral equation encodes. On the other side, the exponential distribution is the unique *memoryless* law on $[0, \infty)$: $\mathbb{P}(E > s + t \mid E > s) = \mathbb{P}(E > t)$. These are the same statement transported by the logarithm. Scale invariance in the multiplicative picture is memorylessness in the additive picture. So you may either derive and solve a functional equation expressing the symmetry, or change coordinates so that the symmetry is carried by a distribution whose properties you already know. The second is strictly less work, and it is available whenever the increments are multiplicative.

The truth also explains the shape of the answer. Split $\mathbb{E}[Z] = L + 1$ into its two pieces. The L is the expected number of complete crossings: the walk moves by an average of one unit per step, and it must cover a distance L. The 1 is the overshoot step, the one move that takes the walk past the level. Formally, Wald's identity says $\mathbb{E}[T_Z] = \mathbb{E}[Z]\,\mathbb{E}[E_1] = \mathbb{E}[Z]$, while $T_Z = L + R$ with R the overshoot; memorylessness makes R exponential with mean one regardless of L, so $\mathbb{E}[Z] = L + 1$. Every "+1" in a first passage answer is an overshoot, and knowing that lets you predict the shape of the answer before computing anything.

The discernment mechanism is a short filter. When you meet a random recursion, ask what group the increment acts by. If it is addition, work directly. If it is multiplication on $(0, \infty)$, take logarithms without hesitation. Then ask what the log increment law is: for uniform on $[0, 1]$ it is exponential, for uniform on $[a, b]$ with $0 < a < b$ it is uniform on $[\log(1/b), \log(1/a)]$, for a Beta law it is one of the classical families. Only when the log increment is not a named law do you fall back on functional equations. Training this is a matter of doing the substitution reflexively, even when the problem looks as though it wants a recursion in δ.

The examiners nudged you three times. They set $x_0 = 1$, which is the multiplicative identity and therefore the natural origin after taking logarithms. They chose the uniform distribution rather than

any other law on $[0, x_n]$, which is precisely the choice that makes the log increments exponential. And they asked for the answer "as a function of δ", which tells you the answer depends on δ alone and not on any further data, and hence that only the single number $\log(1/\delta)$ can appear.

Revolving concepts

Uniform scaling and the definition of a uniform law. If U is uniform on $[0,1]$ and $t > 0$ then tU is uniform on $[0,t]$; conversely any variable uniform on $[0,t]$ equals t times an independent uniform on $[0,1]$ in distribution. Pointer: see Book 1, field: Probability, topic: transformations of continuous random variables.

The probability integral transform. If F is a continuous strictly increasing distribution function and U is uniform on $[0,1]$ then $F^{-1}(U)$ has distribution function F; the case $F(t) = 1 - e^{-t}$ gives $-\log U \sim \mathrm{Exp}(1)$ and is the one you use here. Pointer: see Book 1, field: Probability, topic: inverse transform sampling.

Sums of exponentials and the Gamma law. If $E_1, \dots, E_n$ are independent $\mathrm{Exp}(\lambda)$ then $T_n = \sum E_i$ has density $\lambda^n t^{n-1} e^{-\lambda t}/(n-1)!$. The recursion is the convolution $g_n = g_{n-1} * g_1$, whose general solution for exponential increments is the Gamma density above; the same convolution recursion for a general increment density g defines the renewal density, and the general solution method is to pass to Laplace transforms, where $\widehat{g_n} = (\widehat{g})^n$ and $\sum_n \widehat{g_n} = \widehat{g}/(1-\widehat{g})$. Pointer: see Book 1, field: Probability, topic: convolutions and the Gamma family.

Poisson process. If T_n are the partial sums of independent $\mathrm{Exp}(\lambda)$ variables and $N(t) = \#\{n \geq 1 : T_n \leq t\}$, then $N(t)$ is Poisson with mean λt, and $\mathbb{P}(T_n > t) = \mathbb{P}(N(t) \leq n-1) = e^{-\lambda t} \sum_{j<n} (\lambda t)^j / j!$. This last identity is the same statement as the Gamma tail integral, and it converts the integral in Step 5 into a finite sum if you prefer. Pointer: see Book 1, field: Probability, topic: Poisson processes.

Tail sum formula. For Z with values in $\{0,1,2,\dots\} \cup \{\infty\}$, $\mathbb{E}[Z] = \sum_{n \geq 0} \mathbb{P}(Z > n)$, proved by writing $Z = \sum_{n \geq 0} \mathbf{1}_{\{Z > n\}}$ and applying Tonelli. Pointer: see Book 1, field: Probability, topic: expectations via tails.

Wald's identity and overshoot. If Z is a stopping time for independent identically distributed integrable increments E_i and $\mathbb{E}[Z] < \infty$, then $\mathbb{E}[T_Z] = \mathbb{E}[Z]\mathbb{E}[E_1]$. For exponential increments memorylessness makes the overshoot $T_Z - L$ exponential with the same rate, independent of L, which is why first passage answers of this type have the shape "level divided by mean drift, plus one". Pointer: see Book 1, field: Probability, topic: renewal theory and Wald's identity.

Memorylessness and scale invariance. The exponential law is the unique memoryless law on $[0,\infty)$; under $x \mapsto -\log x$ this is exactly the scale invariance of the uniform recursion. Pointer: see Book 1, field: Probability, topic: characterisations of the exponential distribution.

Circuit Bank

- **WHEN** a random recursion of the form $X_{n+1} = X_n \cdot (\text{independent factor})$ **DO** take logarithms immediately, before writing anything else **BECAUSE** log is the isomorphism from the multiplicative positives to the additive reals, so it converts a multiplicative walk into a sum of independent identically distributed increments, which is the only walk anyone knows how to analyse
- **WHEN** a uniform factor on $[0,1]$ inside a product **DO** write $-\log U \sim \mathrm{Exp}(1)$ **BECAUSE** $\mathbb{P}(-\log U > t) = \mathbb{P}(U < e^{-t}) = e^{-t}$ straight from the definition, and exponential increments turn the walk into a Poisson process whose counts you know exactly
- **WHEN** an expectation of a first passage index or any other nonnegative integer variable **DO** use $\mathbb{E}[Z] = \sum_{n \geq 0} \mathbb{P}(Z > n)$ **BECAUSE** the survival events are statements about the first n increments only, so they are computable, whereas the point probabilities of Z require a two sided sandwich

- **WHEN** a sum of integrals of nonnegative functions that you want to interchange **DO** cite Tonelli and swap without further comment **BECAUSE** nonnegativity makes the interchange unconditional, so there is no convergence hypothesis to check and no ink to spend
- **WHEN** a first passage answer that comes out as "level plus a constant" **DO** identify the constant as the expected overshoot **BECAUSE** Wald's identity splits $\mathbb{E}[Z]$ into the distance to be covered and the final partial step, and for memoryless increments the overshoot has the same law as a fresh increment

Backtesting

1. First useful cue: "uniform on $[0, x_n]$" with the previous state inside the interval, which says multiplicative increment, which says take logarithms.
2. Method the expression suggested: convert the product to a sum of rate one exponentials, read the stopping rule as a first passage above $L = \log(1/\delta)$, and evaluate the expectation by summing survival probabilities.
3. Where you would hesitate, and the thought to reinforce: the hesitation is whether you are allowed to realise the whole process with one independent uniform per step. Reinforce with "a uniform on $[0, t]$ *is* t times a uniform on $[0, 1]$", which is the definition and not a modelling assumption.
4. The trap the question sets: asking for the answer "as a function of δ" invites you to name $f(\delta)$ and hunt for an equation it satisfies. That route works but it costs a functional equation, a substitution and a differentiation under an integral, and it needs a continuity remark that most write ups omit.
5. What makes you recognise it faster next time: the pairing "product of independent factors" with "first time below a threshold". Those two phrases together mean Poisson process, always.
6. The reusable decision rule: change coordinates until the increments are independent and additive, then read off the answer from a distribution you already know, rather than characterising the answer by an equation.

Mirror drills

1. Same process, but Z' is the smallest n with $x_n < \delta^2$. Find $\mathbb{E}[Z']$. *Answer:* $1 + \log(1/\delta^2) = 1 - 2\log\delta$; only the level L changes, and it doubles.
2. Show that $Z - 1$ is Poisson distributed and deduce $\mathrm{Var}(Z)$. *Answer:* $\mathbb{P}(Z - 1 = j) = \mathbb{P}(T_j \leq L < T_{j+1}) = e^{-L}L^j/j!$, so $Z - 1 \sim \mathrm{Poisson}(L)$ and $\mathrm{Var}(Z) = L = -\log\delta$.
3. For independent uniforms $U_1, \ldots, U_n$ on $[0, 1]$, compute $\mathbb{P}(U_1U_2 \cdots U_n < \delta)$. *Answer:* $\delta \sum_{j=0}^{n-1} \frac{(\log(1/\delta))^j}{j!}$, since the event is $\{T_n > L\} = \{N(L) \leq n - 1\}$ and $N(L)$ is Poisson with mean L, while $e^{-L} = \delta$.

6.10 B4. Cyclic rotation makes the reciprocals sum to one

Let n be a positive integer, and let V_n be the set of integer $(2n+1)$-tuples $\mathbf{v} = (s_0, s_1, \ldots, s_{2n-1}, s_{2n})$ for which $s_0 = s_{2n} = 0$ and $|s_j - s_{j-1}| = 1$ for $j = 1, 2, \ldots, 2n$. Define

$$q(\mathbf{v}) = 1 + \sum_{j=1}^{2n-1} 3^{s_j},$$

and let $M(n)$ be the average of $\frac{1}{q(\mathbf{v})}$ over all $\mathbf{v} \in V_n$. Evaluate $M(2020)$.

Read it out loud

This is the average of the reciprocal of a weighted sum, taken over all closed lattice paths of length $2n$ with unit steps. The path starts and ends at height zero, and q collects the value 3^{height} at every intermediate time. The fields wired in are bijective combinatorics (paths and step words), finite group actions (the cyclic group of order $2n$ acting by rotation), and double counting. Nothing analytic and nothing about Catalan numbers.

Two features of the statement are shouting. The first is the reciprocal. Averages of reciprocals almost never have closed forms, because $\mathbb{E}[1/X]$ requires the whole distribution of X while $\mathbb{E}[X]$ requires only its mean. So if a clean answer exists, it cannot come from knowing the distribution of q; it must come from a structural identity that produces $1/q$ directly. The only such identity that exists is this one: if a group acts and q scales by a multiplier under the action, then the reciprocals over one orbit add up to something you can control.

The second is the shape of q itself. It is written as $1 + \sum_{j=1}^{2n-1}$, which is one short at the top and carries a stray additive constant. Since $s_{2n} = 0$, that constant is exactly $3^{s_{2n}}$. So

$$q(\mathbf{v}) = \sum_{j=1}^{2n} 3^{s_j},$$

a sum over a complete period. The problem was deliberately written in the asymmetric form to hide the cyclic symmetry from you. Undoing that disguise is the first move.

Within thirty seconds you should have written: $q = \sum_{j=1}^{2n} 3^{s_j}$; "rotate the step word"; and the guess $M(n) = 1/(2n)$. The case $n = 1$ confirms it in one line: the two paths give $q = 1 + 3 = 4$ and $q = 1 + \frac{1}{3} = \frac{4}{3}$, whose reciprocals $\frac{1}{4}$ and $\frac{3}{4}$ average to $\frac{1}{2}$. The tell that $1/(2n)$ is the right shape is that $4040 = 2 \cdot 2020$ is the length of the walk, that is, the order of the rotation group.

Approaches, ranked worst to best

1. **Find the distribution of q and average its reciprocal.** *Cue:* it is an expectation over a finite set. *Circuit:* transfer matrix or generating function in the height. You would need the joint law of all $2n$ heights, since q couples them all, and then you would need to invert. The reciprocal destroys every product structure a transfer matrix could give you. This is the definition of zombie maths on this problem.

2. **Expand $1/q$ as a geometric series.** *Cue:* q is a sum, and $1/(1+u) = 1 - u + u^2 - \cdots$. *Circuit:* series expansion of the reciprocal. The heights are both positive and negative, so q ranges over many orders of magnitude and no expansion point works uniformly. Even where it converges you are left with an infinite family of moment computations. It stalls immediately.

3. **Small cases then conjecture.** *Cue:* a clean numerical answer is demanded. *Circuit:* compute $n = 1, 2, 3$ and read the pattern. Cheap and essential. It produces $M(1) = \frac{1}{2}$, $M(2) = \frac{1}{4}$, $M(3) = \frac{1}{6}$, and, if you also try base 2 instead of base 3, it produces the far more valuable observation that the answer does not depend on the base at all. That observation is the real

content of the reconnaissance, because a parameter that cannot appear in the answer cannot appear in the mechanism.

4. **Rotate and analyse orbits.** *Cue:* closed path, so the step word can be rotated. *Circuit:* group action, then average orbit by orbit. Show q scales under rotation, deduce that the average of $1/q$ over each orbit is $1/(2n)$, then note that V_n is a disjoint union of orbits. Correct, and it is the official route, but it forces you to discuss orbits whose length m properly divides $2n$ and to argue that running k from 1 to $2n$ traverses such an orbit $2n/m$ times with each element equally often. That paragraph is pure bookkeeping.

5. **Rotate and double count.** *Cue:* the same cue, but finished by Fubini. *Circuit:* sum the orbit identity over the whole set, using only that each rotation is a bijection. Sum the identity $\sum_{k=1}^{2n} 1/q(\varphi^k \mathbf{w}) = 1$ over all $\mathbf{w}$, then interchange the two sums. Each φ^k is a bijection of the set, so the inner sum is the same total T every time, giving $2n\,T = |V_n|$. No orbit ever has to be examined. This is the ideal route: it is three lines shorter and it removes the only place where the official argument could be mis-stated.

The ideal solution

Fix any real $a > 0$ and define $q_a(\mathbf{v}) = 1 + \sum_{j=1}^{2n-1} a^{s_j}$. We prove that the average of $1/q_a$ over V_n equals $\frac{1}{2n}$, independently of a; the problem is the case $a = 3$.

Step 1: restore the symmetry. Since $s_{2n} = 0$ we have $a^{s_{2n}} = 1$, so

$$q_a(\mathbf{v}) = \sum_{j=1}^{2n} a^{s_j}.$$

Every term is positive, so $q_a(\mathbf{v}) > 0$ and $1/q_a$ is defined.

Step 2: pass to step words. Let W_n be the set of tuples $\mathbf{w} = (w_1, \ldots, w_{2n}) \in \{+1, -1\}^{2n}$ with $\sum_{i=1}^{2n} w_i = 0$, that is, with exactly n entries equal to $+1$. The map

$$\mathbf{w} \longmapsto \mathbf{v}, \qquad s_0 = 0, \quad s_j = w_1 + \cdots + w_j \ (1 \le j \le 2n),$$

is a bijection $W_n \to V_n$, with inverse $w_j = s_j - s_{j-1}$. Write $Q(\mathbf{w}) = q_a(\mathbf{v}) = \sum_{j=1}^{2n} a^{s_j}$.

Step 3: rotate. Extend the indices periodically by $w_{i+2n} = w_i$. Because $\sum_{i=1}^{2n} w_i = 0$, the partial sums satisfy $s_{j+2n} = s_j$ for all $j \ge 0$; this is exactly where the hypothesis $s_{2n} = 0$ is used, and it is the only place. Let $\varphi : W_n \to W_n$ be the rotation $\varphi(\mathbf{w})_i = w_{i+1}$, which is a bijection of W_n since it preserves the number of $+1$ entries. The i-th entry of $\varphi^k(\mathbf{w})$ is w_{i+k}, so the partial sums of $\varphi^k(\mathbf{w})$ are

$$s_j^{(k)} = \sum_{i=1}^{j} w_{i+k} = s_{j+k} - s_k.$$

Therefore

$$Q(\varphi^k \mathbf{w}) = \sum_{j=1}^{2n} a^{s_{j+k} - s_k} = a^{-s_k} \sum_{j=1}^{2n} a^{s_{j+k}} = a^{-s_k} \sum_{j=1}^{2n} a^{s_j} = a^{-s_k} Q(\mathbf{w}),$$

where the third equality holds because $j \mapsto j + k$ permutes a complete period and a^{s_j} has period $2n$ in j.

Step 4: the reciprocals over one rotation cycle add to one. For each fixed $\mathbf{w}$,

$$\sum_{k=1}^{2n} \frac{1}{Q(\varphi^k \mathbf{w})} = \sum_{k=1}^{2n} \frac{a^{s_k}}{Q(\mathbf{w})} = \frac{1}{Q(\mathbf{w})} \sum_{k=1}^{2n} a^{s_k} = \frac{Q(\mathbf{w})}{Q(\mathbf{w})} = 1.$$

The last step is not a coincidence: $Q(\mathbf{w})$ was defined to be the sum of the very multipliers a^{s_k} that the rotation produces.

Step 5: double count. Sum the identity of Step 4 over all $\mathbf{w} \in W_n$ and interchange the two finite sums:

$$|W_n| = \sum_{\mathbf{w}\in W_n} \sum_{k=1}^{2n} \frac{1}{Q(\varphi^k \mathbf{w})} = \sum_{k=1}^{2n} \sum_{\mathbf{w}\in W_n} \frac{1}{Q(\varphi^k \mathbf{w})} = \sum_{k=1}^{2n} \sum_{\mathbf{w}'\in W_n} \frac{1}{Q(\mathbf{w}')} = 2n \sum_{\mathbf{w}'\in W_n} \frac{1}{Q(\mathbf{w}')},$$

where the third equality uses only that each φ^k is a bijection of W_n. Hence

$$\frac{1}{|W_n|} \sum_{\mathbf{w}\in W_n} \frac{1}{Q(\mathbf{w})} = \frac{1}{2n},$$

and transporting along the bijection $W_n \to V_n$ gives $M(n) = \frac{1}{2n}$ for every $a > 0$.

Taking $n = 2020$ and $a = 3$,

$$\boxed{M(2020) = \frac{1}{4040}}.$$

Check, $n = 1$. $V_1 = \{(0,1,0),(0,-1,0)\}$, and $q(\mathbf{v}) = 1 + 3^{s_1}$ takes the values 4 and $1 + \frac{1}{3} = \frac{4}{3}$. The average of the reciprocals is $\frac{1}{2}(\frac{1}{4} + \frac{3}{4}) = \frac{1}{2}$, which is $1/(2 \cdot 1)$ as claimed. The same two paths with $a = 2$ give $\frac{1}{2}(\frac{1}{3} + \frac{2}{3}) = \frac{1}{2}$, confirming the independence of a.

Layer 1: WHAT

Block 1. Absorb the stray 1 into the sum using $s_{2n} = 0$, turning q into a sum over a full period $j = 1, \ldots, 2n$.

Block 2. Replace the path by its step word, because rotation is an operation on words and not on paths.

Block 3. Extend the word periodically. This is legitimate exactly because the path is closed, and it is the only use of $s_0 = s_{2n} = 0$.

Block 4. Compute the effect of a rotation on q: the heights shift by $-s_k$, so q is multiplied by a^{-s_k}.

Block 5. Sum the reciprocals over the $2n$ rotations. The multipliers are exactly the terms of q, so the sum telescopes to 1.

Block 6. Double count over all words and all rotations, using bijectivity of each rotation, to convert the per cycle identity into the global average $1/(2n)$.

The nominal route runs: "this is an expectation, so I need the distribution of q; let me set up a transfer matrix in the height and sum over paths". That route never recovers, because $1/q$ has no product structure in the path.

The bifurcation point is Block 1 and the sentence that follows it. The zombie sees $1 + \sum_{j=1}^{2n-1}$ and treats the 1 as a constant to be carried along. The ideal solver sees a sum that stops one short of a full period next to a stray constant, recognises that the constant is the missing term, and asks what symmetry the restored expression has. Everything after that is forced.

Layer 2: HOW

Block 1. Cue. A sum whose upper limit is $2n - 1$, one short of the natural $2n$, with a bare 1 added on. **Why natural.** Bare additive constants in a competition expression are almost never constants. They are values of the summand at a boundary index that has been hidden. Here $s_{2n} = 0$ is given in the hypothesis, so $a^{s_{2n}} = 1$, and the constant is the missing term. Restoring it makes the expression a sum over a complete period, which is the form in which a rotation can act. **Link to the next block.** A complete period invites a cyclic group action.

Block 2. **Cue.** The objects are paths, but the natural group action rotates *steps*, not heights. **Why natural.** Rotating heights makes no sense, since the height sequence is constrained by $s_0 = 0$. The steps, on the other hand, form an unconstrained word except for having n of each sign, and that condition is rotation invariant. So change coordinates from heights to steps first. The change is a bijection with an explicit inverse, so nothing is lost. **Link to the next block.** With the word in hand you can rotate, and you then need to know what rotation does to q.

Block 3. **Cue.** $s_0 = s_{2n} = 0$ is stated twice, once at each end. **Why natural.** A hypothesis stated at both ends of a sequence is a periodicity hypothesis. The total increment is zero, so the partial sums extend to a genuinely periodic sequence, and only then is "the height at time $j + k$" meaningful for $j + k > 2n$. Without this, rotation would change the heights by an amount depending on how far around you went. **Link to the next block.** Now compute the heights of the rotated word.

Block 4. **Cue.** The partial sums of a rotated word are differences of the original partial sums. **Why natural.** This is immediate: starting the walk at time k instead of time 0 shifts all heights down by s_k. A downward shift of all heights multiplies every term a^{s_j} by the same factor a^{-s_k}, so q scales rather than changing in any complicated way. A functional that merely scales under a group action is the best possible situation, because reciprocals then scale too. **Link to the next block.** You now have $2n$ values of q, all proportional to one another with known constants.

Block 5. **Cue.** The proportionality constants are a^{s_k}, and q is the sum of the a^{s_k}. **Why natural.** This is why the problem works, and it is not luck. The definition of q was engineered to be the sum over the group of the multipliers of the action. Whenever that is so, $\sum_k 1/q(\varphi^k \mathbf{w}) = \sum_k a^{s_k}/q(\mathbf{w}) = 1$. Be lazy and notice this before computing anything: the answer $1/(2n)$ is now inevitable, since $2n$ rotations share a total of 1. **Link to the next block.** One identity per rotation cycle now has to be turned into a statement about the whole set.

Block 6. **Cue.** You have an identity indexed by pairs (word, rotation) and want a statement about words alone. **Why natural.** That is a double count. Sum over both indices and interchange. The only property of φ^k you need is that it is a bijection of the finite set, which is obvious. Orbit lengths, stabilisers and Burnside never enter, because you are not counting orbits; you are counting pairs. **Link to the next block.** Divide by $|W_n|$ to get the average, then substitute $n = 2020$.

Layer 3: WHY

The mathematical truth beneath this route is that q is a *multiplier* function, or in the language of group cohomology a coboundary: $Q(\varphi^k \mathbf{w}) = \chi_k(\mathbf{w})\, Q(\mathbf{w})$ with $\chi_k(\mathbf{w}) = a^{-s_k}$. The general principle, which you should install once and reuse forever, is this. Let a finite group G of order N act on a finite set X, and suppose a positive function F on X satisfies $F(gx) = \lambda(g, x)^{-1} F(x)$ for some positive multipliers, with the compatibility

$$F(x) = \sum_{g \in G} \lambda(g, x).$$

Then $\sum_{g \in G} 1/F(gx) = 1$ for every x, and hence the average of $1/F$ over X is $1/N$. Both the rotation structure and the definition of q in this problem are exactly the hypotheses of that principle. The examiners built the function so that the multipliers are the summands.

The abstract skeleton, stripped of all lattice paths, is a two line identity you should keep in your head: for positive reals $x_1, \ldots, x_m$ with cyclic indexing and $S = \sum_j x_j$, set $Q_k = \sum_{j=1}^{m} x_{j+k}/x_k$. Then $Q_k = S/x_k$, so $\sum_{k=1}^{m} 1/Q_k = \sum_k x_k/S = 1$. The whole of B4 is this identity with $x_j = a^{s_j}$, plus the observation that rotating the word is what produces the ratios x_{j+k}/x_k.

The discernment mechanism is a two step filter for any average of a reciprocal. First: is there a group acting on the index set? Look for closed loops, cyclic conditions, and symmetric constraints; "starts and ends at zero" is the standard signal. Second: does the denominator scale under that action, and are the multipliers the summands of the denominator? If yes, the answer is one over the order of the group, and you never compute anything. If the answer is claimed to be independent of a parameter that appears in the definition, this is almost always the mechanism, because a computational proof would have to exhibit the cancellation of that parameter explicitly, while a symmetry proof never touches it.

To train it, treat every "average of $1/(\text{something})$" as a signal, not as an obstacle. Reciprocals are the sign that a partition of unity is hiding somewhere. The rotation trick used here is the same one behind the cycle lemma of Dvoretzky and Motzkin, which says that among the m rotations of a word of integers each at most 1 with total $r > 0$, exactly r have all partial sums positive. That lemma proves the ballot problem and the Catalan number formula in one line, and it is the same circuit: rotate a closed or nearly closed path and count what fraction of rotations have a property.

The examiners nudged you three times. They wrote q in the asymmetric form with a stray 1, which is the nudge (by concealment) toward restoring the period. They imposed $s_0 = s_{2n} = 0$, which is the closed loop condition and the only hypothesis rotation needs. And they asked for $M(2020)$ rather than a general formula, so that the answer $1/4040$ would visibly be one over the path length, which is one over the order of the rotation group.

Revolving concepts

Lattice paths and step words. A path $(s_0, \dots, s_{2n})$ with $s_0 = s_{2n} = 0$ and $|s_j - s_{j-1}| = 1$ corresponds bijectively to a word $\mathbf{w} \in \{\pm 1\}^{2n}$ with n entries of each sign, via $s_j = \sum_{i \le j} w_i$; hence $|V_n| = \binom{2n}{n}$. The recursion $s_j = s_{j-1} + w_j$ is the simplest first order linear recursion, and its general solution is the partial sum; the periodic extension $s_{j+2n} = s_j$ holds precisely when the total increment $\sum_i w_i$ vanishes, which is the general criterion for a linear recursion with an additive forcing term to be periodic. Pointer: see Book 1, field: Combinatorics, topic: lattice paths and Dyck words.

Group actions on finite sets and double counting. If a finite group G acts on a finite set X and $f : X \to \mathbb{R}$, then $\sum_x \sum_g f(gx) = |G| \sum_x f(x)$, because each g acts as a bijection. This is Fubini for finite sums, and it is strictly weaker and strictly easier than the orbit counting lemma; use it whenever you have an identity that holds along orbits. Pointer: see Book 1, field: Abstract algebra, topic: group actions and counting.

Multiplier (cocycle) functions. A positive F on X with $F(gx) = \lambda(g,x)^{-1} F(x)$ and $F(x) = \sum_g \lambda(g,x)$ satisfies $\sum_g 1/F(gx) = 1$. In this problem $\lambda(\varphi^k, \mathbf{w}) = a^{s_k}$. This is the abstract statement of the partition of unity that the problem conceals. Pointer: see Book 1, field: Abstract algebra, topic: cocycles and multiplier identities.

Cycle lemma of Dvoretzky and Motzkin. If $w_1, \dots, w_m$ are integers with each $w_i \le 1$ and $\sum w_i = r > 0$, then exactly r of the m cyclic rotations have all partial sums positive. Consequences include the ballot problem and $\frac{1}{n+1}\binom{2n}{n}$ for the Catalan numbers. Same circuit, different conclusion. Pointer: see Book 1, field: Combinatorics, topic: cycle lemma and ballot problems.

Reciprocal averages and partitions of unity. $\mathbb{E}[1/X]$ generally requires the full law of X, so a closed form for such an average signals an exact identity, typically $\sum_i 1/X_i = 1$ over some structured family. Pointer: see Book 1, field: Combinatorics, topic: partitions of unity in enumeration.

Circuit Bank

- **WHEN** an average of $1/q$ over a structured finite family **DO** look for a group acting on the family under which q scales, not for the distribution of q **BECAUSE** averages of reciprocals have no closed form unless an exact identity produces them, and the only common source of such identities is a family of reciprocals summing to one along an orbit

- **WHEN** a bare additive constant next to a sum whose index range stops one short of a natural period **DO** absorb the constant as the missing boundary term **BECAUSE** competition writers hide symmetry by peeling off an endpoint, and restoring it is what makes the group action visible
- **WHEN** a sequence constrained to have the same value at both ends **DO** extend it periodically and rotate **BECAUSE** equal endpoints means the total increment is zero, which is exactly the condition for the periodic extension of the partial sums to be consistent
- **WHEN** an answer that is claimed to be independent of a parameter appearing in the definition **DO** stop computing and look for a symmetry proof **BECAUSE** any computational proof would have to exhibit the cancellation of that parameter explicitly, whereas a symmetry proof never touches it
- **WHEN** an identity that holds for each orbit of a group action, and you want a global average **DO** sum over the whole set crossed with the group and interchange the two sums **BECAUSE** each group element acts as a bijection, so the inner sum is the same total every time, and orbit lengths never enter

Backtesting

1. First useful cue: the stray 1 in front of a sum that stops at $2n-1$, sitting next to the hypothesis $s_{2n}=0$. Absorbing the 1 is the entire opening move.
2. Method the expression suggested: cyclic rotation of the step word, under which q is multiplied by a^{-s_k}, followed by summation of reciprocals over the rotation cycle.
3. Where you would hesitate, and the thought to reinforce: the hesitation is whether the rotated path is still in V_n and whether the heights behave as claimed. Reinforce with "starting the same closed walk at a later time shifts every height by the same constant", which is a picture, not a computation.
4. The trap the question sets: the reciprocal invites you to hunt for the distribution of q, and the base 3 invites you to think the arithmetic of 3 matters. Neither is true: the answer holds for every positive base, and the distribution of q is never needed.
5. What makes you recognise it faster next time: the combination "closed path" plus "average of a reciprocal" plus "answer is one over the length". Those three together mean rotation, every time.
6. The reusable decision rule: if a positive functional scales under a finite group action and the multipliers are exactly the terms it is built from, then its reciprocals sum to one over each orbit, so its reciprocal averages to one over the order of the group.

Mirror drills

1. Let $x_1,\dots,x_m$ be positive reals indexed cyclically, and set $Q_k=\sum_{j=1}^{m} x_{j+k}/x_k$. Prove $\sum_{k=1}^{m} 1/Q_k = 1$. *Answer:* $Q_k = S/x_k$ with $S=\sum_j x_j$, so $\sum_k 1/Q_k = \sum_k x_k/S = 1$. This is B4 with the lattice path removed.
2. Replace 3 by any $a>0$ in the definition of q. What is the average of $1/q$? *Answer:* still $1/(2n)$; the proof never uses the value of a, only that every a^{s_j} is positive.
3. Where exactly does the argument need $s_{2n}=0$, and what breaks without it? *Answer:* it is needed for $s_{j+2n}=s_j$, so that rotating the word shifts all heights by the single constant s_k. If $s_{2n}=c\neq 0$ then $s_{j+2n}=s_j+c$, the multiplier depends on how far around you have gone, and q no longer merely scales.

6.11 B5. Reciprocal substitution pins four points to one line

For $j \in \{1,2,3,4\}$, let z_j be a complex number with $|z_j| = 1$ and $z_j \neq 1$. Prove that

$$3 - z_1 - z_2 - z_3 - z_4 + z_1 z_2 z_3 z_4 \neq 0.$$

Read it out loud

This is a nonvanishing statement about one specific symmetric polynomial in four unimodular variables. Say the polynomial out loud in symmetric function language: it is $3 - e_1 + e_4$, where e_k denotes the k-th elementary symmetric polynomial in $z_1, \ldots, z_4$. The middle terms e_2 and e_3 are absent, and the constant is $3 = 4 - 1$. Both facts are the same signal.

Substitute $z_1 = z_2 = z_3 = z_4 = 1$: the expression becomes $3 - 4 + 1 = 0$. So the polynomial vanishes at exactly the point that the hypothesis excludes. That is not a coincidence, it is the design of the problem, and it tells you the coordinate to work in. When an expression vanishes at a forbidden point, move that point to the origin. Set

$$u_j = 1 - z_j \neq 0.$$

The fields wired in are: complex numbers and the geometry of Mobius transformations; elementary symmetric polynomials and the reversal identity that inverts roots; and one elementary real inequality at the very end. Nothing requires multivariable calculus, compactness, or the geometry of hypocycloids, even though the published solutions use all three.

What is really being tested is whether you convert a quadratic constraint into a linear one. The hypothesis $|z| = 1$ is a circle, and circles are quadratic conditions that are painful to carry through algebra. But the excluded point $z = 1$ sits on that circle, so the Mobius map that sends $z = 1$ to infinity sends the circle to a straight line. That map is $z \mapsto 1/(1 - z)$, and the line it produces is

$$\operatorname{Re} \frac{1}{1 - z} = \frac{1}{2},$$

which you should verify inside ten seconds. Every hypothesis in the problem is now a single real linear equation per variable, and a nonvanishing claim under linear constraints is something you can finish by separating real and imaginary parts.

Within thirty seconds you should have written: $u_j = 1 - z_j$; $|u|^2 = 2 \operatorname{Re} u$ hence $\operatorname{Re}(1/u) = 1/2$; and $v_j = 1/u_j = \frac{1}{2} + it_j$ with t_j real.

Approaches, ranked worst to best

1. **Write $z_j = e^{i\theta_j}$ and separate into two real trigonometric equations.** *Cue:* four unimodular numbers, so four angles. *Circuit:* parametrise and grind. You obtain two real equations in four unknown angles and no structure whatsoever. There are far too many degrees of freedom to argue by inspection and no natural reduction. This is zombie maths.

2. **Constrained optimisation with Lagrange multipliers.** *Cue:* a nonvanishing claim on a compact set is a claim that a minimum is positive. *Circuit:* minimise $|3 - z_1 - z_2 - z_3|^2 - |1 - z_1 z_2 z_3|^2$ and locate critical points. This is the published first solution. It works: the gradient identity factorises as a product of three sines, forcing $z_i z_j = 1$ for some pair, after which the problem collapses. But it requires compactness, differentiability, a three variable gradient computation and a product to sum factorisation that has to be got exactly right. It costs a great deal of ink for a statement that is ultimately algebraic.

3. **Hypocycloid geometry.** *Cue:* sums of unimodular numbers with prescribed product fill the region bounded by a hypocycloid. *Circuit:* identify S_4, the set of $w_1 + \cdots + w_4$ with $|w_j| = 1$

and $\prod w_j = 1$, as the filled hypocycloid H_4. This is the published second solution and it is the most illuminating one conceptually. It requires an unsmoothing lemma proved by a singular matrix argument, a description of H_n as a rolling circle curve, and a boundary point analysis. Wonderful to know; far too heavy to be the route you take in the arena.

4. **Shift to $u_j = 1 - z_j$ and expand.** *Cue:* the expression vanishes when all $z_j = 1$. *Circuit:* move the forbidden point to the origin. This gets you the clean identity $3 - e_1(z) + e_4(z) = e_2(u) - e_3(u) + e_4(u)$, which already removes the constant term and the linear term. It is the right first move but it does not finish, because you still have to use $|z_j| = 1$, which in the u coordinate is the circle $|u - 1| = 1$.

5. **Shift, then invert: $v_j = 1/(1 - z_j)$.** *Cue:* the circle $|z| = 1$ passes through the excluded point $z = 1$. *Circuit:* a Mobius map sending a point of a circle to infinity turns that circle into a line. The circle condition becomes the line condition $\operatorname{Re} v_j = \frac{1}{2}$; dividing the shifted identity by $e_4(u)$ converts it into $e_2(v) - e_1(v) + 1$ by the reversal identity for elementary symmetric functions; writing $v_j = \frac{1}{2} + it_j$ turns that into $(\frac{1}{2} - \sigma) + i\frac{T}{2}$ with T and σ the first two elementary symmetric functions of the real numbers t_j; and vanishing would force $T = 0$ and $\sigma = \frac{1}{2}$, which contradicts $T = 0 \Rightarrow \sigma \leq 0$. Half a page, no calculus, no geometry, and it generalises. This is the ideal route.

The ideal solution

Lemma 6.11.1. *If $|z| = 1$ and $z \neq 1$, then $u = 1 - z$ satisfies $|u|^2 = 2\operatorname{Re}(u)$ and $\operatorname{Re}(u) > 0$, and consequently*

$$\operatorname{Re}\left(\frac{1}{1-z}\right) = \frac{1}{2}.$$

Proof. Since $z\bar{z} = 1$,

$$|u|^2 = (1-z)(1-\bar{z}) = 1 - z - \bar{z} + z\bar{z} = 2 - (z + \bar{z}) = 2\big(1 - \operatorname{Re} z\big) = 2\operatorname{Re}(u).$$

As $z \neq 1$ we have $u \neq 0$, so $\operatorname{Re}(u) = |u|^2/2 > 0$. Then

$$\operatorname{Re}\left(\frac{1}{u}\right) = \operatorname{Re}\left(\frac{\bar{u}}{|u|^2}\right) = \frac{\operatorname{Re}(u)}{|u|^2} = \frac{\operatorname{Re}(u)}{2\operatorname{Re}(u)} = \frac{1}{2}. \qquad \square$$

Now write $u_j = 1 - z_j$, so $u_j \neq 0$ for each j, and let

$$e_1, e_2, e_3, e_4 \quad \text{denote the elementary symmetric polynomials of } u_1, u_2, u_3, u_4.$$

Step 1: rewrite the expression in the shifted coordinate. We have $\sum_j z_j = \sum_j (1 - u_j) = 4 - e_1$ and

$$\prod_j z_j = \prod_j (1 - u_j) = 1 - e_1 + e_2 - e_3 + e_4.$$

Therefore, writing E for the expression in question,

$$E = 3 - \sum_j z_j + \prod_j z_j = 3 - (4 - e_1) + (1 - e_1 + e_2 - e_3 + e_4) = e_2 - e_3 + e_4.$$

Step 2: invert. Since every $u_j \neq 0$ we have $e_4 = u_1u_2u_3u_4 \neq 0$, so $E = 0$ if and only if $E/e_4 = 0$. Put $v_j = 1/u_j$ and let ε_k denote the elementary symmetric polynomials of v_1, v_2, v_3, v_4. Dividing a product of k of the u_j by $u_1u_2u_3u_4$ leaves the reciprocals of the complementary $4 - k$ of them, so

$$\frac{e_2}{e_4} = \sum_{i<j} \frac{1}{u_iu_j} = \varepsilon_2, \qquad \frac{e_3}{e_4} = \sum_j \frac{1}{u_j} = \varepsilon_1,$$

(in the first identity the complement of a pair is a pair, and every pair occurs exactly once). Hence

$$\frac{E}{e_4} = \varepsilon_2 - \varepsilon_1 + 1.$$

Step 3: use the line. By the Lemma, $\mathrm{Re}(v_j) = \frac{1}{2}$, so we may write

$$v_j = \tfrac{1}{2} + it_j \qquad (t_j \in \mathbb{R}).$$

Set $T = t_1 + t_2 + t_3 + t_4$ and $\sigma = \sum_{i<j} t_i t_j$. Then

$$\varepsilon_1 = 2 + iT,$$

and, since each of the six products contributes $\frac{1}{4} + \frac{i}{2}(t_i + t_j) - t_i t_j$ and each t_i occurs in exactly three pairs,

$$\varepsilon_2 = 6 \cdot \tfrac{1}{4} + \tfrac{i}{2}\,(3T) - \sigma = \tfrac{3}{2} + \tfrac{3i}{2}T - \sigma.$$

Therefore

$$\frac{E}{e_4} = \varepsilon_2 - \varepsilon_1 + 1 = \left(\tfrac{3}{2} - \sigma - 2 + 1\right) + i\left(\tfrac{3}{2}T - T\right) = \left(\tfrac{1}{2} - \sigma\right) + i\,\frac{T}{2}.$$

Step 4: conclude by a dichotomy. Suppose $E = 0$. Then both the real and the imaginary part above vanish, so $T = 0$ and $\sigma = \frac{1}{2}$. But for real numbers,

$$T^2 = \left(\sum_j t_j\right)^2 = \sum_j t_j^2 + 2\sigma,$$

so $T = 0$ forces $\sigma = -\frac{1}{2}\sum_j t_j^2 \le 0$, contradicting $\sigma = \frac{1}{2}$. Hence $E \neq 0$, that is,

$$\boxed{3 - z_1 - z_2 - z_3 - z_4 + z_1 z_2 z_3 z_4 \neq 0}$$

whenever $|z_j| = 1$ and $z_j \neq 1$ for $j = 1, 2, 3, 4$. ■

Sharpness. If $z_1 = z_2 = z_3 = 1$ then $E = 3 - 3 - z_4 + z_4 = 0$, so the hypothesis cannot be dropped entirely. If exactly two of them equal 1, say $z_1 = z_2 = 1$, then $E = 1 - z_3 - z_4 + z_3 z_4 = (1 - z_3)(1 - z_4) \neq 0$. If exactly one equals 1, the expression becomes $2 - z_2 - z_3 - z_4 + z_2 z_3 z_4$, which the same method handles in one line: shifting and inverting gives $E/e_3 = \varepsilon_1 - 1 = \frac{1}{2} + iT$, whose real part is $\frac{1}{2} \neq 0$. So the sharp hypothesis is that at most two of the z_j are equal to 1.

Layer 1: WHAT

Block 1. Evaluate the expression at $z_1 = \cdots = z_4 = 1$ and get zero; conclude that the forbidden point is a root and that $u_j = 1 - z_j$ is the right coordinate.

Block 2. Expand in u: the constant and linear terms cancel and $E = e_2 - e_3 + e_4$.

Block 3. Note $e_4 \neq 0$, divide by it, and use the reversal identity to get $E/e_4 = \varepsilon_2 - \varepsilon_1 + 1$ in terms of $v_j = 1/u_j$.

Block 4. Identify the constraint on v_j: the circle $|z_j| = 1$ punctured at $z = 1$ maps onto the line $\mathrm{Re}\, v = \frac{1}{2}$.

Block 5. Write $v_j = \frac{1}{2} + it_j$ and compute the real and imaginary parts of $\varepsilon_2 - \varepsilon_1 + 1$.

Block 6. Kill both parts at once: the imaginary part vanishes only if $T = 0$, and then the real part is $\frac{1}{2} + \frac{1}{2}\sum t_j^2 \ge \frac{1}{2}$.

The nominal route runs: "$|z_j| = 1$, so put $z_j = e^{i\theta_j}$ and split into real and imaginary parts." It produces two trigonometric equations in four angles and no way forward, and the honest continuation is Lagrange multipliers on a compact set, which is exactly the published first solution and about four times the length.

The bifurcation point is the treatment of the constraint. The zombie keeps $|z| = 1$ as a circle and parametrises by an angle. The ideal solver notices that the excluded point lies on the circle, applies the Mobius map that sends it to infinity, and thereby replaces four quadratic constraints by four real linear ones. Everything downstream is forced by that single decision.

Layer 2: HOW

Block 1. **Cue.** The constant is $3 = 4 - 1$, and the terms e_2 and e_3 in z are missing. **Why natural.** Test the symmetric point. It gives $3 - 4 + 1 = 0$, so the polynomial vanishes exactly where the hypothesis forbids you to be. A polynomial that vanishes at a forbidden point is telling you which coordinate system it was built in: the one centred at that point. So set $u_j = 1 - z_j$ and expect the expression to have no constant and no linear term in u. **Link to the next block.** In the u coordinate the expression should simplify, and it does.

Block 2. **Cue.** Both $\sum z_j$ and $\prod z_j$ expand cleanly under $z_j = 1 - u_j$. **Why natural.** $\prod(1 - u_j) = \sum_k (-1)^k e_k(u)$ is the generating identity for elementary symmetric polynomials, which you already know. The constant cancels against the 3 and the e_1 terms cancel against each other, leaving $e_2 - e_3 + e_4$. This is the payoff for choosing the right origin. **Link to the next block.** You now have a symmetric expression with no low order terms, which means it is divisible by nothing but is dominated by the top term e_4, and e_4 is nonzero.

Block 3. **Cue.** $e_4 = \prod u_j \neq 0$, and the expression $e_2 - e_3 + e_4$ has its indices running from the top downwards when divided by e_4. **Why natural.** Dividing a symmetric expression by the top elementary symmetric polynomial is the standard way to pass to the reciprocals of the variables, because reversing the coefficients of a monic polynomial inverts its roots. Concretely, $e_k(u)/e_n(u) = e_{n-k}(1/u)$. Do it, because the constraint you have not yet used is a statement about $1/u_j$, not about u_j. **Link to the next block.** Now everything is written in the variables $v_j = 1/(1 - z_j)$, which is where the hypothesis becomes usable.

Block 4. **Cue.** The hypothesis is a circle through the point you removed. **Why natural.** A Mobius transformation maps circles and lines to circles and lines, and a circle through the pole of the map goes to a line. The map with pole at $z = 1$ that appears naturally here is $z \mapsto 1/(1 - z)$, and the image line is found by evaluating at one point, say $z = -1$, giving $\frac{1}{2}$. The clean algebraic proof is the identity $|1 - z|^2 = 2\,\mathrm{Re}(1 - z)$, which is nothing more than $z\bar{z} = 1$ rearranged. A real linear constraint is the best possible hypothesis, because it leaves one real parameter per variable. **Link to the next block.** Substituting the parametrisation of the line reduces everything to real polynomials in four real numbers.

Block 5. **Cue.** Each v_j has a fixed real part and a free imaginary part. **Why natural.** Write $v_j = \frac{1}{2} + it_j$ and expand. The elementary symmetric polynomials of the v_j become polynomials in the elementary symmetric polynomials of the t_j with explicit binomial coefficients. Only ε_1 and ε_2 are needed, so only T and σ appear. Keep the real and imaginary parts separate from the start; do not combine them. **Link to the next block.** You now have one complex equation to contradict, which is two real equations.

Block 6. **Cue.** The imaginary part is $T/2$ and the real part is $\frac{1}{2} - \sigma$. **Why natural.** Two real conditions, and they are incompatible for a reason you already have installed: $(\sum t_j)^2 = \sum t_j^2 + 2\sigma$. If $T = 0$ then σ is a negative multiple of a sum of squares, hence at most zero, while the real part would demand $\sigma = \frac{1}{2}$. Do not try to prove the real part is positive in general (it is not, since σ can exceed $\frac{1}{2}$ when $T \neq 0$); prove the dichotomy instead. **Link to the next block.** The contradiction closes the proof.

Layer 3: WHY

The mathematical truth beneath this route is that a Mobius transformation converts one quadratic constraint into one linear constraint whenever the excluded point is on the constraint curve. The

unit circle is $\{|z| = 1\}$; the map $w = 1/(1-z)$ has its pole at $z = 1$, a point of the circle, so it sends the circle to a line and, more precisely, it sends the punctured circle bijectively onto the whole line $\operatorname{Re} w = \frac{1}{2}$. The inverse is $z = (w-1)/w$, and $|z| = 1$ says $|w-1| = |w|$, that is, w is equidistant from 0 and 1, which is exactly the perpendicular bisector $\operatorname{Re} w = \frac{1}{2}$. That last sentence is the geometric reason, and it is a sentence about a perpendicular bisector, not about complex analysis.

The second truth is the reversal identity for symmetric functions: if $p(x) = \prod_j (x - u_j) = \sum_k (-1)^k e_k x^{n-k}$, then $x^n p(1/x)/p(0)$ is the monic polynomial with roots $1/u_j$, and comparing coefficients gives $e_k(1/u) = e_{n-k}(u)/e_n(u)$. That is why dividing by e_4 converts an expression built from e_2, e_3, e_4 into one built from $\varepsilon_2, \varepsilon_1, \varepsilon_0$. Dividing by the top symmetric function *is* inverting the variables.

There is a third truth worth recording because it generalises. Because $\operatorname{Re} v_j = \frac{1}{2}$ we have $\bar{v}_j = 1 - v_j$, hence

$$\sum_{m=0}^{4} (-1)^m \varepsilon_m = \prod_j (1 - v_j) = \prod_j \bar{v}_j = \overline{\varepsilon_4}.$$

Using this, $E/e_4 = \varepsilon_2 - \varepsilon_1 + \varepsilon_0 = \overline{\varepsilon_4} + \varepsilon_3 - \varepsilon_4$, a compact reformulation of the problem. For a general number n of variables the same computation reduces the statement "$(n-1) - \sum z_j + \prod z_j \neq 0$" to "$\sum_{m=0}^{n-2} (-1)^m \varepsilon_m(v) \neq 0$ for points v_j on the line $\operatorname{Re} v = \frac{1}{2}$". For $n = 3$ and $n = 4$ this is settled above. For $n \geq 5$ I have not settled it, and a numerical search over the five variable case found no zero but is not a proof; the published remark connects the general question to the geometry of hypocycloids. Name that as a knowledge gap rather than pretending the argument extends.

The discernment mechanism is a three question filter. First: does the expression vanish at the excluded configuration? If yes, translate that configuration to the origin. Second: is the constraint a circle through the excluded point? If yes, invert, because circles through the pole become lines. Third: once the constraints are affine, can you finish by separating real and imaginary parts? If the answer to the first two is yes, the answer to the third is almost always yes, because affine constraints leave one real degree of freedom per variable and symmetric expressions in such variables have real and imaginary parts that are low degree real polynomials.

To train it, practise the identity $|1 - z|^2 = 2\operatorname{Re}(1 - z)$ for unimodular z until it is reflexive, and practise recognising which Mobius map to apply from where the excluded point sits. The excluded point always becomes the pole. That is the entire choice.

The examiners nudged you clearly. They wrote the constant as 3, one less than the number of variables, which forces the vanishing at the all ones point. They excluded exactly $z_j = 1$ and nothing else, which is the announcement that $z = 1$ is the special point of the circle. And they suppressed e_2 and e_3 from the expression, so that after the shift only the top three symmetric functions survive and the division by e_4 lands on $\varepsilon_2 - \varepsilon_1 + 1$, an expression short enough to expand by hand.

Revolving concepts

Unimodular identity. For $|z| = 1$, $|1 - z|^2 = 2 - (z + \bar{z}) = 2\operatorname{Re}(1 - z)$. Equivalently, $1 - z = 2\sin(\theta/2)\, e^{i(\theta - \pi)/2}$ for $z = e^{i\theta}$, so $1 - z$ traces the circle $|u - 1| = 1$ and $\operatorname{Re}(1 - z) = 1 - \cos\theta \geq 0$. Pointer: see Book 1, field: Complex numbers, topic: chords of the unit circle.

Mobius transformations and the circle to line principle. A Mobius map sends the family of circles and lines to itself; a circle is sent to a line exactly when it passes through the pole. The map $z \mapsto 1/(1-z)$ sends the unit circle minus $\{1\}$ bijectively onto $\{\operatorname{Re} w = \frac{1}{2}\}$, with inverse $w \mapsto (w-1)/w$; the image line is the perpendicular bisector of 0 and 1 because $|z| = 1$ reads $|w - 1| = |w|$. Pointer: see Book 1, field: Complex numbers, topic: Mobius transformations and the Cayley transform.

Elementary symmetric polynomials and reversal. $\prod_j (1 + x u_j) = \sum_k e_k(u) x^k$, and $\prod_j (1 - u_j) = \sum_k (-1)^k e_k(u)$. The recursion in the number of variables is $e_k^{(n)} = e_k^{(n-1)} + u_n e_{k-1}^{(n-1)}$ with $e_0 = 1$ and $e_k^{(n)} = 0$ for $k > n$; its general solution is the generating product above, and the same recursion

with u_n replaced by any weight is the standard method for every symmetric function computation. Reversal: $e_k(1/u_1, \dots, 1/u_n) = e_{n-k}(u)/e_n(u)$, which is the coefficient statement that reversing a polynomial inverts its roots. Pointer: see Book 1, field: Polynomials, topic: symmetric functions and Vieta.

Newton's identity in degree two. For real $t_1, \dots, t_n$, $\left(\sum t_j\right)^2 = \sum t_j^2 + 2e_2(t)$; hence $e_1(t) = 0$ implies $e_2(t) \le 0$ with equality only when all $t_j = 0$. Pointer: see Book 1, field: Inequalities, topic: power sums and symmetric means.

Conjugation on the critical line. If $\operatorname{Re} v = \frac{1}{2}$ then $\bar{v} = 1 - v$, so for any finite family on that line $\prod_j (1 - v_j) = \overline{\prod_j v_j}$, that is, $\sum_m (-1)^m \varepsilon_m = \overline{\varepsilon_n}$. Pointer: see Book 1, field: Complex numbers, topic: reflection identities on a vertical line.

Hypocycloid description of sums with fixed product. $S_n = \{w_1 + \cdots + w_n : |w_j| = 1,\ \prod_j w_j = 1\}$ is, for $n \le 4$, the closed interior of the hypocycloid $H_n = \{(n-1)w + w^{-(n-1)} : |w| = 1\}$; the boundary points are attained only by tuples taking at most two distinct values. This is the geometry underlying the published second solution and the natural home of the general n question. Pointer: see Book 1, field: Complex numbers, topic: hypocycloids and sums of roots of unity.

Circuit Bank

- **WHEN** an expression that vanishes exactly at the configuration the hypothesis forbids **DO** translate that configuration to the origin by substituting the differences as new variables **BECAUSE** the vanishing says the expression has no constant term in those coordinates, so the low order symmetric functions disappear and only the top ones survive
- **WHEN** a constraint $|z| = 1$ together with one excluded point on the circle **DO** apply the Mobius map whose pole is that excluded point **BECAUSE** a Mobius map sends circles through its pole to straight lines, so a quadratic constraint becomes a real linear one and each variable is left with a single real parameter
- **WHEN** a symmetric expression in $u_1, \dots, u_n$ that you wish to write in the reciprocals **DO** divide by $e_n(u)$ and read off $e_k(u)/e_n(u) = e_{n-k}(1/u)$ **BECAUSE** reversing the coefficients of a polynomial inverts its roots, so dividing by the top symmetric function is exactly the change of variable $u \mapsto 1/u$
- **WHEN** a complex quantity to be proved nonzero when each variable has a pinned real part **DO** separate real and imaginary parts and argue by dichotomy rather than bounding one part alone **BECAUSE** the two vanishing conditions are usually incompatible for a cheap reason, whereas neither one alone need be impossible
- **WHEN** the conditions $e_1(t) = 0$ and $e_2(t) = c > 0$ for real numbers t_j **DO** invoke $(\sum t_j)^2 = \sum t_j^2 + 2e_2(t)$ and stop **BECAUSE** a vanishing first symmetric function forces the second to be a nonpositive multiple of a sum of squares

Backtesting

1. First useful cue: the constant 3 equals the number of variables minus one, so the expression vanishes at the all ones point, which is exactly the excluded point.
2. Method the expression suggested: shift by $u_j = 1 - z_j$, invert by $v_j = 1/u_j$ so that the circle becomes the line $\operatorname{Re} v = \frac{1}{2}$, then separate real and imaginary parts.
3. Where you would hesitate, and the thought to reinforce: the hesitation is at the inversion, which feels unmotivated if you only see it as algebra. Reinforce it geometrically: $|z| = 1$ becomes $|w - 1| = |w|$, the perpendicular bisector of 0 and 1. Once you can see the line, the substitution stops feeling like a manoeuvre and starts feeling like a change of chart.

4. The trap the question sets: the phrase $|z_j| = 1$ invites the parametrisation $z_j = e^{i\theta_j}$, which is the one coordinate system in which the constraint is free but every expression becomes trigonometric. The four angles then have to be handled by optimisation, which is the long published route.
5. What makes you recognise it faster next time: the pair "constraint is a circle" plus "one point of the circle is excluded". That pair means invert at the excluded point, always.
6. The reusable decision rule: choose coordinates in which the hypothesis is affine. A circle with a marked point becomes a line under inversion at that point, and affine hypotheses turn nonvanishing claims into real polynomial dichotomies.

Mirror drills

1. Prove that $2 - z_1 - z_2 - z_3 + z_1z_2z_3 \neq 0$ for $|z_j| = 1$, $z_j \neq 1$. *Answer:* the same shift gives $e_2(u) - e_3(u)$, and dividing by $e_3(u)$ gives $\varepsilon_1 - 1 = \frac{1}{2} + iT$, whose real part is $\frac{1}{2}$.
2. Show that $z \mapsto 1/(1-z)$ maps $\{|z| = 1\} \setminus \{1\}$ bijectively onto $\{\operatorname{Re} w = \frac{1}{2}\}$. *Answer:* the inverse is $z = (w-1)/w$, and $|z| = 1$ says $|w-1| = |w|$, the perpendicular bisector of 0 and 1.
3. Determine the sharp hypothesis: for how many of the z_j may we allow the value 1? *Answer:* at most two. Three forces the expression to vanish; two gives $(1 - z_3)(1 - z_4) \neq 0$; one reduces to the three variable statement of drill 1.

6.12 B6. Run lengths renormalise a Beatty sign sequence

Let n be a positive integer. Prove that

$$\sum_{k=1}^{n} (-1)^{\lfloor k(\sqrt{2}-1) \rfloor} \geq 0.$$

(As usual, $\lfloor x \rfloor$ denotes the greatest integer less than or equal to x.)

Read it out loud

This is a partial sum positivity statement for a sign sequence generated by the parity of a Beatty sequence. The signs are $(-1)^{\lfloor k\alpha \rfloor}$ with $\alpha = \sqrt{2} - 1 \approx 0.4142$, and you are asked to show that the running total never dips below zero. The fields wired in are: Diophantine approximation of quadratic irrationals and their continued fractions; Beatty sequences and complementary sequences; self-similar (substitutive) sequences and their run length codings; and strong induction with a change of scale.

Write out the first few signs. Since $\lfloor k\alpha \rfloor$ for $k = 0, 1, 2, \ldots$ runs $0, 0, 0, 1, 1, 2, 2, 2, 3, 3, 4, 4, 4, \ldots$, the sign sequence for $k \geq 0$ is

$$+, +, +, -, -, +, +, +, -, -, +, +, +, \ldots$$

so it is a sequence of *runs*, alternating in sign, of lengths $3, 2, 3, 2, 3, \ldots$ Every run has length 2 or 3, because α lies strictly between $\frac{1}{3}$ and $\frac{1}{2}$. The partial sum can only be small at the end of a negative run, so the whole problem is the question: are the alternating partial sums of the run lengths always positive?

Now the crucial observation, and it is the only genuinely nonobvious idea in the problem. The irrational $\alpha = \sqrt{2} - 1$ was not chosen for flavour. Its reciprocal is

$$\beta = \frac{1}{\alpha} = \sqrt{2} + 1 = \alpha + 2,$$

so β and α differ by an *even* integer. Consequently, for every integer $j \geq 0$,

$$\lfloor j\beta \rfloor = \lfloor j\alpha \rfloor + 2j, \qquad \text{hence} \qquad (-1)^{\lfloor j\beta \rfloor} = (-1)^{\lfloor j\alpha \rfloor}.$$

That single line is the engine. The run lengths of the sign sequence are governed by the Beatty sequence of β, while the signs themselves are governed by α; because their parities agree, the run length data reproduces the original sign sequence at a compressed scale. The problem is therefore self-similar, and self-similar statements are proved by strong induction on the scale.

Within thirty seconds you should have written: $\alpha = \sqrt{2} - 1$, $1/\alpha = \alpha + 2$, "the reciprocal differs by an even integer"; the run lengths $3, 2, 3, 2, \ldots$; and the word "renormalise".

Approaches, ranked worst to best

1. **Compute a large partial sum and assert a pattern.** *Cue:* the statement is about all n, but the sequence looks regular. *Circuit:* numerical reconnaissance. You will confirm the inequality for millions of terms and prove nothing. Worse, the partial sums are unbounded, so no finite check tells you anything about the tail.

2. **Equidistribution of $\{k\alpha\}$.** *Cue:* α irrational, so the fractional parts equidistribute by Weyl. *Circuit:* averaging. Equidistribution says the density of each sign is $\frac{1}{2}$ and the partial sum is $o(n)$. That is a statement about the size of the partial sum, not its sign, and it is useless here: the partial sums genuinely reach arbitrarily large positive values, so no averaging argument can control the sign. Ranks low because it feels like progress and is not.

3. **Telescoping or a monotone quantity.** *Cue:* partial sum positivity often follows from a clever monotone functional. *Circuit:* invariants. There is no monotone functional: the partial sum decreases on every negative run. Any attempt to bound the sum below by a local quantity fails because the minima occur at unboundedly spaced places.

4. **Ostrowski representation via the continued fraction convergents.** *Cue:* α is a quadratic irrational, so its convergents obey a linear recursion. *Circuit:* expand k in the numeration system attached to α. With $q_0 = 0$, $q_1 = 1$, $q_j = 2q_{j-1} + q_{j-2}$ (the Pell numbers $0, 1, 2, 5, 12, 29, 70, \ldots$), one proves $f(n) = f(q_j) - f(n - q_j)$ for even j and $f(n) = f(n - q_j) + 1$ for odd j, then inducts. This is the published second solution and it is correct, but it requires the best approximation property of convergents, the parity fact $q_j \equiv j \pmod 2$, and a careful treatment of the exceptional indices $k \in \{q_j, 2q_j\}$ where $\lfloor k\alpha \rfloor$ and $\lfloor kq_{j-1}/q_j \rfloor$ disagree. Every one of those is a place to be wrong under time pressure.

5. **Run length renormalisation with an explicit self-similarity identity.** *Cue:* the signs form runs of lengths 2 and 3, and $1/\alpha - \alpha$ is an even integer. *Circuit:* code the sequence by its run lengths and observe that the coding reproduces the original sequence. Count how many k satisfy $\lfloor k\alpha \rfloor = i$, get $c_i \in \{2, 3\}$ with $c_i = 3$ exactly on the Beatty sequence $\lfloor j\beta \rfloor$, subtract 2 from every c_i and use the parity transfer to see that the alternating sum of the c_i is literally a partial sum of the original sequence, at an index compressed by the factor $\alpha < \frac{1}{2}$. Then strong induction on n, with the observation that the running total is minimised at the end of a negative run. No continued fraction theory beyond $\beta = \alpha + 2$, every constant explicit. This is the ideal route.

The ideal solution

Throughout, $\alpha = \sqrt{2} - 1$ and $\beta = \sqrt{2} + 1$, so that

$$\alpha\beta = 1, \qquad \beta = \alpha + 2, \qquad 0 < \alpha < \tfrac{1}{2} < 1 < \beta.$$

Set $a_k = \lfloor k\alpha \rfloor$ for $k \geq 0$ and

$$F(n) = \sum_{k=0}^{n} (-1)^{a_k} \qquad (n \geq 0).$$

Since $a_0 = 0$, the assertion to be proved is exactly $F(n) \geq 1$ for all $n \geq 0$.

Lemma 6.12.1 (parity transfer)**.** *For every integer $j \geq 0$, $\lfloor j\beta \rfloor = 2j + \lfloor j\alpha \rfloor$, and hence $(-1)^{\lfloor j\beta \rfloor} = (-1)^{a_j}$.*

Proof. $j\beta = 2j + j\alpha$ and $2j$ is an integer, so the floors differ by $2j$, which is even. □

Lemma 6.12.2 (run structure)**.** *For $i \geq 0$ let $c_i = \#\{k \geq 0 : a_k = i\}$ and $C_m = c_0 + c_1 + \cdots + c_m$. Then every c_i is finite and positive,*

$$C_m = \lfloor (m+1)\beta \rfloor + 1 = 2m + 3 + \lfloor (m+1)\alpha \rfloor \qquad (m \geq 0),$$

and $c_0 = 3$, while $c_i = 2 + \lfloor (i+1)\alpha \rfloor - \lfloor i\alpha \rfloor \in \{2, 3\}$ for $i \geq 1$.

Proof. Since $0 < \alpha < 1$, the sequence a_k is nondecreasing with $a_{k+1} - a_k \in \{0, 1\}$, starts at $a_0 = 0$ and tends to infinity, so it attains every nonnegative integer on a nonempty block of consecutive k. Next,

$$C_m = \#\{k \geq 0 : a_k \leq m\} = \#\{k \geq 0 : k\alpha < m + 1\} = \#\{k \geq 0 : k < (m+1)\beta\},$$

using $\alpha\beta = 1$. As β is irrational, $(m+1)\beta$ is not an integer, so this count is $\lfloor (m+1)\beta \rfloor + 1$. Substituting $\beta = \alpha + 2$ gives $C_m = 2(m+1) + \lfloor (m+1)\alpha \rfloor + 1$. Finally $c_0 = C_0 = 2 + \lfloor \alpha \rfloor + 1 = 3$ and, for $i \geq 1$, $c_i = C_i - C_{i-1} = 2 + \lfloor (i+1)\alpha \rfloor - \lfloor i\alpha \rfloor$, which lies in $\{2, 3\}$ because consecutive floors of $i\alpha$ differ by 0 or 1. □

Lemma 6.12.3 (long runs sit on a Beatty sequence)**.** *For every $i \geq 0$: $c_i = 3$ if and only if $i = \lfloor j\beta \rfloor$ for some integer $j \geq 0$; otherwise $c_i = 2$.*

Proof. For $i = 0$: $c_0 = 3$ and $0 = \lfloor 0 \cdot \beta \rfloor$, so the statement holds; and no $j \geq 1$ gives $\lfloor j\beta \rfloor = 0$, since $\lfloor \beta \rfloor = 2$ and $j \mapsto \lfloor j\beta \rfloor$ is increasing.

For $i \geq 1$, Lemma 2 gives $c_i = 3$ if and only if $\lfloor (i+1)\alpha \rfloor > \lfloor i\alpha \rfloor$, that is, if and only if there is an integer j with $i\alpha < j < (i+1)\alpha$; the inequalities are strict because $i\alpha$ and $(i+1)\alpha$ are irrational. Multiplying through by $\beta > 0$ and using $\alpha\beta = 1$, this says $i < j\beta < i+1$, that is, $i = \lfloor j\beta \rfloor$. Such a j satisfies $j > i\alpha > 0$, so $j \geq 1$. □

Lemma 6.12.4 (self-similarity)**.** *For $m \geq 0$ put $S_m = \sum_{i=0}^{m} (-1)^i c_i$ and $J_m = \lfloor (m+1)\alpha \rfloor$. Then*

$$S_m = F(J_m) + 2 \cdot [\, m \text{ even} \,].$$

Proof. Since $\sum_{i=0}^{m} (-1)^i$ equals 1 for even m and 0 for odd m,

$$S_m = \sum_{i=0}^{m} (-1)^i (c_i - 2) + 2 \cdot [\, m \text{ even} \,].$$

By Lemma 3, $c_i - 2$ is the indicator of the event $i \in \{\lfloor j\beta \rfloor : j \geq 0\}$, and $j \mapsto \lfloor j\beta \rfloor$ is strictly increasing, hence injective. Therefore

$$\sum_{i=0}^{m} (-1)^i (c_i - 2) = \sum_{\substack{j \geq 0 \\ \lfloor j\beta \rfloor \leq m}} (-1)^{\lfloor j\beta \rfloor} = \sum_{\substack{j \geq 0 \\ \lfloor j\beta \rfloor \leq m}} (-1)^{a_j},$$

the second equality by Lemma 1. Finally $\lfloor j\beta \rfloor \leq m$ if and only if $j\beta < m+1$, if and only if $j < (m+1)\alpha$; since $(m+1)\alpha$ is irrational, the admissible j are exactly $0, 1, \ldots, \lfloor (m+1)\alpha \rfloor = J_m$. So the displayed sum equals $F(J_m)$. □

Theorem 6.12.5. *$F(n) \geq 1$ for every integer $n \geq 0$; equivalently $\sum_{k=1}^{n} (-1)^{\lfloor k(\sqrt{2}-1) \rfloor} \geq 0$ for every $n \geq 1$.*

Proof. Strong induction on n. For $n = 0$, $F(0) = 1$. Let $n \geq 1$ and assume $F(n') \geq 1$ for all $0 \leq n' < n$.

Set $C_{-1} = 0$ and let $m \geq 0$ be the unique index with $C_{m-1} \leq n < C_m$, so that $k = n$ lies in the m-th run, on which every term equals $(-1)^m$. By Lemma 2, for $m \geq 1$,

$$C_{m-1} = 2(m-1) + 3 + \lfloor m\alpha \rfloor = 2m + 1 + \lfloor m\alpha \rfloor.$$

Also $F(C_m - 1) = S_m$ for every $m \geq 0$, since the first C_m terms of the sequence are exactly the runs $0, 1, \ldots, m$.

Case $m = 0$. Then $n < C_0 = 3$, and $a_0 = a_1 = a_2 = 0$, so $F(n) = n + 1 \geq 1$.

Case m odd. On the m-th run every term is -1, so F is decreasing there and

$$F(n) \geq F(C_m - 1) = S_m = F(J_m),$$

the last equality by Lemma 4 since m is odd. Now $J_m = \lfloor (m+1)\alpha \rfloor \leq (m+1)\alpha < \frac{m+1}{2} \leq m$ because $\alpha < \frac{1}{2}$ and $m \geq 1$, whereas $n \geq C_{m-1} \geq 2m + 1 > m$. Hence $J_m < n$ and the induction hypothesis gives $F(J_m) \geq 1$, so $F(n) \geq 1$.

Case m even, $m \geq 2$. On the m-th run every term is $+1$, so

$$F(n) = F(C_{m-1} - 1) + (n - C_{m-1} + 1) = S_{m-1} + (n - C_{m-1} + 1) \geq S_{m-1} + 1.$$

Since $m - 1$ is odd, Lemma 4 gives $S_{m-1} = F(J_{m-1})$ with $J_{m-1} = \lfloor m\alpha \rfloor$. And $n \geq C_{m-1} = 2m + 1 + \lfloor m\alpha \rfloor > \lfloor m\alpha \rfloor = J_{m-1}$, so the induction hypothesis gives $S_{m-1} \geq 1$ and therefore $F(n) \geq 2$.

In every case $F(n) \geq 1$, completing the induction. Subtracting the $k = 0$ term gives $\sum_{k=1}^{n} (-1)^{a_k} = F(n) - 1 \geq 0$. □

Layer 1: WHAT

Block 1. Include the term $k = 0$, which is $+1$, and restate the target as $F(n) \geq 1$. Working with a strictly positive quantity is easier to induct on than a nonnegative one.

Block 2. Record the parity transfer $(-1)^{\lfloor j\beta \rfloor} = (-1)^{\lfloor j\alpha \rfloor}$, which holds because $\beta - \alpha = 2$ is even.

Block 3. Decompose the sign sequence into alternating runs and count the run lengths: $c_i = \#\{k : \lfloor k\alpha \rfloor = i\}$, with the closed form $C_m = \lfloor (m+1)\beta \rfloor + 1$.

Block 4. Show $c_i \in \{2, 3\}$ and that $c_i = 3$ exactly when i lies in the Beatty sequence $\lfloor j\beta \rfloor$.

Block 5. Subtract 2 from every c_i and take the alternating sum. The parity transfer converts it into a partial sum of the original sequence, at index $J_m = \lfloor (m+1)\alpha \rfloor$, which is less than half of m.

Block 6. Observe that the running total is smallest at the end of a negative run, and run a strong induction: inside a negative run, bound $F(n)$ below by S_m; inside a positive run, bound it below by $S_{m-1} + 1$. Both bounds are values of F at strictly smaller indices.

The nominal route runs: "the fractional parts of $k\alpha$ equidistribute, so the signs are balanced on average; let me estimate the discrepancy". That gives $F(n) = o(n)$ and stops, because the true statement is about a sign, not a size, and the partial sums are unbounded.

The bifurcation point is Block 3. The zombie sums the sequence term by term and tries to control the running total directly. The ideal solver stops looking at terms and looks at *runs*, because a sequence whose values are ± 1 carries all of its information in its run lengths, and because the alternating sum of run lengths is precisely the quantity whose positivity is in question. Once you are summing runs rather than terms, the parity transfer does the rest.

Layer 2: HOW

Block 1. **Cue.** The sum starts at $k = 1$, but $\lfloor 0 \cdot \alpha \rfloor = 0$ contributes $+1$. **Why natural.** Adding the $k = 0$ term shifts the target from "≥ 0" to "≥ 1", and an induction that must prove strict positivity of an integer quantity is easier than one proving nonnegativity, because "positive integer" gives you a usable margin of one. Free moves that make the statement stronger and the bookkeeping cleaner should always be taken. **Link to the next block.** You now want the partial sums of the full sequence indexed from 0.

Block 2. **Cue.** The number $\sqrt{2} - 1$, not $\sqrt{2}$, not $\sqrt{3} - 1$. **Why natural.** Any competition problem naming a specific quadratic irrational is naming a specific continued fraction. Compute the reciprocal immediately: $1/(\sqrt{2} - 1) = \sqrt{2} + 1$, which exceeds α by exactly 2. An even difference means the floors of $j\alpha$ and $j\beta$ have equal parity. That is the only special property used anywhere in the proof, and it is the reason the problem is true. **Link to the next block.** The Beatty sequence of β is about to appear as the set of positions of long runs, and you will need its parities to match those of α.

Block 3. **Cue.** The sequence takes only two values, $+1$ and -1. **Why natural.** A two valued sequence is completely described by its run lengths. So change the object of study from the sequence to its run length sequence, exactly as you would replace a binary word by its coding. The run containing the value i is $\{k : i \leq k\alpha < i + 1\}$, and counting integers in an interval is the cheapest computation there is: C_m counts k with $k\alpha < m + 1$, that is, $k < (m+1)\beta$. **Link to the next block.** You now need to know which runs are long.

Block 4. **Cue.** c_i is 2 plus the increment of $\lfloor i\alpha \rfloor$, which is 0 or 1. **Why natural.** The increment of a floor is 1 exactly when an integer is crossed, that is, when some j lies in $(i\alpha, (i+1)\alpha)$. Dividing by α turns that into $j\beta \in (i, i+1)$, so the long runs sit precisely at the positions $\lfloor j\beta \rfloor$. This is a Beatty sequence, and it is the standard answer to "where are the exceptional indices?" in every problem

of this type. **Link to the next block.** The long run positions are indexed by j, and their signs are $(-1)^{\lfloor j\beta \rfloor}$, which by Block 2 equal $(-1)^{\lfloor j\alpha \rfloor}$.

Block 5. Cue. An alternating sum of numbers all equal to 2 or 3. **Why natural.** Subtract the common part. $\sum(-1)^i c_i = \sum(-1)^i(c_i - 2) + 2\sum(-1)^i$, and the second sum is 0 or 1 depending only on the parity of m. The first sum is an alternating sum over the long run positions, and by the parity transfer its terms are exactly the terms of the original sequence. So the run length data is the original sequence again, read at a scale compressed by α. Recognising the compressed copy is the moment the problem is solved. **Link to the next block.** Self-similarity plus a strict contraction of scale means induction.

Block 6. Cue. The partial sum decreases only during negative runs. **Why natural.** Therefore its minimum over any interval is attained at the end of a negative run, and those are exactly the values S_m with m odd, which Lemma 4 identifies with $F(J_m)$. You never need to control the sum inside a run; you only need to control it at the run boundaries. For a positive run you gain at least one over the previous boundary. The two cases are the only two cases. **Link to the next block.** The scale contracts by more than a factor of two each time, since $\alpha < \frac{1}{2}$, so the induction terminates at the base case $F(0) = 1$.

Layer 3: WHY

The mathematical truth beneath this route is that $(-1)^{\lfloor k\alpha \rfloor}$ is a Sturmian type sequence, and the run length coding of a Sturmian sequence is again Sturmian with a new parameter obtained by applying the Gauss map $T(x) = \{1/x\}$ to the old one. That is the general renormalisation theorem in this area: coding by runs on the sequence side corresponds to the continued fraction shift on the parameter side. It is why a run length argument ever closes.

For a generic irrational this renormalisation produces an infinite family of different parameters and no self-referential induction is possible. Here it does close, and for a specific reason: from $\beta = \alpha + 2$ we get $\alpha = 1/(2 + \alpha)$, so

$$\alpha = [0; 2, 2, 2, \dots],$$

a purely periodic continued fraction with all partial quotients equal to 2, and α is a fixed point of the Gauss map. The derived sequence is therefore the *same* sequence, not a relative of it. Two properties are needed and both hold: the partial quotients are all equal (so the renormalisation returns to the same parameter) and the difference $1/\alpha - \alpha = 2$ is even (so the parity survives the renormalisation). Drop either and the argument fails. For the golden section $\alpha = (\sqrt{5} - 1)/2$ the first property holds but $1/\alpha - \alpha = 1$ is odd, so the parity transfer picks up an extra factor $(-1)^j$ and the run length coding reproduces a *twisted* copy of the sequence rather than the sequence itself.

This also explains, without any extra work, the natural generalisation: for $\alpha_N = \sqrt{N^2 + 1} - N$ we have $1/\alpha_N = \sqrt{N^2 + 1} + N = \alpha_N + 2N$, an even difference, and $\alpha_N = [0; 2N, 2N, \dots]$, again a Gauss map fixed point. The identical proof gives $\sum_{k=1}^{n}(-1)^{\lfloor k\alpha_N \rfloor} \geq 0$ for every positive integer N, with run lengths in $\{2N, 2N + 1\}$ and the scale contracting by the factor $\alpha_N < 1/(2N)$.

The other structural fact worth naming is the complementary Beatty pair. With $\beta = 1 + \sqrt{2}$ and $\beta' = 1 + \frac{\sqrt{2}}{2}$ one has $1/\beta + 1/\beta' = (\sqrt{2} - 1) + (2 - \sqrt{2}) = 1$, so by Rayleigh's theorem the sequences $\lfloor j\beta \rfloor$ and $\lfloor j\beta' \rfloor$ partition the positive integers. In our language: the long runs sit at the β positions and the short runs at the β' positions. Knowing this in advance is what tells you that "which runs are long" has a clean answer at all.

The discernment mechanism is a short filter for any problem containing $\lfloor k\theta \rfloor$ with θ irrational. First, compute $1/\theta$ and its continued fraction. Second, ask what invariant of θ the question is testing: if the statement involves a parity, the relevant invariant is the parity of $1/\theta - \theta$ or of the partial quotients. Third, if the sequence takes finitely many values, code it by runs and see whether

the coding reproduces it. If the continued fraction is purely periodic with period one, the coding will reproduce the sequence exactly and an induction is available. Training this means doing the reciprocal computation reflexively and always writing out the first twenty terms, because the run structure is invisible in the formula and obvious in the list.

The examiners nudged you in three places. They chose $\sqrt{2}-1$ rather than $\sqrt{2}$ or $1/\sqrt{2}$, which is the choice that makes the reciprocal differ by an even integer. They asked for ≥ 0 rather than for an asymptotic, which signals that the mechanism is exact and structural rather than analytic. And they used a floor inside an exponent of -1, which is the standard packaging for "the parity of a Beatty sequence", a phrase you should be able to read off the notation instantly.

Revolving concepts

Beatty sequences and Rayleigh's theorem. For irrational $\beta > 1$, the Beatty sequence is $\lfloor j\beta \rfloor$, $j \geq 1$. If $\beta, \beta' > 1$ are irrational with $1/\beta + 1/\beta' = 1$, the two Beatty sequences partition the positive integers. Here $\beta = 1+\sqrt{2}$ and $\beta' = 1+\sqrt{2}/2$. Pointer: see Book 1, field: Number theory, topic: Beatty and complementary sequences.

Continued fractions of quadratic irrationals. Every quadratic irrational has an eventually periodic continued fraction (Lagrange), and it is purely periodic exactly when it is reduced. Here $\alpha = 1/(2+\alpha)$ gives $\alpha = [0;\overline{2}]$, and the convergent denominators satisfy the Pell recursion $q_j = 2q_{j-1} + q_{j-2}$ with $q_0 = 0$, $q_1 = 1$, giving $0, 1, 2, 5, 12, 29, 70, \ldots$ The general solution of that recursion is $q_j = (\beta^j - (-\alpha)^j)/(2\sqrt{2})$, and in particular $q_j \equiv j \pmod 2$. The same recursion with 2 replaced by $2N$ handles $\alpha_N = \sqrt{N^2+1} - N$. Pointer: see Book 1, field: Number theory, topic: continued fractions and Pell recursions.

The Gauss map and renormalisation. $T(x) = \{1/x\}$ acts as the shift on continued fraction expansions. Coding a Sturmian sequence by its run lengths corresponds to applying T to its parameter; a parameter fixed by T therefore has a run length coding equal to itself, which is exactly what makes a self-referential induction possible. Pointer: see Book 1, field: Number theory, topic: Gauss map and substitutive sequences.

Sturmian words and run length coding. A sequence $(\lfloor (k+1)\theta \rfloor - \lfloor k\theta \rfloor)$ with $0 < \theta < 1$ irrational takes two values and is Sturmian; equivalently, for $1/(L+1) < \theta < 1/L$ the level sets of $\lfloor k\theta \rfloor$ have sizes L or $L+1$, and the positions of the longer ones form a Beatty sequence. The recursion to install is: run lengths of the level sets of $\lfloor k\theta \rfloor$ equal $\lfloor 1/\theta \rfloor$ plus the increments of $\lfloor i\theta \rfloor$, and the increment indicator is again a Beatty indicator, so the construction can be iterated indefinitely. Pointer: see Book 1, field: Discrete structures and graphs, topic: Sturmian words.

Ostrowski representation. Every positive integer has a unique representation $n = \sum_j d_j q_j$ subject to digit constraints determined by the partial quotients; it is the numeration system in which $\lfloor n\theta \rfloor$ and quantities like $F(n)$ have clean recursive descriptions. This is the machinery behind the published second solution. Pointer: see Book 1, field: Number theory, topic: Ostrowski numeration.

Three distance theorem. For irrational θ and any N, the points $\{\theta\}, \{2\theta\}, \ldots, \{N\theta\}$ partition the circle into arcs of at most three distinct lengths. It is the geometric cousin of the run length statement and the reason such problems always have finitely many local patterns. Pointer: see Book 1, field: Number theory, topic: three distance theorem.

Circuit Bank

- **WHEN** an expression $(-1)^{\lfloor k\theta \rfloor}$ with θ irrational **DO** compute $1/\theta$ at once and check whether $1/\theta - \theta$ is an even integer **BECAUSE** $\lfloor j/\theta \rfloor$ and $\lfloor j\theta \rfloor$ differ by an integer multiple of j, so only an even difference preserves parity, and parity preservation is what lets the run length data reproduce the original sign sequence
- **WHEN** a sequence taking only two values whose partial sums you must control **DO** replace the sequence by its run length sequence and control the alternating sum of run lengths

BECAUSE a two valued sequence carries all of its information in its runs, and the partial sums are extremal exactly at run boundaries

- **WHEN** run lengths of the level sets of $\lfloor k\theta \rfloor$ **DO** write the cumulative count as $\lfloor (m+1)/\theta \rfloor + 1$ and take differences **BECAUSE** counting the k with $\lfloor k\theta \rfloor \leq m$ is counting integers below $(m+1)/\theta$, which is the cheapest possible computation and gives every run length at once
- **WHEN** run lengths lying in $\{L, L+1\}$ **DO** subtract L and read the remainder as the indicator of a Beatty sequence **BECAUSE** the difference of consecutive floors is exactly the indicator that an integer was crossed, and crossing points of $i\theta$ are the Beatty positions of $1/\theta$
- **WHEN** a statement about a self-similar sequence at all scales **DO** strong induction on the index, using that the renormalised index is smaller by a definite factor **BECAUSE** self-similarity gives an exact identity between a quantity at scale n and the same quantity at a strictly smaller scale, and a contraction factor bounded away from one guarantees the induction terminates
- **WHEN** a partial sum positivity claim **DO** prove positivity only at the local minima of the partial sum, and bound the rest by monotonicity **BECAUSE** the running total decreases only on negative runs, so its minimum over any range is at the end of one, and every other value is dominated by such a value

Backtesting

1. First useful cue: $\sqrt{2}-1$ is the reciprocal of $\sqrt{2}+1$ and differs from it by the even integer 2. Compute the reciprocal before doing anything else.
2. Method the expression suggested: code the two valued sign sequence by its run lengths, identify the long runs with the Beatty sequence of $1/\alpha$, and use the parity transfer to see the run length data as a compressed copy of the original sequence, then induct on the scale.
3. Where you would hesitate, and the thought to reinforce: the hesitation is at the step where the alternating sum of $c_i - 2$ becomes a partial sum of the original sequence. Reinforce it by naming the two ingredients out loud: the long runs sit at $i = \lfloor j\beta \rfloor$, and $(-1)^{\lfloor j\beta \rfloor} = (-1)^{\lfloor j\alpha \rfloor}$. Without the second, the identity is about a different sequence and the induction has nothing to feed on.
4. The trap the question sets: the irrational invites you to reach for equidistribution and discrepancy bounds. Those are the right tools for questions about the *size* of $\sum(-1)^{\lfloor k\theta \rfloor}$ and completely useless for its sign, since the partial sums here are unbounded and the statement is exact.
5. What makes you recognise it faster next time: the triple "floor of k times a quadratic irrational", "inside a power of -1", "inequality valid for all n". That triple means Beatty parity plus renormalisation, and the very first computation is $1/\theta$.
6. The reusable decision rule: for a two valued sequence generated by $\lfloor k\theta \rfloor$, the run lengths are $\lfloor 1/\theta \rfloor$ or $\lfloor 1/\theta \rfloor + 1$, the long ones sit on the Beatty sequence of $1/\theta$, and if $1/\theta - \theta$ is an even integer the run length coding reproduces the original sign sequence at scale θ; then induct.

Mirror drills

1. Show that $(-1)^{\lfloor j(\sqrt{2}+1) \rfloor} = (-1)^{\lfloor j(\sqrt{2}-1) \rfloor}$ for every integer $j \geq 0$. *Answer:* $\sqrt{2}+1 = (\sqrt{2}-1)+2$, so the two floors differ by $2j$.
2. Prove that $\lfloor j(1+\sqrt{2}) \rfloor$ and $\lfloor j(1+\frac{\sqrt{2}}{2}) \rfloor$, for $j \geq 1$, partition the positive integers, and say what this means for the run lengths. *Answer:* $\frac{1}{1+\sqrt{2}} + \frac{1}{1+\sqrt{2}/2} = (\sqrt{2}-1) + (2-\sqrt{2}) = 1$, so

Rayleigh's theorem applies; the first sequence gives the positions of the runs of length 3 and the second the positions of the runs of length 2.

3. For which θ of the form $\sqrt{N^2+1}-N$ does the proof above go through unchanged, and why? *Answer:* all of them. Each satisfies $1/\theta = \theta + 2N$ with $2N$ even, and $\theta = [\,0;\overline{2N}\,]$ is a fixed point of the Gauss map, so the run lengths lie in $\{2N, 2N+1\}$ and the coding reproduces the same sequence.

Chapter 7

Putnam 2019

7.1 A1. Sum of cubes minus triple product, modulo nine

Determine all possible values of the expression

$$A^3 + B^3 + C^3 - 3ABC$$

where A, B, and C are nonnegative integers.

Read it out loud

This is the one symmetric cubic in three variables that every syllabus makes you factorise, evaluated on the nonnegative integer lattice, and the command term is "determine all possible values". Say it plainly: you are being asked for the image of a polynomial map $\mathbb{Z}^3_{\geq 0} \to \mathbb{Z}$. An image question is always two questions. First, an obstruction: every value has some property. Second, a construction: every integer with that property is hit. If you only do one of the two you have half the marks and you know it.

The fields wired in are polynomial identities (symmetric functions, the factorisation of $A^3 + B^3 + C^3 - 3ABC$) and elementary number theory (residues modulo 3 and 9). What is really being tested is whether you treat the expression as a structured object (a product of two symmetric factors, each with a known sign) or as three independent variables to be case-bashed.

The first useful cue is the expression itself: the circuit fires and you write $A^3 + B^3 + C^3 - 3ABC = (A + B + C)(A^2 + B^2 + C^2 - AB - BC - CA)$, and in the same breath the second factor as $\frac{1}{2}\big((A-B)^2 + (B-C)^2 + (C-A)^2\big)$. The second cue is "nonnegative": it is planted to make the first factor nonnegative, so the whole expression is nonnegative. Within thirty seconds you should also have a small table: $(1,0,0) \mapsto 1$, $(1,1,0) \mapsto 2$, $(2,1,1) \mapsto 4$, $(2,2,1) \mapsto 5$, $(3,2,2) \mapsto 7$, $(2,0,0) \mapsto 8$, $(2,1,0) \mapsto 9$, and 3 and 6 never appear. The conjecture "everything except 3 and 6 modulo 9" is on the page before any proof starts, and the rest of the problem is making the conjecture rigorous in both directions.

Approaches, ranked worst to best

1. **Tabulate and guess.** *Cue:* "determine all possible values". *Circuit:* small cases first. (Correct as a first move, worthless as a last one. The table gives the conjecture but says nothing about why 3, 6, 12, 15 are missing. It stalls exactly where the marks are.)

2. **Cubes modulo nine, case bash.** *Cue:* the cubes and the modulus 9 in the conjecture. *Circuit:* residues of cubes: $a^3 \equiv 0, \pm 1 \pmod 9$. (It works: if 3 divides the expression then $A + B + C \equiv 0 \pmod 3$, which leaves four residue patterns for (A, B, C) modulo 3, and each gives a multiple of 9. Four cases of consumption where one structural line would do; and it hides the reason.)

3. **Norm form on the circulant ring.** *Cue:* the expression is the determinant of the circulant matrix with rows $(A, B, C), (C, A, B), (B, C, A)$. *Circuit:* norm forms are multiplicative. (Conceptually the deepest: it explains why the value set is closed under multiplication and why 3 behaves like a ramified prime. It costs a whole ring's worth of theory for a ten-minute problem. Keep it for the WHY layer, not for the arena.)

4. **Factorise, then symmetric functions.** *Cue:* a symmetric polynomial asked modulo a prime power. *Circuit:* write everything in $s = A + B + C$ and $e = AB + BC + CA$. (Ideal. The obstruction is one line once $X = s^3 - 3se$ is on the page; the construction uses the smallest possible differences to make the second factor equal to 1 or 3.)

The ideal solution

Write $X = A^3 + B^3 + C^3 - 3ABC$, $s = A + B + C$ and $e = AB + BC + CA$. Expanding confirms the identity

$$X = (A+B+C)(A^2+B^2+C^2-AB-BC-CA) = \tfrac{1}{2}\, s\left((A-B)^2+(B-C)^2+(C-A)^2\right).$$

Since $A^2 + B^2 + C^2 = s^2 - 2e$, the second factor equals $s^2 - 3e$, so also $X = s^3 - 3se$.

Obstruction. Both factors are nonnegative when $A, B, C \geq 0$, so $X \geq 0$. Suppose $3 \mid X$. Then $3 \mid s^3 - 3se$ forces $3 \mid s^3$, and as 3 is prime, $3 \mid s$. But then $9 \mid s^3$ and $9 \mid 3se$, so $9 \mid X$. Thus no value of X is congruent to 3 or 6 modulo 9.

Construction. Let $n \geq 0$ be an integer. For $(A, B, C) = (n+1, n, n)$ the half sum of squares is $\frac{1}{2}(1+0+1) = 1$ and $s = 3n+1$, so $X = 3n+1$. For $(n+1, n+1, n)$ the half sum is $\frac{1}{2}(0+1+1) = 1$ and $s = 3n+2$, so $X = 3n+2$. For $n \geq 1$ and $(n+1, n, n-1)$ the half sum is $\frac{1}{2}(1+1+4) = 3$ and $s = 3n$, so $X = 9n$. Finally $(0, 0, 0)$ gives $X = 0$. As n runs over the nonnegative integers these families produce every nonnegative integer congruent to 1 or 2 modulo 3 and every nonnegative multiple of 9.

Combining the two parts, the set of values is

$$\boxed{\{\, m \in \mathbb{Z}_{\geq 0} :\ m \not\equiv 3, 6 \pmod 9 \,\}}$$

Layer 1: WHAT

Block 1: name the object. The expression is the standard cubic and factorises as s times a quadratic form. Block 2: read the quadratic factor as a half sum of squared differences, which fixes its sign and tells you its smallest positive values (1 when two variables agree and the third differs by one; 3 when the three variables are consecutive). Block 3: rewrite everything in the elementary symmetric functions, $X = s^3 - 3se$, so that divisibility by 3 and by 9 is read off s alone. Block 4: construct, using the two smallest quadratic factors and letting s sweep the residue classes. Block 5: box the answer as a set, with both directions stated.

Juxtapose with the nominal route: tabulate, conjecture "not 3 or 6 modulo 9", then try to prove it by listing the residues of A, B, C modulo 3 and checking cubes modulo 9 in each case. The bifurcation point is the moment you choose between three independent variables and two symmetric functions. The nominal solver keeps A, B, C separate because that is how they were handed over; the ideal solver notices the expression is symmetric and refuses to carry three letters when two symmetric quantities carry the same information with the prime already exposed.

Layer 2: HOW

Block 1. **Cue.** The literal shape $A^3 + B^3 + C^3 - 3ABC$. **Why natural.** This is a memorised identity, and the reason it is worth memorising is definitional: the expression vanishes whenever $A + B + C = 0$ (put $C = -A - B$ and expand), so $A + B + C$ is a factor by the factor theorem in three variables, and the cofactor is forced by degree and symmetry. **Link to the next block.** A product is easier to control than a sum: the sign, the size and the divisibility of X now come from two factors separately.

Block 2. **Cue.** The word "nonnegative" and the quadratic factor $A^2 + B^2 + C^2 - AB - BC - CA$. **Why natural.** A quadratic form that is symmetric and vanishes on the diagonal $A = B = C$ must be a combination of squared differences; here it is exactly half their sum. That gives nonnegativity for free and, more usefully, a catalogue of its small values in terms of how far apart the three variables are. **Link to the next block.** The obstruction needs the residues of X, and the construction needs the small values of the second factor; Block 2 supplies the second, Block 3 the first.

Block 3. **Cue.** A symmetric polynomial questioned modulo 3 and 9. **Why natural.** Symmetric polynomials are polynomials in s, e and ABC, and ABC has already cancelled. Writing $X = s^3 - 3se$ places the prime 3 in front of the only term that is not a pure power of s; divisibility questions then reduce to s. This is not a revelation, it is what "symmetric" means. **Link to the next block.** "$3 \mid X \Rightarrow 3 \mid s \Rightarrow 9 \mid X$" is the whole obstruction; the remaining question is whether every other residue occurs.

Block 4. **Cue.** The obstruction only mentions residues modulo 9, so the construction must be indexed by residue classes. **Why natural.** To hit a residue class you want one factor equal to a small constant and the other to sweep. The half sum of squares is 1 for $(n+1, n, n)$ type triples and 3 for consecutive triples, so X equals s or $3s$ with s controlled by n. **Link to the next block.** Two families cover residues 1 and 2 modulo 3; the consecutive family covers the multiples of 9; $(0, 0, 0)$ covers zero. That is every class the obstruction allowed.

Block 5. **Cue.** The command term "determine all". **Why natural.** A set answer needs both inclusions written explicitly; a grader looks for the sentence that says the construction exhausts the classes the obstruction permits. **Link to the next block.** Box the set and stop.

Layer 3: WHY

The mathematical truth beneath the route is Newton's identity for three variables: $A^3 + B^3 + C^3 = s^3 - 3se + 3ABC$, so $X = s^3 - 3se$ is not a coincidence you spotted, it is the power sum p_3 with the e_3 term deliberately subtracted. The examiners chose the coefficient -3 on ABC precisely so that e_3 disappears and the expression becomes a function of s and e only. Once you see it that way, the modulus 9 is not a mystery either: $X \equiv s^3 \equiv s \pmod 3$, and when $3 \mid s$ every term of $s^3 - 3se$ is divisible by 9.

A deeper reason the value set looks the way it does: X is the determinant of the circulant matrix with first row (A, B, C), equivalently the product $(A + B + C)(A + B\omega + C\omega^2)(A + B\omega^2 + C\omega)$ over a primitive cube root of unity ω. Products of circulants are circulants, so the value set is closed under multiplication, and $\{m \geq 0 : m \not\equiv 3, 6 \pmod 9\}$ is indeed multiplicatively closed. The prime 3 is special because $3 = -\omega^2(1-\omega)^2$ ramifies in the Eisenstein integers, and the three factors are congruent modulo $1 - \omega$; that is the ring-theoretic shadow of "if 3 divides X then it divides both rational factors".

The discernment mechanism: when a symmetric expression is questioned modulo a prime power, do not touch the individual variables. Move to the elementary symmetric functions, because the prime you care about will appear as a visible coefficient there. Train it by taking every symmetric identity you know ($p_2 = e_1^2 - 2e_2$, $p_3 = e_1^3 - 3e_1e_2 + 3e_3$) and reading off which primes they expose. The nudges here were three: the coefficient -3, the word "nonnegative", and the phrase "all possible values", which promises a clean description and therefore a modular one.

Revolving concepts

The cubic identity. $a^3 + b^3 + c^3 - 3abc = (a + b + c)(a^2 + b^2 + c^2 - ab - bc - ca)$, with the second factor $\frac{1}{2}\sum(a-b)^2 \geq 0$ and equal to zero only when $a = b = c$. This is also the AM-GM inequality for three terms in disguise: for $a, b, c \geq 0$ put $a = x^3$ and so on. See Book 1, field: Polynomials, topic: symmetric factorisations.

Newton's identities and their recursion. For three variables with $e_1 = s$, $e_2 = e$, $e_3 = ABC$, the power sums satisfy $p_1 = e_1$, $p_2 = e_1p_1 - 2e_2$, $p_3 = e_1p_2 - e_2p_1 + 3e_3$, and for $k > 3$ the pure recurrence $p_k = e_1p_{k-1} - e_2p_{k-2} + e_3p_{k-3}$. The generalised form for n variables is $p_k = e_1p_{k-1} - e_2p_{k-2} + \cdots + (-1)^{n-1}e_np_{k-n}$ for $k > n$, with the truncated versions (ending in $(-1)^{k-1}ke_k$) for $k \leq n$. Solution method: the power sums obey the same linear recurrence as the roots of

$t^n - e_1 t^{n-1} + \cdots$, so any question "power sums modulo a prime" becomes "coefficients modulo a prime". The same generalisation runs any problem where you are given $a+b+c$, $ab+bc+ca$, abc and asked about $a^k + b^k + c^k$. See Book 1, field: Polynomials, topic: Newton's identities.

Cubes modulo nine. $a^3 \equiv 0, 1$ or $-1 \pmod 9$ according as $a \equiv 0, 1, -1 \pmod 3$. See Book 1, field: Number theory, topic: residues of powers.

Circulant determinants and norm forms. The circulant with first row $(a_0, \ldots, a_{n-1})$ has eigenvectors $(1, \zeta^j, \zeta^{2j}, \ldots)$ and eigenvalues $\sum_k a_k \zeta^{jk}$, hence determinant $\prod_j \sum_k a_k \zeta^{jk}$. Multiplicativity of value sets (a^2+b^2, a^2+ab+b^2, a^2-db^2, and X here) always comes from a ring. See Book 1, field: Matrices and determinants, topic: circulants; and field: Number theory, topic: norm forms.

Circuit Bank

- **WHEN** you see $a^3+b^3+c^3-3abc$ **DO** write $(a+b+c)\cdot\frac{1}{2}\sum(a-b)^2$ and also s^3-3se **BECAUSE** because the first form gives sign and small values, the second exposes the prime 3
- **WHEN** you see "determine all possible values" of an integer expression **DO** write two headings, Obstruction and Construction, before anything else **BECAUSE** because an image is exactly the intersection of what is forbidden and what is achieved, and a grader marks the two halves separately
- **WHEN** you see a symmetric polynomial questioned modulo a prime power **DO** rewrite in elementary symmetric functions **BECAUSE** because Newton's identities put the prime in front of the mixed terms and the analysis collapses onto e_1
- **WHEN** you see the constraint "nonnegative integers" **DO** ask which factor it controls the sign of **BECAUSE** because a sign constraint is planted to kill one half of the value set and to hint that a factorisation exists

Backtesting

1. First useful cue: the literal expression $A^3+B^3+C^3-3ABC$; the factorisation must be written before reading the rest of the sentence.
2. Method the expression suggested: factor, sign from the half sum of squares, residues from s^3-3se, construction from triples with small spread.
3. Where you would hesitate, and the thought to reinforce: after conjecturing "not 3 or 6 modulo 9", the temptation is to case-bash residues of A, B, C. Reinforce: symmetric means work in s and e.
4. The trap the question sets: proving only the obstruction, or only the construction, and calling it done; also forgetting $X = 0$ and forgetting that $(n+1, n, n-1)$ needs $n \geq 1$.
5. What makes you recognise it faster next time: any coefficient -3 on abc is Newton's identity with e_3 cancelled; that is the signature of "this cubic factorises".
6. The reusable decision rule: image of a polynomial on the integers equals obstruction (modular) plus construction (parametrised families); both must appear on the page.

Mirror drills

1. (drill) Can $A^3+B^3+C^3-3ABC = 2019$ for nonnegative integers A, B, C? *Answer:* No; $2019 \equiv 3 \pmod 9$, and any value divisible by 3 is divisible by 9.

2. (drill) Show that if m and n are values of $A^3 + B^3 + C^3 - 3ABC$ on nonnegative integers then so is mn. *Answer:* X is the determinant of the circulant with first row (A, B, C); the product of two circulants with nonnegative entries is a circulant with nonnegative entries, and determinants multiply.
3. (drill) Show that $A^2 + B^2 + C^2 - AB - BC - CA$ is never congruent to 2 modulo 3. *Answer:* With $u = A - B$, $v = B - C$ it equals $u^2 + uv + v^2 \equiv (u - v)^2 \pmod 3$, a square modulo 3.

7.2 A2. Centroid and incentre parallel to a side

In the triangle $\triangle ABC$, let G be the centroid, and let I be the centre of the inscribed circle. Let α and β be the angles at the vertices A and B, respectively. Suppose that the segment IG is parallel to AB and that $\beta = 2\tan^{-1}(1/3)$. Find α.

Read it out loud

A triangle, two of its centres, a parallelism between the segment joining them and one side, and one angle handed to you not as β but as twice an arctangent. Read that last cue exactly as written: the examiners are telling you $\tan(\beta/2) = 1/3$. They could have written $\cos\beta = 4/5$ or "a 3, 4, 5 shape at B"; they chose the half angle. Half angles at the vertices live on the incircle, because the incentre sits on the bisectors and the touch points make right triangles with the vertices. That is the guiding light for the whole problem.

The fields wired in are triangle geometry (the centroid as an average of the vertices, the incentre through its tangent lengths and inradius), half-angle trigonometry, and the area bookkeeping $K = rs = \frac{1}{2}c\,h_c$. What is really being tested is a translation skill: can you convert each geometric condition into the parameter that defines the object named? G is defined by cutting each median in the ratio $2:1$, so its distance from AB is a third of the altitude from C. I is defined as the centre of a circle tangent to the three sides, so its distance from AB is r. "Parallel to AB" for two interior points is "same distance from AB". Nothing else is going on in the first half of the problem.

Within thirty seconds you should have written $r = h_c/3$, and next to it $\tan(\beta/2) = 1/3$, $\tan\beta = 3/4$, $\cos\beta = 4/5$, $\sin\beta = 3/5$. The rest is choosing which language to finish in. The ideal choice stays in the incircle's language, because the incircle already carries both hypotheses: r from the parallel condition and $\tan(\beta/2)$ from the given angle.

Approaches, ranked worst to best

1. **Sine rule with two unknown angles.** *Cue:* "find α" with β known. *Circuit:* angle sum plus sine rule. (After $a + b = 2c$ you get $\sin\alpha + \sin\beta = 2\sin(\alpha+\beta)$, which with $\sin\beta = 3/5$, $\cos\beta = 4/5$ reduces to $\sin\alpha + 2\cos\alpha = 1$. Squaring produces the spurious root $\cos\alpha = 4/5$, which must be rejected by a sign check. It works, but you paid for a squaring and a rejected root, and you still needed $a + b = 2c$ first.)

2. **Coordinates.** *Cue:* $\tan(\beta/2) = 1/3$ puts I at $(3r, r)$. *Circuit:* fix B at the origin, A on the x-axis. (With $B = (0,0)$, $I = (3r, r)$, C on the ray of slope $3/4$ at height $3r$, so $C = (4r, 3r)$; then $A = (t, 0)$ is fixed by $a + b = 2c$ or by tangency of CA to the incircle, giving $t = 4r$. Reliable, a page of ink, a quadratic in t to solve.)

3. **Law of cosines on $a + b = 2c$.** *Cue:* a linear relation between sides plus a known cosine. *Circuit:* eliminate one side. (With $b = 2c - a$ and $\cos\beta = 4/5$: $(2c-a)^2 = a^2 + c^2 - \frac{8}{5}ac$ gives $c = \frac{4}{5}a$, $b = \frac{3}{5}a$, so $a : b : c = 5 : 3 : 4$ and the right angle is opposite a, at A. Short and sound; it computes the whole triangle when only one angle was asked.)

4. **Synthetic: the altitude is tangent to the incircle.** *Cue:* $h_c = 3r$ and $\tan\beta = 3/4$ give the foot D of the altitude at $BD = 4r$, while the touch point F has $BF = 3r$. *Circuit:* a line at distance r from I is tangent. (Then $FD = r$, so the altitude line CD is tangent to the incircle; the tangents from C are CA and CB, and $CD \neq CB$, so $D = A$ and $\alpha = \pi/2$. Two lines, one delicate sentence about the two tangents from an external point.)

5. **Half-angle product identity.** *Cue:* a half angle given and the incentre present. *Circuit:* $\tan\frac{\alpha}{2}\tan\frac{\beta}{2} = \frac{s-c}{s}$. (Ideal. The parallel condition says $s = 3(s-c)$, the identity turns that into $\tan\frac{\alpha}{2}\tan\frac{\beta}{2} = \frac{1}{3}$, and the given $\tan\frac{\beta}{2} = \frac{1}{3}$ leaves $\tan\frac{\alpha}{2} = 1$. No squaring, no coordinates, nothing computed that was not asked.)

The ideal solution

Let $a = BC$, $b = CA$, $c = AB$, $s = \frac{1}{2}(a+b+c)$, let K be the area, r the inradius and h_c the altitude from C.

Step 1: the parallel condition means $a + b = 2c$. The centroid G lies on the median from C to the midpoint M of AB with $CG : GM = 2 : 1$, so the distance from G to the line AB is $\frac{1}{3}h_c$. The distance from I to AB is r, since the incircle is tangent to AB. Both points are interior, hence on the same side of AB, so $IG \parallel AB$ exactly when $r = \frac{1}{3}h_c$. (The segment is nondegenerate: $I = G$ would force an equilateral triangle, where $\tan\frac{\beta}{2} = \frac{1}{\sqrt{3}} \neq \frac{1}{3}$.) Now $2K = c\,h_c$, and $K = rs$ because the segments IA, IB, IC cut the triangle into three triangles of heights r on bases a, b, c. Hence $c\,h_c = 2rs$, and with $h_c = 3r$ this is $3c = a + b + c$, that is $a + b = 2c$. Equivalently $s = \frac{3}{2}c$ and $s - c = \frac{1}{2}c$, so

$$\frac{s-c}{s} = \frac{1}{3}.$$

Step 2: a lemma. In every triangle,

$$\tan\frac{\alpha}{2}\,\tan\frac{\beta}{2} = \frac{s-c}{s}.$$

Let the incircle touch BC, CA, AB at D, E, F. The two tangent segments from a point to a circle are equal, so with $AE = AF = x$, $BF = BD = y$, $CD = CE = z$ we have $x + y = c$, $y + z = a$, $z + x = b$, whence $x = s - a$, $y = s - b$, $z = s - c$. The incentre lies on the bisector at A and $IF \perp AB$ with $IF = r$, so in the right triangle AFI, $\tan\frac{\alpha}{2} = \frac{r}{s-a}$; similarly $\tan\frac{\beta}{2} = \frac{r}{s-b}$. Heron's formula $K^2 = s(s-a)(s-b)(s-c)$ together with $K = rs$ gives $r^2 = \frac{(s-a)(s-b)(s-c)}{s}$. Therefore

$$\tan\frac{\alpha}{2}\,\tan\frac{\beta}{2} = \frac{r^2}{(s-a)(s-b)} = \frac{s-c}{s}.$$

Step 3: conclude. By Steps 1 and 2 and the hypothesis $\tan\frac{\beta}{2} = \frac{1}{3}$,

$$\tan\frac{\alpha}{2}\cdot\frac{1}{3} = \frac{1}{3}, \qquad \text{so} \qquad \tan\frac{\alpha}{2} = 1.$$

Since $0 < \frac{\alpha}{2} < \frac{\pi}{2}$, this forces $\frac{\alpha}{2} = \frac{\pi}{4}$.

Step 4: the hypotheses are consistent. For $A = (0,0)$, $B = (4,0)$, $C = (0,3)$ we have $a = 5$, $b = 3$, $c = 4$, so $a + b = 2c$; $\tan\beta = \frac{3}{4}$ gives $\tan\frac{\beta}{2} = \frac{\sin\beta}{1+\cos\beta} = \frac{3/5}{9/5} = \frac{1}{3}$; and $r = K/s = 6/6 = 1$, so $I = (1,1)$ while $G = (\frac{4}{3}, 1)$, both on the line $y = 1$ parallel to AB.

$$\boxed{\alpha = \frac{\pi}{2}}$$

Layer 1: WHAT

Block 1: translate $IG \parallel AB$ into equal distances from AB, then through $K = rs = \frac{1}{2}ch_c$ into $a + b = 2c$, and store it as $(s-c)/s = 1/3$. Block 2: translate $\beta = 2\tan^{-1}(1/3)$ into $\tan(\beta/2) = 1/3$ and recognise a half angle as an incircle quantity. Block 3: prove the half-angle product lemma from tangent lengths and Heron. Block 4: solve $\tan(\alpha/2) = 1$ on the correct range, box, and exhibit the $3, 4, 5$ witness.

Juxtapose with the nominal route: coordinates for everything, or the sine rule with two unknown angles and a squaring. Both finish. The bifurcation point is the line after $a + b = 2c$: the nominal solver now computes the triangle (law of cosines, coordinates) because computing feels like progress; the ideal solver notices that the remaining hypothesis is a half angle, that half angles are ratios $r/(s-a)$, and that $a + b = 2c$ is itself a statement about s and $s - c$. Everything stays in one coordinate system, the incircle's.

Layer 2: HOW

Block 1. **Cue.** "The segment IG is parallel to AB." **Why natural.** Parallel to a line means equal signed distance from it. The distance of each named centre from a side is part of that centre's definition: G cuts the median in thirds, so its height is $h_c/3$; I is the centre of a circle tangent to AB, so its height is r. The identity $K = rs$ is then the natural bridge because it is the only standard formula containing r and the sides together, and $K = \frac{1}{2}ch_c$ is the only one containing h_c. **Link to the next block.** $a + b = 2c$ is the parallel condition in side language; rewriting it as $(s - c)/s = 1/3$ is what lets Block 3 use it.

Block 2. **Cue.** $\beta = 2\tan^{-1}(1/3)$. **Why natural.** The examiners chose to present the angle through its half. The half angle at B is the angle IBF in the right triangle with legs r and $BF = s - b$. So the given number is a ratio of incircle quantities, $r/(s - b) = 1/3$, not merely a trigonometric constant. **Link to the next block.** Both hypotheses are now statements about r, s, and the tangent lengths; the finishing identity must be one that relates exactly these.

Block 3. **Cue.** Two half-angle tangents and the ratio $(s - c)/s$ on the page. **Why natural.** $\tan\frac{\alpha}{2}\tan\frac{\beta}{2} = \frac{r^2}{(s-a)(s-b)}$ by definition of the tangent lengths, and Heron with $K = rs$ converts r^2 into $(s - a)(s - b)(s - c)/s$. The $(s - a)(s - b)$ cancels. There is no leap: you multiply the two things you have and simplify with the one formula that expresses r in terms of the sides. **Link to the next block.** The product equals $1/3$ by Block 1, and one factor equals $1/3$ by Block 2.

Block 4. **Cue.** $\tan(\alpha/2) = 1$ with α an angle of a triangle. **Why natural.** Inverting a tangent needs a range; $\alpha/2 \in (0, \pi/2)$ makes the inverse unique. The witness triangle is not decoration: a "find the angle" question with several hypotheses could be vacuous, and a $3, 4, 5$ check costs three lines and certifies the answer against a sign error. **Link to the next block.** Box and stop.

Layer 3: WHY

Three truths make this route ideal. First, both centres are weighted averages of the vertices: $G = \frac{A+B+C}{3}$ and $I = \frac{aA+bB+cC}{a+b+c}$. The signed distance of a weighted average from the line AB is the weight of C times h_c. So $IG \parallel AB$ is literally the equation of C-weights, $\frac{1}{3} = \frac{c}{a+b+c}$, which is $a + b = 2c$ without any area argument at all. That is the definitional reason the side relation is so clean, and it generalises instantly: $IG \parallel BC$ iff $b + c = 2a$.

Second, the natural coordinates of the incircle are the tangent lengths $(s - a, s - b, s - c)$ and r; every half angle is r over a tangent length, and Heron is the relation $r^2 s = (s - a)(s - b)(s - c)$ that closes the system. The identity $\tan\frac{\alpha}{2}\tan\frac{\beta}{2} = \frac{s-c}{s}$ is nothing but this closure. An equivalent closure is the angle-sum identity $\tan\frac{\alpha}{2}\tan\frac{\beta}{2} + \tan\frac{\beta}{2}\tan\frac{\gamma}{2} + \tan\frac{\gamma}{2}\tan\frac{\alpha}{2} = 1$, from $\frac{\alpha+\beta+\gamma}{2} = \frac{\pi}{2}$; with $\tan\frac{\gamma}{2} = \frac{r}{s-c} = \frac{2r}{c}$ and $a + b = 2c$ it also yields $\tan\frac{\alpha}{2}\tan\frac{\beta}{2} = \frac{1}{3}$, so you can finish without Heron if you prefer.

Third, the geometry of the answer: $a + b = 2c$ places C on an ellipse with foci A and B, and fixing β restricts C to a ray from B, which meets the ellipse once. So the triangle is unique up to similarity and the answer had to be a specific number; the examiners chose $\tan\frac{\beta}{2} = \frac{1}{3}$ so that the number is $\pi/2$ and the triangle is the $3, 4, 5$ one. The discernment mechanism is: translate every hypothesis into the defining parameters of the objects named, then look for the one standard identity that links those parameters. Train it by writing, for each triangle centre you know, its barycentric weights and its distance to each side; after that, any "parallel to a side" or "on the bisector" condition is a one-line equation.

Revolving concepts

Centroid. $G = \frac{A+B+C}{3}$; it divides each median 2 : 1 from the vertex; its distance from side BC is $h_a/3$. See Book 1, field: Geometry, topic: triangle centres and barycentric coordinates.

Incentre and incircle. $I = \frac{aA+bB+cC}{a+b+c}$; $r = K/s$; the tangent lengths from A, B, C are $s-a, s-b, s-c$; $\tan\frac{\alpha}{2} = \frac{r}{s-a} = \sqrt{\frac{(s-b)(s-c)}{s(s-a)}}$; and the products $\tan\frac{\alpha}{2}\tan\frac{\beta}{2} = \frac{s-c}{s}$. The half-angle tangents satisfy $xy + yz + zx = 1$. See Book 1, field: Geometry, topic: incircle and tangent lengths.

Heron and the area identities. $K = \sqrt{s(s-a)(s-b)(s-c)} = rs = \frac{1}{2}ab\sin\gamma = \frac{1}{2}c\,h_c$. Each formula is a bridge between one family of parameters and another; you choose the pair of bridges that connect the hypotheses you were given. See Book 1, field: Geometry, topic: area formulae.

Parallelism in weighted-average language. If P and Q are weighted averages of A, B, C with normalised weights, then $PQ \parallel AB$ iff their C-weights agree, because the C-weight times h_c is the signed distance from AB. This is the general form of Step 1 and it handles the Nagel point, the symmedian point, and any other centre with known weights. See Book 1, field: Geometry, topic: barycentric coordinates.

Recursion. None in this problem; the only iteration is the protocol "translate, then link", applied once per hypothesis.

Circuit Bank

- **WHEN** you see "segment XY parallel to side AB" for two triangle centres **DO** write "distance of X from AB equals distance of Y from AB" in each centre's own parameters, or equate their C-weights **BECAUSE** because parallel means equal signed distance, and each centre's distance to a side is part of its definition
- **WHEN** you see an angle given as $2\tan^{-1}(t)$ **DO** write $\tan(\theta/2) = t$ and reach for the incircle: $\tan\frac{\alpha}{2} = r/(s-a)$ **BECAUSE** because half angles at the vertices are the acute angles of the right triangles formed by the incentre, a vertex and a touch point
- **WHEN** you see the incentre together with a relation among the sides **DO** write $s-a$, $s-b$, $s-c$, $K = rs$ and Heron **BECAUSE** because these are the incircle's coordinates and Heron is the single relation that closes them
- **WHEN** you see a "find the angle" question with several hypotheses **DO** after solving, exhibit one explicit triangle satisfying everything **BECAUSE** because a unique answer must be consistent and a witness catches a sign or squaring error at the cost of three lines

Backtesting

1. First useful cue: $\beta = 2\tan^{-1}(1/3)$, read as $\tan(\beta/2) = 1/3$, which points at the incircle before the parallel condition is even processed.
2. Method the expression suggested: convert the parallel condition to $r = h_c/3$ and then $a + b = 2c$; convert the half angle to $r/(s-b) = 1/3$; close with $\tan\frac{\alpha}{2}\tan\frac{\beta}{2} = \frac{s-c}{s}$.
3. Where you would hesitate, and the thought to reinforce: after $a + b = 2c$, the pull toward the law of cosines or coordinates. Reinforce: the remaining datum is a half angle, so stay in tangent lengths; the finishing identity is one line.
4. The trap the question sets: solving $\sin\alpha + 2\cos\alpha = 1$ by squaring and keeping the spurious $\cos\alpha = 4/5$; or forgetting that $\tan\frac{\alpha}{2} = 1$ needs the range $\alpha/2 \in (0, \pi/2)$ to invert.
5. What makes you recognise it faster next time: any angle presented as a double arctangent is a half-angle cue, and half angles are incircle ratios; any centroid condition is a statement about thirds of an altitude.

6. The reusable decision rule: translate each hypothesis into the defining parameters of the objects it names, then finish with the one standard identity linking those parameters; compute the triangle only if the question asks for the triangle.

Mirror drills

1. (drill) In triangle ABC the segment IG is parallel to BC. Show that $b + c = 2a$. *Answer:* distances of G and I from BC are $h_a/3$ and r; $a\,h_a = 2K = 2rs$ with $h_a = 3r$ gives $3a = 2s$.
2. (drill) Prove $\tan\frac{\alpha}{2}\tan\frac{\beta}{2} + \tan\frac{\beta}{2}\tan\frac{\gamma}{2} + \tan\frac{\gamma}{2}\tan\frac{\alpha}{2} = 1$ in any triangle. *Answer:* $\frac{\alpha}{2} + \frac{\beta}{2} = \frac{\pi}{2} - \frac{\gamma}{2}$; take tangents, $\frac{x+y}{1-xy} = \frac{1}{z}$, and clear denominators.
3. (drill) In a triangle with $IG \parallel AB$, express $\tan\frac{\gamma}{2}$ through $x + y$ where $x = \tan\frac{\alpha}{2}$, $y = \tan\frac{\beta}{2}$. *Answer:* $xy = \frac{1}{3}$ by the lemma, so the identity of the previous drill gives $\tan\frac{\gamma}{2} = \frac{2}{3(x+y)}$.

7.3 A3. Mean root modulus by Vieta and AM-GM

Given real numbers $b_0, b_1, \ldots, b_{2019}$ with $b_{2019} \neq 0$, let $z_1, z_2, \ldots, z_{2019}$ be the roots in the complex plane of the polynomial

$$P(z) = \sum_{k=0}^{2019} b_k z^k.$$

Let $\mu = (|z_1| + \cdots + |z_{2019}|)/2019$ be the average of the distances from $z_1, z_2, \ldots, z_{2019}$ to the origin. Determine the largest constant M such that $\mu \geq M$ for all choices of $b_0, b_1, \ldots, b_{2019}$ that satisfy

$$1 \leq b_0 < b_1 < b_2 < \cdots < b_{2019} \leq 2019.$$

Read it out loud

A polynomial of degree 2019 whose real coefficients increase strictly from at least 1 to at most 2019, and you are asked about the arithmetic mean of the moduli of its roots. "The largest constant M such that $\mu \geq M$ for all choices" is the infimum of μ over the constraint set, so the command term is again double: prove a lower bound, then show the bound is attained (or at least approached). A bound without an extremal example is half an answer.

Now read the constraints as the examiners wrote them. Only two coefficients carry absolute bounds, $b_0 \geq 1$ and $b_{2019} \leq 2019$; all the middle coefficients are tied to each other by strict monotonicity alone. Which symmetric function of the roots depends on b_0 and b_{2019} and on nothing else? The product: $\prod z_i = (-1)^{2019} b_0/b_{2019}$. So the data control the product of the moduli, and the question asks about their arithmetic mean. The circuit that connects an arithmetic mean of nonnegative numbers to their product is AM-GM. Within thirty seconds you should have written $\prod |z_i| = b_0/b_{2019} \geq 1/2019$ and $\mu \geq (1/2019)^{1/2019}$.

The fields wired in are polynomials (the fundamental theorem of algebra, Vieta), inequalities (AM-GM with its equality case), and complex numbers (roots of unity, rescaling). What is really being tested is whether you attack a mean of moduli through the product rather than through the location of individual roots. One more planted cue: "real numbers", not integers. The equality case will need coefficients $2019^{k/2019}$, which are irrational; the examiners wrote "real" so that the extremal polynomial is admissible.

Approaches, ranked worst to best

1. **Root location theorems.** *Cue:* positive increasing coefficients. *Circuit:* Eneström and Kakeya: all roots lie in $|z| \leq 1$, refined to the annulus between min and max of b_k/b_{k+1}. (A theorem-name reflex that bounds every root separately. The lower radius $\min_k b_k/b_{k+1}$ can be as small as about $1/2019$ (take $b_0 = 1$, b_1 near 2019), so the mean is only shown to exceed roughly $1/2019$, far below the truth. Individual bounds are the wrong tool for a statement about a mean.)

2. **Triangle inequality on the sum of roots.** *Cue:* "average" suggests $\sum z_i = -b_{2018}/b_{2019}$. *Circuit:* mean of moduli is at least modulus of the mean. (Gives $\mu \geq b_{2018}/(2019\, b_{2019})$, which can be tiny, and in any case the triangle inequality can only certify a mean of moduli from below by a quantity that may be zero. Dead on arrival.)

3. **Small analogues first.** *Cue:* a 2019 that is clearly a placeholder. *Circuit:* replace 2019 by n and test $n = 2$. (For $1 \leq b_0 < b_1 < b_2 \leq 2$ the product of the moduli is $b_0/b_2 \geq \frac{1}{2}$ and $b_k = 2^{k/2}$ gives roots of modulus $2^{-1/2}$. This is not a proof but it tells you the answer is $2019^{-1/2019}$ and that a geometric progression of coefficients is the extremal shape. Worth sixty seconds.)

4. **Vieta, AM-GM, roots of unity.** *Cue:* bounds on b_0 and b_{2019} only; "average"; "largest constant". *Circuit:* mean $\geq$ geometric mean $=$ (product)$^{1/n}$, product from Vieta, equality forces all moduli equal, so rescale $1 + w + \cdots + w^{2019}$. (Ideal. Three lines for the bound, four for the example.)

The ideal solution

Since $b_{2019} \neq 0$, P has degree exactly 2019, so by the fundamental theorem of algebra it has 2019 roots $z_1, \ldots, z_{2019}$ counted with multiplicity and $P(z) = b_{2019} \prod_{i=1}^{2019} (z - z_i)$. Comparing constant terms, $b_0 = b_{2019}(-1)^{2019} \prod_i z_i$, hence

$$\prod_{i=1}^{2019} |z_i| = \frac{|b_0|}{|b_{2019}|} = \frac{b_0}{b_{2019}} \;\geq\; \frac{1}{2019},$$

using $b_0 \geq 1$ and $0 < b_{2019} \leq 2019$.

Lower bound. The moduli $|z_i|$ are nonnegative reals, so by the inequality of arithmetic and geometric means,

$$\mu = \frac{1}{2019} \sum_{i=1}^{2019} |z_i| \;\geq\; \Big(\prod_{i=1}^{2019} |z_i| \Big)^{1/2019} \;\geq\; 2019^{-1/2019}.$$

Sharpness. Let $\rho = 2019^{1/2019} > 1$ and put $b_k = \rho^k$ for $0 \leq k \leq 2019$. Then $b_0 = 1$, $b_{2019} = 2019$, and $b_0 < b_1 < \cdots < b_{2019}$ because $\rho > 1$; so this choice is admissible. For every z with $\rho z \neq 1$,

$$P(z) = \sum_{k=0}^{2019} (\rho z)^k = \frac{(\rho z)^{2020} - 1}{\rho z - 1},$$

and $P(1/\rho) = 2020 \neq 0$. So the roots of P are exactly the z with $(\rho z)^{2020} = 1$ and $\rho z \neq 1$, namely $z_j = \rho^{-1} e^{2\pi i j/2020}$ for $j = 1, \ldots, 2019$. These are 2019 distinct numbers, so they are all the roots, and each has modulus ρ^{-1}. Hence for this choice $\mu = \rho^{-1} = 2019^{-1/2019}$, and the lower bound is attained.

Therefore the largest constant is

$$\boxed{M = 2019^{-1/2019}}$$

Layer 1: WHAT

Block 1: parse "largest constant with $\mu \geq M$ for all choices" as an infimum, so the write-up has a Bound and a Sharpness paragraph. Block 2: identify the product of the moduli as the one symmetric function fixed by the two bounded coefficients, via Vieta. Block 3: pass from arithmetic mean to geometric mean by AM-GM. Block 4: read the equality conditions (all moduli equal, $b_0 = 1$, $b_{2019} = 2019$) as a specification for the extremal polynomial: coefficients in geometric progression with ratio $2019^{1/2019}$, which is the geometric series $\sum(\rho z)^k$, whose roots are rescaled roots of unity. Block 5: check admissibility and count the roots.

Juxtapose with the nominal route: try to locate the roots (Cauchy bounds, Eneström and Kakeya), or to bound the mean through the sum of the roots. The bifurcation point is the word "average": the nominal solver hears "each root is at least this far from the origin" and reaches for a location theorem; the ideal solver hears "arithmetic mean of nonnegative quantities" and asks which quantity the data control, finds the product, and writes AM-GM.

Layer 2: HOW

Block 1. Cue. "Determine the largest constant M such that $\mu \geq M$ for all choices." **Why natural.** This sentence defines M as an infimum. The largest valid lower bound is proved by two separate facts: the inequality, and an admissible choice where it is tight. Writing the two headings first prevents the classic half-answer. **Link to the next block.** The Bound paragraph needs a handle on μ; Block 2 finds it.

Block 2. **Cue.** Bounds on b_0 and b_{2019} only; the middle coefficients constrained merely by order. **Why natural.** Vieta says each coefficient ratio b_{2019-k}/b_{2019} is $(-1)^k$ times the k-th elementary symmetric function of the roots. The product e_{2019} is the only one that depends on the two bounded coefficients alone. The examiners bounded exactly those two; that is a planted cue, not a coincidence. Moduli enter because $|\prod z_i| = \prod |z_i|$. **Link to the next block.** You now hold $\prod |z_i| \geq 1/2019$ and want $\frac{1}{2019}\sum |z_i|$; an inequality between a mean and a product is required.

Block 3. **Cue.** An arithmetic mean of nonnegative reals to be bounded below, with their product known. **Why natural.** AM-GM is by definition the statement that the arithmetic mean dominates the geometric mean, and the geometric mean is the 2019-th root of the product. The moduli are nonnegative, which is exactly the hypothesis. One line. **Link to the next block.** The bound is $2019^{-1/2019}$; to show it is the largest constant you need equality, so read the equality conditions.

Block 4. **Cue.** Equality in AM-GM holds iff all $|z_i|$ are equal; equality in $b_0/b_{2019} \geq 1/2019$ iff $b_0 = 1$, $b_{2019} = 2019$. **Why natural.** A polynomial with all roots on one circle $|z| = 1/\rho$ is a rescaling $Q(\rho z)$ of a polynomial with all roots on the unit circle. Rescaling multiplies the k-th coefficient by ρ^k, so the coefficients of $Q(\rho z)$ form a geometric progression precisely when Q has constant coefficients, that is $Q(w) = 1 + w + \cdots + w^{2019}$, whose roots are the 2020-th roots of unity other than 1. Increasing coefficients means $\rho > 1$; the endpoint conditions fix $\rho^{2019} = 2019$. **Link to the next block.** The example must be verified, not merely proposed.

Block 5. **Cue.** A proposed extremal polynomial. **Why natural.** Three checks are owed to the grader: the coefficients satisfy the strict inequalities and the endpoint bounds; the roots are found completely (the geometric sum formula needs $\rho z \neq 1$, and $z = 1/\rho$ is not a root); and the number of distinct roots found equals the degree, so nothing is missing and μ is computed correctly. **Link to the next block.** Box M.

Layer 3: WHY

The route is ideal because of three truths. First, the elementary symmetric functions of the roots are the coefficients, and among them the product is the cheapest: it sees only the two ends of the coefficient list. Any constraint set that pins down b_0 and b_n is really a constraint on $\prod |z_i|$. Second, the arithmetic mean of nonnegative numbers is bounded below by their geometric mean and by nothing weaker that uses only the product; AM-GM is not one choice among many here, it is the exact inequality for the data you hold. Third, AM-GM is tight precisely on constant tuples, so the extremal configuration must have all roots on one circle, and the polynomial with all roots on a circle and monotone coefficients is a rescaled geometric series.

There is also a scaling truth worth repeating. If you replace z by z/λ the roots multiply by λ and the coefficients b_k become $b_k\lambda^{-k}$. So μ has the dimensions of a length and the constraints must fix a scale; they do it through b_0 and b_{2019}, whose ratio has dimension length^{2019}, which is why the answer is a 2019-th root. Dimensional reading alone predicts $M = (\text{ratio})^{1/2019}$ up to a constant.

The discernment mechanism: when asked to bound a mean of nonnegative quantities, ask which symmetric function the data control. Product: AM-GM. Sum of squares: QM-AM or Cauchy. Second symmetric function: Maclaurin. Train it by listing, for each Vieta coefficient, the inequality that links it to the arithmetic mean. The examiners nudged with three details: bounds on the two end coefficients only, the word "average", and "real numbers" so that the irrational geometric progression is admissible. The number 2019 is decoration; every step works for any degree n with bounds $L \leq b_0$, $b_n \leq U$, giving $M = (L/U)^{1/n}$.

Revolving concepts

Vieta's formulas. For $P(z) = b_n \prod(z - z_i)$, $e_k(z_1, \ldots, z_n) = (-1)^k b_{n-k}/b_n$; in particular $\prod z_i = (-1)^n b_0/b_n$ and $\sum z_i = -b_{n-1}/b_n$. The fundamental theorem of algebra guarantees the n roots with multiplicity. See Book 1, field: Polynomials, topic: Vieta and symmetric functions.

AM-GM and its relatives. For nonnegative x_i, $\frac{1}{n}\sum x_i \geq (\prod x_i)^{1/n}$ with equality iff all x_i are equal. The generalisation that orbits this problem is Maclaurin's chain: with $S_k = e_k/\binom{n}{k}$, $S_1 \geq S_2^{1/2} \geq \cdots \geq S_n^{1/n}$, so every symmetric mean of the moduli bounds the arithmetic mean from below. See Book 1, field: Inequalities, topic: means and Maclaurin.

Geometric sums, roots of unity, rescaling. $\sum_{k=0}^{n} w^k = \frac{w^{n+1}-1}{w-1}$ for $w \neq 1$, with roots the $(n+1)$-th roots of unity other than 1. The substitution $w = \rho z$ multiplies the coefficient of z^k by ρ^k and divides every root by ρ. The recursion beneath the geometric sum is $S_{m+1} = wS_m + 1$; its general solution $S_m = \frac{w^m-1}{w-1}$ is the template for every first-order linear recurrence with constant coefficients, $u_{m+1} = au_m + b$, solved by a fixed point plus a geometric term. See Book 1, field: Complex numbers, topic: roots of unity; and field: Sequences and recurrences, topic: first-order linear recurrences.

Eneström and Kakeya. If $0 < b_0 \leq b_1 \leq \cdots \leq b_n$ then every root of $\sum b_k z^k$ satisfies $|z| \leq 1$; more generally all roots lie in the annulus $\min_k(b_k/b_{k+1}) \leq |z| \leq \max_k(b_k/b_{k+1})$. Know it so that you know it bounds roots individually and is therefore the wrong instrument for a mean. See Book 1, field: Polynomials, topic: root location.

Circuit Bank

- **WHEN** you see a mean of nonnegative quantities to be bounded below, with their product controlled by the data **DO** write AM-GM: mean $\geq$ (product)$^{1/n}$, and immediately write its equality condition **BECAUSE** because AM-GM is the exact inequality between an arithmetic mean and a product, and the equality condition designs the extremal example
- **WHEN** you see absolute bounds on b_0 and b_n only **DO** write $\prod z_i = (-1)^n b_0/b_n$ **BECAUSE** because the product of the roots is the one Vieta quantity that depends on exactly those two coefficients
- **WHEN** you see "largest constant M such that $\ldots \geq M$ for all" **DO** write two headings, Bound and Sharpness, before any algebra **BECAUSE** because the largest constant is an infimum, and a bound without an admissible choice attaining it determines nothing
- **WHEN** you need a polynomial with all roots on a circle and monotone coefficients **DO** write $\sum_{k=0}^{n}(\rho z)^k$ with $\rho > 1$ **BECAUSE** because rescaling the geometric series puts the roots of unity on the circle $|z| = 1/\rho$ and makes the coefficients a geometric progression

Backtesting

1. First useful cue: the constraints bound b_0 from below and b_{2019} from above, and nothing else absolutely; that is Vieta pointing at the product of the roots.
2. Method the expression suggested: product of moduli from Vieta, arithmetic mean from AM-GM, extremal example from the equality case via a rescaled geometric series.
3. Where you would hesitate, and the thought to reinforce: after the bound, wondering whether $2019^{-1/2019}$ is really attained with strictly increasing coefficients. Reinforce: equality needs all moduli equal, and the geometric series with ratio $\rho > 1$ has exactly that and is strictly increasing.
4. The trap the question sets: reaching for a root-location theorem because the coefficients are positive and increasing; or presenting the example without verifying the strict inequalities, without excluding $\rho z = 1$, or without counting that 2019 distinct roots were found.

5. What makes you recognise it faster next time: "average of $|z_i|$" plus a polynomial is AM-GM on Vieta's product; "real coefficients" in a problem that could have said integers is a hint that the extremal example is irrational.
6. The reusable decision rule: bound a mean through the symmetric function the data control, then build the extremal case from the equality condition of the inequality you used.

Mirror drills

1. (drill) Real $b_0 < \cdots < b_n$ with $L \le b_0$ and $b_n \le U$ ($0 < L < U$). Find the largest M with $\mu \ge M$ always. *Answer:* $M = (L/U)^{1/n}$, by the same AM-GM bound and $b_k = L\,(U/L)^{k/n}$.
2. (drill) With $0 < b_0 \le b_1 \le \cdots \le b_n$, show every root of $\sum b_k z^k$ satisfies $|z| \le 1$. *Answer:* for $|z| > 1$, $|(1-z)P(z)| \ge b_n|z|^{n+1} - \left(b_0 + \sum_{k\ge 1}(b_k - b_{k-1})|z|^k\right) > b_n|z|^{n+1} - b_n|z|^n > 0$.
3. (drill) If $z^n + c_{n-1}z^{n-1} + \cdots + c_0$ has $|c_0| = 1$, show some root has modulus at least 1 and some root has modulus at most 1. *Answer:* the product of the moduli is $|c_0| = 1$, so they cannot all exceed 1 nor all fall below 1.

7.4 A4. Fixed radius spherical means have a kernel

Let f be a continuous real-valued function on $\mathbb{R}^3$. Suppose that for every sphere S of radius 1, the integral of $f(x,y,z)$ over the surface of S equals 0. Must $f(x,y,z)$ be identically 0?

Read it out loud

Say the structure out loud before you touch a single integral. This is an averaging question. There is one linear operator in the room: the map that sends a continuous function to its average over the sphere of radius 1 centred at a point. The hypothesis says that operator kills f. The question asks whether that operator is injective. So the entire problem is: does the fixed radius spherical mean have a nonzero kernel on $C(\mathbb{R}^3)$? The fields wired in are multivariable calculus (a genuine surface integral, with its Jacobian), a scrap of classical geometry (the area of a zone of a sphere), and, underneath everything, harmonic analysis (a translation invariant operator is a convolution, and a convolution is diagonalised by exponentials).

Now the cue that should have been circled within thirty seconds: *radius* 1. Not "every sphere". Not "spheres of every radius". One fixed radius. Ask immediately what the problem would look like with that restriction lifted: if the averages over spheres of *all* radii r vanished, then letting $r \to 0^+$ and using continuity of f would give $f(c) = 0$ at every centre c, and the answer would be a two line yes. The setter removed exactly that. When a "Must ...?" question carries a restriction whose removal would make the answer trivially yes, the restriction is the whole content of the problem and the answer is almost always no. You should have written "answer: no, build a counterexample" before doing any calculation.

Second observation, so that you do not waste time on a dimension count. The hypothesis is one scalar equation for each centre in $\mathbb{R}^3$, imposed on one unknown function on $\mathbb{R}^3$. The constraints and the unknowns are indexed by the same space, so no cheap counting argument decides the question either way. You have to look at the operator itself.

Third observation, and this is the one that shortens the search. The hypothesis is invariant under every translation and every rotation of $\mathbb{R}^3$. That means you are free to hunt for a counterexample inside a family that respects part of that symmetry, and the cheapest such family is functions of a single coordinate, $f(x,y,z) = g(z)$. Inside that family the surface integral collapses to a one dimensional integral, and a one dimensional integral condition is something you can solve exactly rather than estimate.

Approaches, ranked worst to best

1. **Shrink the spheres.** *Cue:* the phrase "for every sphere". *Circuit:* the mean value circuit: the average of a continuous function over a sphere of radius r about c tends to $f(c)$ as $r \to 0^+$. This is the reflex that fires if you read the question carelessly, and it is dead on arrival: you are given exactly one radius, so there is no limit to take. Cost: the entire time slot, and no marks, because you are trying to prove a false statement.

2. **Differentiate the identity in the centre.** *Cue:* the condition holds for every centre, so the centre is a free parameter. *Circuit:* differentiate an identity with respect to a free parameter to generate new identities. If f were smooth you would deduce that the spherical means of all its partial derivatives vanish too, and you would drift toward the Darboux equation for spherical means. Every statement is true and none of them closes the problem, and f is only assumed continuous, so you would also owe a smoothing argument. Costs a page, yields nothing.

3. **Hunt for a radial counterexample.** *Cue:* a sphere is the most rotationally symmetric object there is. *Circuit:* match the symmetry of the unknown to the symmetry of the constraint. Setting $f(v) = F(|v|)$ turns the condition into a one dimensional integral equation relating F

to a weighted average over an interval depending on $|c|$, of Volterra type. It is solvable, but the kernel is ugly and you will spend real ink before you see anything.

4. **Hunt for a counterexample depending on one coordinate.** *Cue:* a sphere meets each plane $z = \text{const}$ in a circle whose contribution to the area you can write down. *Circuit:* slice a surface integral along the axis of symmetry and integrate the slabs. Cheap and complete. The condition becomes a statement about the integral of a function of one variable over every window of length 2, which you can solve exactly. This is what you write up.

5. **Read the symbol of the operator.** *Cue:* "for every sphere of radius 1" is a convolution with the surface measure of the unit sphere. *Circuit:* the eigenfunction circuit: a translation invariant operator is diagonalised by $e^{i\xi\cdot v}$, so injectivity is exactly the statement that its symbol has no real zeros. This is the best route for understanding and it is how the example in route 4 is found rather than guessed. The average of $e^{i\xi\cdot v}$ over the unit sphere is $\sin|\xi|/|\xi|$, which vanishes whenever $|\xi|$ is a nonzero multiple of π. Take $|\xi| = \pi$ with ξ along the z axis and take the imaginary part: $\sin(\pi z)$. Write up route 4, but think in route 5.

The ideal solution

The answer is $\boxed{\text{no}}$: the hypothesis does not force f to vanish.

Take

$$f(x, y, z) = \sin(\pi z),$$

which is continuous on $\mathbb{R}^3$ and is not identically 0, since $f(0, 0, \frac{1}{2}) = 1$.

Let S be the sphere of radius 1 centred at an arbitrary point (x_0, y_0, z_0). Parametrise S by

$$S(\varphi, \theta) = (x_0 + \sin\varphi\cos\theta,\ y_0 + \sin\varphi\sin\theta,\ z_0 + \cos\varphi),$$

for $\varphi \in [0, \pi]$, $\theta \in [0, 2\pi]$. Then

$$\frac{\partial S}{\partial \varphi} = (\cos\varphi\cos\theta, \cos\varphi\sin\theta, -\sin\varphi), \qquad \frac{\partial S}{\partial \theta} = (-\sin\varphi\sin\theta, \sin\varphi\cos\theta, 0),$$

and a direct computation gives

$$\frac{\partial S}{\partial \varphi} \times \frac{\partial S}{\partial \theta} = -\sin\varphi\,\big(\sin\varphi\cos\theta,\ \sin\varphi\sin\theta,\ \cos\varphi\big),$$

whose length is $|\sin\varphi| = \sin\varphi$ on $[0, \pi]$. Hence $dS = \sin\varphi\, d\varphi\, d\theta$ and

$$\iint_S f\, dS = \int_0^{\pi}\int_0^{2\pi} \sin\big(\pi(z_0 + \cos\varphi)\big)\sin\varphi\, d\theta\, d\varphi = 2\pi\int_0^{\pi} \sin\big(\pi(z_0 + \cos\varphi)\big)\sin\varphi\, d\varphi.$$

Substituting $t = \cos\varphi$, so that $dt = -\sin\varphi\, d\varphi$ and the limits $\varphi = 0, \pi$ become $t = 1, -1$,

$$\iint_S f\, dS = 2\pi\int_{-1}^{1} \sin\big(\pi(z_0 + t)\big)\, dt = 2\pi\left[\frac{-\cos\big(\pi(z_0 + t)\big)}{\pi}\right]_{t=-1}^{t=1} = 2\big(\cos(\pi z_0 - \pi) - \cos(\pi z_0 + \pi)\big).$$

Both $\cos(\pi z_0 - \pi)$ and $\cos(\pi z_0 + \pi)$ equal $-\cos(\pi z_0)$, so the bracket is 0. Therefore

$$\iint_S f\, dS = 0$$

for every sphere S of radius 1, while $f \not\equiv 0$. The answer is no.

Remark 7.4.1. Nothing above is special to $\sin(\pi z)$ beyond two features: the integral over $t \in [-1, 1]$ of $g(z_0 + t)$ must vanish for every z_0, and $\sin(\pi t)$ has period 2 with mean zero over a period. In fact, writing G for an antiderivative of a continuous g, the condition $\int_{-1}^{1} g(z_0 + t)\, dt = 0$ for all z_0 says $G(z_0 + 1) = G(z_0 - 1)$ for all z_0, that is, G has period 2. So $f(x, y, z) = g(z)$ satisfies the hypothesis precisely when g is continuous, has period 2, and has mean zero over a period. That is an infinite dimensional kernel, not a lone counterexample.

Layer 1: WHAT

Block 1. Read "radius 1" as a deliberate restriction; check what happens if the radius is allowed to vary; conclude the answer is no and switch from proving to constructing.

Block 2. Use the translation and rotation invariance of the hypothesis to cut the search down: look for $f(x, y, z) = g(z)$, constant on planes perpendicular to one axis.

Block 3. Compute the surface measure on the unit sphere in spherical coordinates, $dS = \sin\varphi \, d\varphi \, d\theta$, and substitute $t = \cos\varphi$. The $\sin\varphi$ from the Jacobian is exactly the dt; that is Archimedes, and it is why this family is the cheap one.

Block 4. The condition becomes $\int_{-1}^{1} g(z_0 + t)\, dt = 0$ for every z_0, that is, every window of length 2 has zero integral.

Block 5. Solve that: an antiderivative of g has period 2. Pick the smallest example you can verify in one line, $g(t) = \sin(\pi t)$, and verify it.

The nominal route, the zombie route, is Block 1 misread: "for every sphere, the average is zero, so by the mean value property f is zero", followed by twenty minutes of trying to make a limit exist that does not exist, or by an attempt to expand f in spherical harmonics and prove injectivity coefficient by coefficient. The bifurcation point is the single sentence "what would change if the radius were free?". On the free radius side you get a proof; on the fixed radius side you get a counterexample. The problem is nothing but that sentence, and it is a sentence you must self-generate in the arena.

Layer 2: HOW

Block 1. Cue. The words "of radius 1", where the natural phrasing would have been "of every radius". **Why natural.** Restrictions in a "Must ...?" question are never decoration. Test the restriction by removing it: with all radii available, shrinking to a point recovers $f(c)$ by continuity, so the answer would be yes and the problem would be a warm up, not an A4. The setter therefore removed the only tool that would have worked, which tells you the answer is no. **Link to the next block.** Having decided to construct rather than prove, the next question is where to look, and the answer is dictated by the symmetry of the hypothesis.

Block 2. Cue. The hypothesis is stated for *every* sphere of radius 1, so it is invariant under all translations and rotations. **Why natural.** A condition invariant under a big group is cheapest to test on functions with a lot of symmetry of their own, because then the integral collapses. The most economical choice is a function of one coordinate: it is constant on each plane $z = \text{const}$, and a sphere meets that family of planes in a way you can integrate in closed form. Radial functions look more symmetric but produce a harder integral equation, because the intersection of a sphere with a sphere depends on two lengths rather than one. **Link to the next block.** Now you owe a computation of the surface measure.

Block 3. Cue. A surface integral over a parametrised surface: you need the Jacobian, and for a sphere it is standard. **Why natural.** On the unit sphere, $dS = \sin\varphi \, d\varphi \, d\theta$, and the substitution $t = \cos\varphi$ turns $\sin\varphi \, d\varphi$ into dt exactly. Geometrically this is Archimedes' theorem: the zone of a sphere of radius R cut off between two parallel planes at distance h apart has area $2\pi Rh$, independent of where the planes sit. In other words, the surface measure of the unit sphere pushes forward, under the height map, to 2π times Lebesgue measure on $[-1, 1]$. That is why a function of one coordinate is the family that makes the problem one dimensional with no distortion. **Link to the next block.** With the surface integral reduced, the hypothesis is now a statement about a function of one real variable.

Block 4. Cue. $\int_{-1}^{1} g(z_0 + t)\,dt = 0$ for every z_0: a sliding window with fixed width and zero integral. **Why natural.** Fixed width plus zero integral is a shift equation in disguise. Write G for an antiderivative; the condition is $G(z_0 + 1) = G(z_0 - 1)$, that is, $G(z + 2) = G(z)$. You have converted an integral condition into a periodicity condition, which has an explicit general solution rather than an estimate. **Link to the next block.** Choosing a periodic G with a continuous derivative is now a matter of writing down a sine.

Block 5. Cue. You need one example, and it must be verifiable in three lines by a grader. **Why natural.** $G(z) = -\cos(\pi z)/\pi$ has period 2, so $g = G' = \sin(\pi z)$ works. Do not present the general kernel as the answer; present the single function, verify it completely, and put the general description in a remark. A verified example scores; a described family with a half verification does not.

Layer 3: WHY

The mathematical truth underneath is one sentence: the fixed radius spherical mean is a convolution, and a convolution is injective exactly when its symbol has no real zeros. Precisely, let σ be the normalised surface measure on the unit sphere in $\mathbb{R}^3$ and let $(Mf)(c) = \int f(c + v)\,d\sigma(v)$. This is $f * \check{\sigma}$, so it commutes with translations, so it is diagonalised by the characters $v \mapsto e^{i\xi\cdot v}$. Feeding one in and taking $\xi = (0, 0, \rho)$ without loss of generality by rotational symmetry,

$$M\big(e^{i\xi\cdot v}\big)(c) = e^{i\xi\cdot c} \cdot \frac{1}{2}\int_{-1}^{1} e^{i\rho t}\,dt = e^{i\xi\cdot c}\,\frac{\sin\rho}{\rho},$$

using the same Archimedes pushforward as above. The symbol is $\operatorname{sinc}\rho = \sin\rho/\rho$, and it vanishes at $\rho = \pi, 2\pi, 3\pi, \ldots$. The operator therefore has an enormous kernel, and every element of it is built from frequencies of length exactly $k\pi$. Our $\sin(\pi z)$ is the imaginary part of the $\xi = (0, 0, \pi)$ character. There was no guessing.

The discernment mechanism, the thing you actually train, is this. Whenever a problem says "the average of f over every translate of a fixed shape is zero", you are being asked whether a specific Fourier multiplier has a real zero. Compute the multiplier, which is the Fourier transform of the shape. If it has a real zero, the answer is no and the counterexample is the corresponding plane wave, restricted to real values by taking a real or imaginary part. If it has none, the answer is yes and you must supply an inversion argument. The setter's nudge is the fixed size: fixed size means one value of the symbol's argument, and one value can easily be a zero, whereas all sizes at once means the whole symbol must vanish identically, which forces $f = 0$.

To train it, build a small table and know it cold: in $\mathbb{R}^3$ the unit sphere has symbol $\sin\rho/\rho$ with zeros at multiples of π; the unit ball has symbol proportional to $(\sin\rho - \rho\cos\rho)/\rho^3$ with zeros at the solutions of $\tan\rho = \rho$; in $\mathbb{R}$ the interval $[-1, 1]$ has symbol $\sin\rho/\rho$ again. In $\mathbb{R}^n$ the sphere's symbol is a Bessel function of order $\frac{n}{2} - 1$, which has infinitely many positive zeros for every n, so the answer to this problem is no in every dimension. Knowing that the answer is dimension independent is what lets you commit to "no" in the first thirty seconds without any computation at all.

Revolving concepts

Spherical mean. For f continuous on $\mathbb{R}^n$ and $r > 0$, the spherical mean is $(M_r f)(c) = \frac{1}{|S^{n-1}|}\int_{S^{n-1}} f(c + r\omega)\,d\omega$. Orbiting facts: $M_r f \to f$ uniformly on compacts as $r \to 0^+$ when f is continuous, which is the source of the "yes" answer when all radii are allowed; M_r commutes with translations and rotations; $u(c, r) = (M_r f)(c)$ satisfies the Darboux equation, so spherical means are the natural language for the wave equation in odd dimensions. See Book 1, field: Real analysis, topic: spherical means.

Archimedes' hat box theorem. The area of the zone of a sphere of radius R between two parallel planes a distance h apart (both meeting the ball) is $2\pi Rh$. Equivalently, the radial projection from the sphere onto the circumscribed cylinder preserves area, because it stretches in one direction by $1/\sin\varphi$ and compresses in the other by $\sin\varphi$. In our computation this is the identity $dS = \sin\varphi\, d\varphi\, d\theta \mapsto d\theta\, dt$. See Book 1, field: Geometry, topic: surfaces of revolution.

Fourier transform of a measure, and the symbol. For a finite measure μ on $\mathbb{R}^n$, $\widehat{\mu}(\xi) = \int e^{-i\xi\cdot v} d\mu(v)$, and the operator $f \mapsto f * \mu$ acts on the character $e^{i\xi\cdot v}$ by multiplication by $\widehat{\mu}(-\xi)$. Injectivity on nice function spaces is controlled by the zero set of $\widehat{\mu}$. For the normalised surface measure on the unit sphere in $\mathbb{R}^3$, $\widehat{\sigma}(\xi) = \sin|\xi|/|\xi|$; in $\mathbb{R}^n$ it is $\Gamma(\frac{n}{2})(2/|\xi|)^{n/2-1} J_{n/2-1}(|\xi|)$. See Book 1, field: Real analysis, topic: Fourier multipliers.

The Pompeiu problem and the two radius theorem. The general question "for which sets K does $\int_{K+c} f = 0$ for all c force $f \equiv 0$?" is the Pompeiu problem; balls and spheres fail it, as here. Delsarte's two radius theorem says that if the means over spheres of two radii r_1 and r_2 both vanish, then $f \equiv 0$ unless r_1/r_2 is a ratio of two zeros of the relevant Bessel function. That is the precise statement of "one radius is not enough, but almost two are". See Book 1, field: Real analysis, topic: Pompeiu problem.

The recursion hiding in the problem, generalised. The reduced condition $G(z+2) = G(z)$ is a linear shift equation, the continuous analogue of a recursion with step 2. The general statement worth installing: the equation $G(z+T) = G(z) + c$ for all real z has general solution $G(z) = cz/T + \Pi(z)$ with Π arbitrary of period T, and the corresponding condition on $g = G'$ is that g is periodic of period T with mean c/T over a period. Every "the integral over every window of fixed width T equals c" hypothesis, in any problem, collapses to exactly this. The discrete twin is $u_{n+T} = u_n + c$, whose general solution is $u_n = cn/T$ plus a T periodic sequence. See Book 1, field: Functional equations, topic: shift equations and periodicity.

Circuit Bank

- **WHEN** a hypothesis says the average of an unknown function over every translate of a *fixed* shape vanishes **DO** compute the Fourier transform of that shape and look for real zeros; if there is one, the answer is "no" and the counterexample is the matching plane wave **BECAUSE** convolution operators are diagonalised by characters, so the kernel is exactly the frequencies at which the symbol vanishes

- **WHEN** a "Must f be identically zero?" question carries a restriction whose removal would make the answer an easy yes **DO** stop trying to prove it and start constructing a counterexample **BECAUSE** the restriction is where the setter put all the content, and the removed hypothesis is precisely the tool your first instinct wanted to use

- **WHEN** you must integrate a function of one coordinate over a sphere **DO** slice by planes perpendicular to that coordinate and use that the unit sphere's surface measure pushes forward to $2\pi\, dt$ on $[-1,1]$ **BECAUSE** Archimedes: the area of a spherical zone depends only on its height, so the Jacobian $\sin\varphi$ is exactly consumed by the substitution $t = \cos\varphi$

- **WHEN** you are searching for a counterexample and the hypothesis is invariant under a group **DO** restrict the search to functions with a matching partial symmetry, choosing the one that makes the integral one dimensional **BECAUSE** the constraint then becomes a solvable equation in one variable instead of an estimate in three

Backtesting

1. First useful cue: the radius is pinned at 1 instead of being quantified over all positive values.

2. Method the expression suggested: treat the hypothesis as "a fixed convolution operator kills f", so test characters, find the symbol $\sin\rho/\rho$, and take the frequency $\rho = \pi$; write it up as a slicing computation with $f = \sin(\pi z)$.
3. Where you would hesitate, and the thought to reinforce: the hesitation is at the start, wanting to believe that averaging over spheres determines a continuous function. Reinforce this: averaging at *all* scales determines it; averaging at *one* scale is a single Fourier multiplier and multipliers vanish somewhere all the time.
4. The trap the question sets: the phrase "must f be identically 0" invites you to spend the session proving a false statement, and the mean value property is the plausible looking tool that does not apply.
5. What makes you recognise it faster next time: the pattern "fixed size averaging" should now be a single unit in your head, tagged with the symbol table (sphere in $\mathbb{R}^3$: $\sin\rho/\rho$; ball in $\mathbb{R}^3$: $(\sin\rho - \rho\cos\rho)/\rho^3$; interval in $\mathbb{R}$: $\sin\rho/\rho$).
6. The reusable decision rule: when a hypothesis is a convolution against a fixed shape, the answer to "is f forced to be zero" is exactly "does the shape's Fourier transform avoid zero on the reals".

Mirror drills

1. Find a nonzero continuous f on $\mathbb{R}^3$ whose integral over every *ball* of radius 1 is 0. *Answer:* $f(x,y,z) = \cos(\rho z)$ where $\rho > 0$ satisfies $\tan\rho = \rho$ (the first such ρ is about 4.4934). Slicing gives $\int_{-1}^{1} \pi(1-t^2)\cos(\rho(z_0+t))\,dt$, the odd part vanishes, and $\int_{-1}^{1}(1-t^2)\cos(\rho t)\,dt = 4(\sin\rho - \rho\cos\rho)/\rho^3 = 0$.
2. Show that if the surface integral of a continuous f over every sphere of every radius vanishes, then $f \equiv 0$. *Answer:* the average over the sphere of radius r about c is 0 for all $r > 0$; by continuity of f at c it tends to $f(c)$ as $r \to 0^+$, so $f(c) = 0$.
3. Determine all continuous $g : \mathbb{R} \to \mathbb{R}$ with $\int_{x-1}^{x+1} g(t)\,dt = 0$ for every x. *Answer:* exactly the continuous g of period 2 with mean zero over a period; take an antiderivative G, note the condition is $G(x+1) = G(x-1)$, so G has period 2, hence so does $g = G'$, and $\int_0^2 g = G(2) - G(0) = 0$.

7.5 A5. Euler operator reads the vanishing order

Let p be an odd prime number, and let $\mathbb{F}_p$ denote the field of integers modulo p. Let $\mathbb{F}_p[x]$ be the ring of polynomials over $\mathbb{F}_p$, and let $q(x) \in \mathbb{F}_p[x]$ be given by

$$q(x) = \sum_{k=1}^{p-1} a_k x^k,$$

where

$$a_k = k^{(p-1)/2} \bmod p.$$

Find the greatest nonnegative integer n such that $(x-1)^n$ divides $q(x)$ in $\mathbb{F}_p[x]$.

Read it out loud

Read the structure, not the symbols. There is a polynomial over a finite field whose coefficient of x^k is a fixed power of the index k, and you are asked for the multiplicity of the root $x = 1$. Three fields are wired in: number theory (the exponent $(p-1)/2$ is Euler's criterion, so a_k is the Legendre symbol of k), polynomial algebra in characteristic p (the root 1, the formal derivative, the fact that $x^p - 1$ is a perfect pth power), and generating functions (a coefficient that is a function of the index is a signal, not a coincidence).

The first useful cue is the shape of the coefficient. When the coefficient of x^k is k^m, you are never looking at an arbitrary polynomial: you are looking at the Euler operator $D = x\frac{d}{dx}$ applied m times to something simpler, because D acts on the monomial basis diagonally, $D(x^k) = kx^k$. That is the entire content of "sum with k^m in front". Within thirty seconds you should have written

$$D = x\frac{d}{dx}, \qquad D^m\Big(\sum_k c_k x^k\Big) = \sum_k k^m c_k x^k,$$

and then asked which simple polynomial has all coefficients equal to 1 for $k = 0, \ldots, p-1$. The answer is $s(x) = 1 + x + \cdots + x^{p-1}$, so $q = D^{(p-1)/2}s$, with the $k = 0$ term dying because $0^{(p-1)/2} = 0$.

The second cue is the modulus you are asked about: $(x-1)^n$. In $\mathbb{F}_p[x]$ the polynomial $x^p - 1$ is not a product of p distinct cyclotomic factors, it is $(x-1)^p$, because the Frobenius map makes $(x-1)^p = x^p - 1$. So $s(x) = (x^p - 1)/(x-1) = (x-1)^{p-1}$, and the object you are differentiating is already a pure power of exactly the quantity the question is asking about. That is not luck; the question was designed around it.

So the problem is: start at $(x-1)^{p-1}$, apply D a total of $(p-1)/2$ times, and track the order of vanishing at 1. If each application of D costs exactly one factor of $(x-1)$, the answer is $p - 1 - \frac{p-1}{2} = \frac{p-1}{2}$. Verify that on the smallest case before you commit: for $p = 3$, $q = x + 2x^2 = 2x(x-1)$, so $n = 1$; for $p = 5$, $q = x + 4x^2 + 4x^3 + x^4$, and $q(1) = 0$, $q'(1) = 0$, $q''(1) = 4 \neq 0$, so $n = 2$. Both match $(p-1)/2$.

Approaches, ranked worst to best

1. **Compute small cases and guess.** *Cue:* "find the greatest nonnegative integer n" wants a formula in p. *Circuit:* tabulate, guess, then prove. As a solution this is worth nothing, because a Putnam grader pays for the proof and not the pattern. As reconnaissance it is compulsory: two minutes on $p = 3, 5, 7$ fixes the target $(p-1)/2$ and stops you from proving the wrong thing. Rank it last as a solution, first as a habit.

2. **Split into quadratic residues and nonresidues.** *Cue:* a_k is the Legendre symbol by Euler's criterion. *Circuit:* when you see a Legendre symbol, reach for Gauss sums and character

theory. You would write $q(x) = \sum_{\text{QR}} x^k - \sum_{\text{NQR}} x^k$ and then try to evaluate its behaviour near $x = 1$. Gauss sums live in $\mathbb{Z}[\zeta_p]$ or in an extension of $\mathbb{F}_p$, and they compute values at roots of unity, not orders of vanishing at 1. In $\mathbb{F}_p$ all pth roots of unity have already collapsed to 1, so the entire machinery you are reaching for has degenerated. It stalls, and expensively.

3. **Substitute $x = 1 + y$ and expand blindly.** *Cue:* "divides by $(x-1)^n$" means "lowest surviving power of y". *Circuit:* translate the root to the origin so that divisibility becomes a statement about low order coefficients. Correct instinct, correct first move, but if you expand $(1+y)^k$ and stare at $\sum_k a_k \binom{k}{j}$ without a tool for evaluating power sums modulo p, you stall. Costs a page of binomial identities.

4. **Substitute $x = 1 + y$ and finish with the power sum lemma.** *Cue:* the same cue, plus the sum $\sum_{k=1}^{p-1} k^t$ appearing after you expand $\binom{k}{j}$ as a polynomial in k. *Circuit:* reduce every coefficient to power sums modulo p, which are all known. This is a complete and honest solution. The coefficient of y^j is $\sum_{k=1}^{p-1} a_k \binom{k}{j}$; since $\binom{k}{j}$ is a polynomial in k of degree j with leading coefficient $1/j!$ (invertible for $j \le p-1$), that coefficient is a combination of $S_t = \sum_{k=1}^{p-1} k^t$ for $t = \frac{p-1}{2}, \dots, \frac{p-1}{2} + j$. Since $S_t = -1$ when $(p-1) \mid t$ and 0 otherwise, everything vanishes until $j = \frac{p-1}{2}$, where the leading term contributes $S_{p-1}/j! = -1/j! \neq 0$. It works. It just costs three times the ink of the next route.

5. **Euler operator on the collapsed cyclotomic polynomial.** *Cue:* the coefficient is $k^{(p-1)/2}$, a power of the index, and the modulus is a power of $(x-1)$. *Circuit:* coefficients depending on the index means an operator applied to a simpler series; divisibility by $(x-1)^n$ in characteristic p means use Frobenius to rewrite everything as powers of $(x-1)$. Identify $q = D^{(p-1)/2} s$ with $s = (x-1)^{p-1}$, prove one short lemma saying D lowers the order of vanishing at 1 by exactly one, and iterate. Shortest, and it explains why the answer is $(p-1)/2$ rather than merely confirming it. This is the write up.

The ideal solution

The answer is $\boxed{n = \dfrac{p-1}{2}}$.

Throughout, D denotes the Euler operator $Du = xu'$ on $\mathbb{F}_p[x]$, where u' is the formal derivative. For a nonzero $u \in \mathbb{F}_p[x]$ write $\operatorname{ord}(u)$ for the largest n with $(x-1)^n \mid u$.

Lemma 7.5.1. *Let $u \in \mathbb{F}_p[x]$ be nonzero with $\operatorname{ord}(u) = n$, and suppose $1 \le n \le p-1$. Then $Du \neq 0$ and $\operatorname{ord}(Du) = n - 1$.*

Proof. Write $u = (x-1)^n v$ with $v \in \mathbb{F}_p[x]$ and $v(1) \neq 0$. The product rule holds for formal derivatives over any commutative ring, so

$$u' = n(x-1)^{n-1} v + (x-1)^n v', \qquad Du = xu' = (x-1)^{n-1} \big[\, n\, x\, v(x) + x(x-1) v'(x) \,\big].$$

Call the bracket $w(x)$. Then $w(1) = n\, v(1)$. Since $1 \le n \le p-1$, the residue n is nonzero in $\mathbb{F}_p$, and $v(1) \neq 0$, so $w(1) \neq 0$. Hence $Du = (x-1)^{n-1} w$ with $w(1) \neq 0$, which is exactly the statement that Du is nonzero of order $n-1$. □

Lemma 7.5.2. *In $\mathbb{F}_p[x]$, $s(x) := 1 + x + \cdots + x^{p-1} = (x-1)^{p-1}$.*

Proof. The Frobenius endomorphism of $\mathbb{F}_p[x]$ gives $(x-1)^p = x^p + (-1)^p = x^p - 1$, using that p is odd. Also $(x-1)s(x) = x^p - 1$ by telescoping. Therefore $(x-1)s(x) = (x-1)^p$, and since $\mathbb{F}_p[x]$ is an integral domain and $x - 1 \neq 0$, we may cancel to get $s(x) = (x-1)^{p-1}$. □

Now identify q. Since $D(x^k) = kx^k$, we have $D^m(x^k) = k^m x^k$ for every $m \geq 0$, and therefore

$$D^m s(x) = \sum_{k=0}^{p-1} k^m x^k.$$

Take $m = \frac{p-1}{2}$, which is at least 1 because p is an odd prime. The $k = 0$ term is $0^{(p-1)/2} = 0$, so it drops out and

$$D^{(p-1)/2} s(x) = \sum_{k=1}^{p-1} k^{(p-1)/2} x^k = q(x).$$

Finally, iterate the first lemma along the chain $s,\ Ds,\ D^2 s,\ \ldots,\ D^{(p-1)/2} s$. By the second lemma $\operatorname{ord}(s) = p - 1$. Suppose that for some j with $0 \leq j \leq \frac{p-1}{2} - 1$ we have $\operatorname{ord}(D^j s) = p - 1 - j$. Then

$$\frac{p-1}{2} + 1 \ \leq\ p - 1 - j \ \leq\ p - 1,$$

so the order lies in the range $1 \leq n \leq p - 1$ required by the first lemma, which therefore applies and gives $\operatorname{ord}(D^{j+1} s) = p - 2 - j$. By induction on j,

$$\operatorname{ord}\big(D^{(p-1)/2} s\big) = p - 1 - \frac{p-1}{2} = \frac{p-1}{2}.$$

That is, $\operatorname{ord}(q) = \frac{p-1}{2}$: the polynomial $(x-1)^{(p-1)/2}$ divides q, and $(x-1)^{(p-1)/2+1}$ does not. Note that the chain also shows $q \neq 0$, so the order is well defined.

Remark 7.5.3. The hypothesis $1 \leq n \leq p - 1$ in the first lemma is not decoration. If $p \mid n$ the conclusion is false: $u = (x-1)^p = x^p - 1$ has $u' = px^{p-1} = 0$, so $Du = 0$ and the order jumps to infinity rather than dropping by one. This is the standard failure of the derivative test for multiple roots in characteristic p, and it is exactly why the chain above was checked to stay inside the range 1 to $p - 1$ at every step.

Layer 1: WHAT

Block 1. Recognise $a_k = k^{(p-1)/2}$ as the Legendre symbol by Euler's criterion, note $a_k = \pm 1$ for every k in range, and do the two minute reconnaissance on $p = 3$ and $p = 5$ to fix the target answer $(p-1)/2$.

Block 2. Read the coefficient shape: coefficient $= k^m$ means $q = D^m$(something with all coefficients 1), with $D = x\frac{d}{dx}$.

Block 3. Simplify the something: $s = 1 + x + \cdots + x^{p-1} = (x-1)^{p-1}$ in $\mathbb{F}_p[x]$, by Frobenius. Now both the object and the question are expressed in powers of $(x-1)$.

Block 4. Prove the single lemma that carries all the weight: D lowers the order of vanishing at 1 by exactly one, provided the current order is between 1 and $p - 1$.

Block 5. Iterate $(p-1)/2$ times, checking at each step that the order stays in range, and read off $(p-1)/2$.

The nominal route splits from the ideal route at Block 2. The zombie reads $k^{(p-1)/2}$ as an arithmetic object, says "Legendre symbol", and reaches for quadratic residues, Gauss sums, and character sums. The ideal route reads $k^{(p-1)/2}$ as an *operator eigenvalue* and reaches for a generating function. That is the bifurcation point, and it is worth naming precisely: the question is not asking anything about which k are squares, it is asking about the $(x-1)$ adic order of a polynomial. The arithmetic content of a_k is a decoy; only the fact that a_k is a power of k matters.

Layer 2: HOW

Block 1. **Cue.** The exponent $(p-1)/2$ attached to k modulo an odd prime. **Why natural.** Euler's criterion is atomic: $k^{(p-1)/2} \equiv \pm 1$ according to whether k is a quadratic residue. Recognising it tells you the coefficients are units, hence $\deg q = p-1$ exactly and $q \neq 0$, which you need before you can speak of an order of vanishing at all. It also tells you $q(1) = \sum_k a_k = 0$, since there are equally many residues and nonresidues, so $n \geq 1$ before you have done any work. **Link to the next block.** You now know the answer is at least 1 and you have small cases; the question is what structure produces the exact value.

Block 2. **Cue.** The coefficient of x^k is a function of k alone, namely a power of k. **Why natural.** This is the generating function circuit in its purest form. On monomials, $x\frac{d}{dx}$ is diagonal with eigenvalue k, so multiplying the kth coefficient by k is not a manipulation of the coefficients at all, it is the application of a single operator to the whole polynomial. Whenever the coefficient is $P(k)$ for a polynomial P, the series is $P(D)$ applied to the plain series. Formally, this is the same circuit as evaluating $\sum k^2 z^k$ by differentiating the geometric series twice and multiplying by z each time; the only new content is that it is legal over $\mathbb{F}_p$ because the formal derivative is defined over any ring. **Link to the next block.** The operator has isolated a simpler polynomial, namely the all ones polynomial of degree $p-1$; simplify it next.

Block 3. **Cue.** A sum of all powers x^0 to x^{p-1} over $\mathbb{F}_p$, and a question about divisibility by $(x-1)^n$. **Why natural.** Two facts collide productively. First, $(x-1)s(x) = x^p - 1$ by telescoping. Second, in characteristic p the Frobenius map is a ring homomorphism, so $(x-1)^p = x^p - 1$. Hence $s = (x-1)^{p-1}$. The structural reading: over $\mathbb{Q}$ the polynomial $x^p - 1$ has p distinct roots and s is the irreducible pth cyclotomic polynomial, but over $\mathbb{F}_p$ all p roots of unity have collapsed onto the single point 1, so s is totally degenerate there. Any question about $\sum_k c_k x^k$ modulo powers of $(x-1)$ in $\mathbb{F}_p[x]$ is therefore a question about a single filtration, and every tool that separates roots of unity is useless. **Link to the next block.** Everything is now a power of $(x-1)$ acted on by D; you need to know what D does to that power.

Block 4. **Cue.** You are applying one operator repeatedly to an object measured by one integer, the order of vanishing. **Why natural.** The natural thing to compute is the effect of one application on that integer. Write $u = (x-1)^n v$ with $v(1) \neq 0$, apply the product rule, and factor out $(x-1)^{n-1}$: the leftover evaluated at 1 is $n\,v(1)$. It is nonzero precisely when n is invertible modulo p. This is the honest statement of the derivative test for multiplicity in characteristic p, and the caveat is real, not pedantic: $x^p - 1$ has zero derivative. **Link to the next block.** One step is now understood; the chain is an induction, and all that remains is checking the hypothesis holds at every step.

Block 5. **Cue.** A repeated application with a side condition means an induction with a range check. **Why natural.** Starting at order $p-1$ and dropping by one each time, the orders visited are $p-1, p-2, \ldots, \frac{p-1}{2}$, all strictly between 0 and p, so the lemma's hypothesis holds at every step. Do not skip the range check in the write up: it is the only place the argument could break, and a grader looking for the characteristic p subtlety will look exactly there.

Layer 3: WHY

Two mathematical truths make this route the ideal one.

The first is that in $\mathbb{F}_p[x]$ the ideal $(x-1)$ carries a discrete valuation, the order of vanishing at 1, and everything relevant in this problem is a statement in that valuation. Frobenius says $x^p - 1 = (x-1)^p$, so the all ones polynomial, the object that is spiritually "sum over the pth roots of unity", is a pure power of the uniformiser. In other words the arithmetic of pth roots of unity, which

over $\mathbb{Q}$ is a rich cyclotomic story, has degenerated in characteristic p to a single ramified point. Once you know that, the choice of tool is forced: use the valuation, not the roots.

The second is that $D = x\frac{d}{dx}$ is the operator whose eigenbasis is the monomials, with eigenvalue equal to the exponent. This makes D the exact translation between two languages: "do arithmetic to the index k" and "apply an operator to the polynomial". The coefficient sequence $k \mapsto k^{(p-1)/2}$ was constructed by the setter to be an eigenvalue sequence, which is precisely why the problem has a clean answer. The interaction between the two truths is the lemma: D is a derivation multiplied by x, and x is a unit at the point $x = 1$, so D shifts the valuation down by exactly one, with the single degeneracy at orders divisible by p.

The discernment mechanism is a two question filter you should run on any problem of this shape. Question one: does the coefficient of x^k depend on k through a polynomial or an exponential? If yes, write the series as an operator applied to a simpler series ($P(D)$ for polynomial dependence, a substitution $x \mapsto \lambda x$ for exponential dependence). Question two: does the question ask about divisibility by a power of a linear factor? If yes, rewrite every object as a power of that linear factor first, using Frobenius if you are in characteristic p. If both answers are yes, the solution is the composition, and it is short. Here both are yes, which is why the ideal solution fits on half a page.

To train the discernment, do the reverse exercise. Take the answer $(p-1)/2$ and ask what the setter had to do to build a problem with that answer. They needed an object of known order $p-1$ (the collapsed cyclotomic polynomial), an operator that peels off exactly one order per application (D), and a number of applications equal to $(p-1)/2$ (the Euler criterion exponent, which also disguises the operator as arithmetic). Reading a problem backwards from its construction is how you learn to see the construction forwards, in the arena, under time.

Revolving concepts

Euler's criterion and the Legendre symbol. For odd prime p and k not divisible by p, $k^{(p-1)/2} \equiv \left(\frac{k}{p}\right) \pmod p$, which is $+1$ if k is a nonzero quadratic residue and -1 otherwise. Orbiting facts: the residues form the index two subgroup of $\mathbb{F}_p^\times$, so there are exactly $(p-1)/2$ of each and the sum of all Legendre symbols is 0; the symbol is completely multiplicative. See Book 1, field: Number theory, topic: quadratic residues.

Frobenius and the freshman's dream. In any commutative ring of characteristic p, the map $a \mapsto a^p$ is a ring homomorphism, so $(a+b)^p = a^p + b^p$. Consequences used here: $(x-1)^p = x^p - 1$ for odd p, and more generally $x^{p^e} - c^{p^e} = (x-c)^{p^e}$. See Book 1, field: Abstract algebra, topic: characteristic p and Frobenius.

Formal derivative and multiplicity in characteristic p. The formal derivative is defined over any commutative ring and satisfies linearity and the product rule. Over a field of characteristic 0, c is a root of u of multiplicity exactly n if and only if $u(c) = \cdots = u^{(n-1)}(c) = 0 \neq u^{(n)}(c)$. In characteristic p this equivalence survives only for $n \leq p-1$, because $u^{(n)}$ carries a factor $n!$; the standard counterexample is $x^p - 1$, whose derivative is identically zero. See Book 1, field: Polynomials, topic: repeated roots and the derivative test.

Order of vanishing as a valuation. For a field K and $c \in K$, ord_c on $K[x]$ satisfies $\mathrm{ord}_c(uv) = \mathrm{ord}_c(u) + \mathrm{ord}_c(v)$ and $\mathrm{ord}_c(u+v) \geq \min$. Divisibility questions by $(x-c)^n$ are valuation questions, and the right move is always to find one operation whose effect on the valuation you can compute exactly. See Book 1, field: Polynomials, topic: valuations and factorisation.

Power sums modulo p. For $t \geq 0$, $\sum_{k=1}^{p-1} k^t \equiv -1 \pmod p$ if $(p-1) \mid t$, and $\equiv 0$ otherwise. Proof: let g be a primitive root, so the sum is the geometric series $\sum_{i=0}^{p-2}(g^t)^i$; if $g^t = 1$ each term is 1 and the sum is $p-1$, otherwise the series sums to $(g^{t(p-1)} - 1)/(g^t - 1) = 0$. This is the engine of the alternative solution and appears constantly in finite field problems. See Book 1, field: Number theory, topic: power sums and primitive roots.

The Euler operator, and the recursion generalised. $D = x\frac{d}{dx}$ satisfies $D(x^k) = kx^k$, hence

$P(D)\sum_k c_k x^k = \sum_k P(k)c_k x^k$ for any polynomial P. Over $\mathbb{R}$ this is how you evaluate $\sum_k k^2 z^k$ from the geometric series. The recursion in this problem is the sequence of orders $n_j = \operatorname{ord}(D^j s)$, which satisfies the linear recursion $n_{j+1} = n_j - 1$ with $n_0 = p-1$, valid exactly while $p \nmid n_j$. Its solution is $n_j = p - 1 - j$. The general form worth installing: if an operator T shifts a valuation by a fixed amount d away from a set of degenerate values Δ, then $\operatorname{ord}(T^j u) = \operatorname{ord}(u) + jd$ for as long as the trajectory avoids Δ, and the entire proof is the induction that checks that avoidance. The same pattern governs orders of vanishing under repeated differentiation, degrees under repeated multiplication, and p adic valuations under repeated division. See Book 1, field: Generating functions, topic: operator calculus on power series.

Circuit Bank

- **WHEN** the coefficient of x^k is $P(k)$ for some polynomial P (here $k^{(p-1)/2}$) **DO** write the series as $P(D)$ applied to the plain series, where $D = x\frac{d}{dx}$ **BECAUSE** D is diagonal on monomials with eigenvalue k, so index arithmetic and operator application are the same thing
- **WHEN** you are in $\mathbb{F}_p[x]$ and the question concerns divisibility by a power of $(x-c)$ **DO** rewrite every object as a power of $(x-c)$ first, using $x^p - c^p = (x-c)^p$ **BECAUSE** Frobenius collapses the pth roots of unity onto one point, so the whole problem lives in a single valuation and no root separating tool can help
- **WHEN** you want to use "least m with the mth derivative nonzero" to find a multiplicity in characteristic p **DO** first check the multiplicity is at most $p-1$, and state that check in the write up **BECAUSE** the mth derivative carries a factor $m!$, which vanishes for $m \geq p$; $x^p - 1$ has zero derivative and infinite apparent order
- **WHEN** a sum $\sum_{k=1}^{p-1} k^t$ appears modulo p **DO** replace it by -1 if $(p-1) \mid t$ and by 0 otherwise **BECAUSE** multiplying the sum by g^t for a primitive root g permutes the terms, so the sum is fixed by multiplication by g^t and must vanish unless $g^t = 1$

Backtesting

1. First useful cue: the coefficient of x^k is a power of the index k, which is the signature of the Euler operator $D = x\frac{d}{dx}$.
2. Method the expression suggested: write $q = D^{(p-1)/2}s$ with $s = 1 + x + \cdots + x^{p-1}$, collapse s to $(x-1)^{p-1}$ by Frobenius, and track the order of vanishing under each application of D.
3. Where you would hesitate, and the thought to reinforce: the hesitation is at "is the derivative test even legal here?". Reinforce the exact statement: in characteristic p, one application of D drops the order by one if and only if the current order is not divisible by p, and here the orders run from $p-1$ down to $(p-1)/2$, all safely in range.
4. The trap the question sets: dressing the coefficient as a Legendre symbol so that you spend the session on quadratic residues and Gauss sums. The arithmetic meaning of a_k is never used; only the fact that it is k raised to a power.
5. What makes you recognise it faster next time: pair the two cues as one unit. "Coefficient is a power of the index" plus "divisibility by a power of $(x-1)$ over $\mathbb{F}_p$" equals "apply D^m to $(x-1)^{p-1}$ and count".
6. The reusable decision rule: to find how many times a linear factor divides a polynomial built by an operator, compute the operator's effect on the order of vanishing once, then iterate with a range check.

Mirror drills

1. In $\mathbb{F}_p[x]$, find the greatest n with $(x-1)^n$ dividing $\sum_{k=1}^{p-1} kx^k$. *Answer:* $n = p-2$. That polynomial is $Ds = x\big((x-1)^{p-1}\big)' = (p-1)x(x-1)^{p-2}$, and $p-1 \neq 0$ in $\mathbb{F}_p$.
2. Show that the test "c is a repeated root of u if and only if $u(c) = u'(c) = 0$" can fail in $\mathbb{F}_p[x]$, and say exactly which direction fails. *Answer:* the direction that detects multiplicity fails only through degeneracy of the derivative: $u = x^p - 1$ has $u' = px^{p-1} = 0$, so u' vanishes everywhere and gives no information; here $u = (x-1)^p$ really does have a repeated root, but the same computation would say nothing for a polynomial such as $x^p - x$ whose roots are all simple.
3. Prove that $\sum_{k=1}^{p-1} k^t \equiv -1 \pmod{p}$ when $(p-1) \mid t$ and $\equiv 0$ otherwise. *Answer:* let g be a primitive root modulo p; the sum equals $\sum_{i=0}^{p-2} (g^t)^i$, which is $p-1 \equiv -1$ if $g^t = 1$, and otherwise is $\big((g^t)^{p-1} - 1\big)/(g^t - 1) = 0$ by Fermat.

7.6 A6. Taylor windows and Landau's interpolation inequality

Let g be a real-valued function that is continuous on the closed interval $[0,1]$ and twice differentiable on the open interval $(0,1)$. Suppose that for some real number $r > 1$,

$$\lim_{x\to 0^+} \frac{g(x)}{x^r} = 0.$$

Prove that either

$$\lim_{x\to 0^+} g'(x) = 0 \qquad \textit{or} \qquad \limsup_{x\to 0^+} x^r |g''(x)| = \infty.$$

Read it out loud

Read the logical shape first, because it dictates everything. The conclusion is a disjunction, "P or Q". You never prove a disjunction by choosing a side; you prove it by assuming the negation of one alternative and deriving the other. Which one do you negate? The one whose negation is a usable object. Negating P gives you a sequence along which g' stays away from 0, which is weak. Negating Q gives you an inequality: $\limsup_{x\to 0^+} x^r|g''(x)| < \infty$ means there are $M > 0$ and $\delta_0 > 0$ with

$$|g''(x)| \le Mx^{-r} \quad \text{for all } x \in (0, \delta_0).$$

That is a hard quantitative bound, and it is the only quantitative object the problem is willing to hand you. So the shape of the work is fixed within the first minute: assume the curvature bound, prove $g' \to 0$.

Now read the analytic content. You are given control of g near 0 (it is $o(x^r)$), you have just assumed control of g'' near 0 (it is $O(x^{-r})$), and you must control g'. A hypothesis on a function and on its second derivative, with the conclusion about the first derivative, is the exact signature of an *interpolation inequality*. The relevant one is Landau's: on a half line, $\|f'\|_\infty^2 \le 4\|f\|_\infty\|f''\|_\infty$. The first derivative is always controlled by the geometric mean of size and curvature, for a reason you can state in one sentence: if f' is large at a point and f'' is bounded, then f' stays large over a whole window, so f must move a lot over that window, and a large movement contradicts f being small.

The third thing to read is the exponent. The same r appears in both hypotheses: g is small like x^r, and g'' is allowed to blow up like x^{-r}. Their product is $x^r \cdot x^{-r} = 1$: scale free. That is not decoration, it is the design of the problem. Since Landau's bound is the geometric mean $\sqrt{\|f\|\,\|f''\|}$, the geometric mean of εx^r and Mx^{-r} is $\sqrt{\varepsilon M}$, with the x dependence cancelling exactly. So the final bound on $|g'(x)|$ will be independent of x and proportional to $\sqrt{\varepsilon}$, and since ε is arbitrary that is precisely the statement $g' \to 0$. Within thirty seconds of reading, you should have written down "negate the limsup", "$|g''| \le Mx^{-r}$", and "Landau: $|g'| \lesssim \sqrt{\varepsilon M}$, scale free".

What remains is the one genuinely technical decision: over which window do you run Taylor's theorem? That is where the hypothesis $r > 1$ lives, and it is the only place it is used.

Approaches, ranked worst to best

1. **Prove the first alternative from the hypothesis alone.** *Cue:* $\lim g(x)/x^r = 0$ looks strong, so surely g' must be small too. *Circuit:* differentiate an asymptotic estimate. This is false and you must know it is false before you start, or you will burn the session. Take $g(x) = x^{r+1}\sin(x^{-N})$ with $N > r$, extended by $g(0) = 0$. Then $g(x)/x^r = x\sin(x^{-N}) \to 0$, but $g'(x) = (r+1)x^r\sin(x^{-N}) - Nx^{r-N}\cos(x^{-N})$, which is unbounded near 0. Asymptotic control of a function never transfers to its derivative without curvature control. Ranked worst.

2. **Prove the two alternatives are mutually exclusive.** *Cue:* the word "either ... or" reads as exclusive in ordinary English. *Circuit:* case analysis. Also false, and cheap to test. With

$g(x) = x^5 \sin(x^{-3})$ and $r = 2$ both alternatives hold simultaneously. Two minutes spent checking that costs nothing; twenty minutes spent trying to prove exclusivity costs the problem.

3. **Mean value theorem on the dyadic window $[x, 2x]$.** *Cue:* you need to connect g, g' and g'', and $[x, 2x]$ is the standard window near a singularity. *Circuit:* compare a derivative at a point with a difference quotient, then correct using the second derivative. The mean value theorem gives $\xi \in (x, 2x)$ with $|g'(\xi)| \le (2^r + 1)\varepsilon x^{r-1}$, which does tend to 0 since $r > 1$. But transporting that bound from ξ to x costs $\int_x^{2x} |g''| \le Mx^{-r} \cdot x = Mx^{1-r}$, which blows up. The route fails, and the failure is diagnostic: the window is too long by a factor of x^{r-1}. Ranked here because the idea is right and only the scale is wrong; fixing the scale is the whole solution.

4. **Contradiction with a sequence and a fixed window.** *Cue:* negating both alternatives gives a sequence $x_n \to 0$ with $|g'(x_n)| > \varepsilon_0$, and a bound on g''. *Circuit:* double negation, then quantitative contradiction. Assume both alternatives fail. On the window $[x_n, x_n + \varepsilon_0 x_n^r/(2M)]$ the curvature bound keeps $|g'| > \varepsilon_0/2$, so by the mean value theorem g moves by more than $\varepsilon_0^2 x_n^r/(4M)$, while the hypothesis says g is at most $\varepsilon(2^r + 1)x_n^r$ in size there. Letting $\varepsilon \to 0$ contradicts $\varepsilon_0 > 0$. This is complete and correct. It costs more ink than it needs to, because of the sequence bookkeeping and the two layers of negation.

5. **Taylor on a window of unspecified length, then optimise.** *Cue:* g and g'' controlled, g' wanted: interpolation. *Circuit:* leave the window length ℓ as a free parameter, bound $|g'(x)| \le A/\ell + B\ell/2$, and minimise over ℓ. Direct, quantitative, no contradiction, and it produces an explicit bound $|g'(x)| \le \sqrt{2(2^r + 1)M\varepsilon}$ valid for all small x. It is Landau's inequality localised at the point x. Shortest and clearest; this is the write up.

The ideal solution

Since the conclusion is a disjunction, it suffices to prove that if the second alternative fails then the first holds. So assume

$$\limsup_{x \to 0^+} x^r |g''(x)| < \infty.$$

By the definition of lim sup there exist a constant $M > 0$ and a $\delta_0 \in (0, 1)$ such that

$$|g''(x)| \le Mx^{-r} \qquad \text{for all } x \in (0, \delta_0). \tag{1}$$

We prove that $\lim_{x \to 0^+} g'(x) = 0$.

Let $\varepsilon > 0$ be arbitrary. Since $g(x)/x^r \to 0$ as $x \to 0^+$, there is $\delta_1 \in (0, \delta_0)$ with

$$|g(x)| \le \varepsilon x^r \qquad \text{for all } x \in (0, \delta_1). \tag{2}$$

Put

$$c = \sqrt{\frac{2(2^r + 1)\varepsilon}{M}} > 0, \qquad \delta = \min\Big\{ \frac{\delta_1}{2},\ c^{-1/(r-1)} \Big\} > 0,$$

where the second entry is finite and positive precisely because $r > 1$. Fix any $x \in (0, \delta)$ and set

$$\ell = c\, x^r.$$

Because $x \le c^{-1/(r-1)}$ we have $cx^{r-1} \le 1$, hence $\ell \le x$; and because $x < \delta_1/2$ we get

$$[x,\ x + \ell] \subseteq [x, 2x] \subset (0, \delta_1) \subset (0, \delta_0) \subset (0, 1).$$

In particular g is differentiable on an open interval containing $[x, x + \ell]$ and g'' exists on $(x, x + \ell)$, so Taylor's theorem with Lagrange remainder applies: there is $\xi \in (x, x + \ell)$ with

$$g(x + \ell) = g(x) + g'(x)\,\ell + \tfrac{1}{2} g''(\xi)\,\ell^2.$$

Solving for $g'(x)$ and taking absolute values,

$$|g'(x)| \;\le\; \frac{|g(x+\ell)|+|g(x)|}{\ell} \;+\; \tfrac{1}{2}|g''(\xi)|\,\ell. \tag{3}$$

Now bound the three pieces. Since $x+\ell \le 2x < \delta_1$, estimate (2) gives $|g(x+\ell)| \le \varepsilon(x+\ell)^r \le \varepsilon(2x)^r = 2^r\varepsilon x^r$ and $|g(x)| \le \varepsilon x^r$. Since $\xi > x$ and $t \mapsto t^{-r}$ is decreasing on $(0,\infty)$, estimate (1) gives $|g''(\xi)| \le M\xi^{-r} \le Mx^{-r}$. Substituting into (3),

$$|g'(x)| \;\le\; \frac{(2^r+1)\varepsilon x^r}{\ell} + \frac{Mx^{-r}\ell}{2} \;=\; \frac{(2^r+1)\varepsilon}{c} + \frac{Mc}{2},$$

where the last equality is exactly the substitution $\ell = cx^r$, and this is the point of choosing ℓ proportional to x^r: both terms become independent of x. With $c = \sqrt{2(2^r+1)\varepsilon/M}$ the two terms are equal, and

$$\frac{(2^r+1)\varepsilon}{c} + \frac{Mc}{2} = 2\sqrt{\frac{(2^r+1)M\varepsilon}{2}} = \sqrt{2(2^r+1)M\varepsilon}.$$

Therefore

$$|g'(x)| \le \sqrt{2(2^r+1)M\varepsilon} \qquad \text{for every } x \in (0,\delta).$$

Here M and r are fixed while $\varepsilon > 0$ was arbitrary, and $\sqrt{2(2^r+1)M\varepsilon} \to 0$ as $\varepsilon \to 0^+$. Hence for every $\eta > 0$ we may choose $\varepsilon = \eta^2/\big(2(2^r+1)M\big)$ and obtain $\delta > 0$ with $|g'(x)| \le \eta$ on $(0,\delta)$. That is $\lim_{x\to 0^+} g'(x) = 0$, which is the first alternative. ■

Remark 7.6.1. The hypothesis $r > 1$ was used exactly once, to guarantee that a window of length proportional to x^r fits inside $[x, 2x]$, so that both estimates (1) and (2) are valid throughout the window with the constants they have at the scale x. Everything else in the argument is Landau's interpolation inequality applied on that window.

Remark 7.6.2. The "or" is inclusive and you should not spend a second trying to make it exclusive. Take $g(x) = x^5\sin(x^{-3})$ on $(0,1]$ with $g(0) = 0$, and $r = 2$. Then $g(x)/x^2 = x^3\sin(x^{-3}) \to 0$; also $g'(x) = 5x^4\sin(x^{-3}) - 3x\cos(x^{-3}) \to 0$, so the first alternative holds; and $g''(x) = (20x^3 - 9x^{-3})\sin(x^{-3}) - 18\cos(x^{-3})$, so $x^2g''(x) = (20x^5 - 9x^{-1})\sin(x^{-3}) - 18x^2\cos(x^{-3})$ is unbounded along $x^{-3} = \frac{\pi}{2} + 2k\pi$, so the second alternative holds as well.

Layer 1: WHAT

Block 1. Convert the disjunction into an implication by negating the alternative whose negation is quantitative: assume $\limsup x^r|g''(x)| < \infty$, extract $|g''(x)| \le Mx^{-r}$ near 0, and aim at $g' \to 0$.

Block 2. Check that this is necessary, that is, that the hypothesis on g alone does not force $g' \to 0$; the example $x^{r+1}\sin(x^{-N})$ settles it. Now you know the curvature bound must appear in the proof, and you know roughly where.

Block 3. Recognise the pattern "control on f and f'', conclusion about f'" as interpolation, and write the only identity that links all three at once: Taylor to second order over a window $[x, x+\ell]$, solved for $g'(x)$.

Block 4. Do not choose ℓ. Leave it free, obtain $|g'(x)| \le A/\ell + B\ell/2$ with $A = (2^r+1)\varepsilon x^r$ and $B = Mx^{-r}$, and only then minimise, which gives $\ell \propto x^r$ and the scale free bound $\sqrt{2AB} = \sqrt{2(2^r+1)M\varepsilon}$.

Block 5. Check the window fits ($\ell \le x$, which is where $r > 1$ is spent), and let $\varepsilon \to 0$.

The nominal route and the ideal route split at Block 4. The zombie picks a window because it looks natural, almost always $[x, 2x]$ or $[0, x]$, computes with it, gets Mx^{1-r} blowing up, and either gives up or starts patching with sequences. The ideal route refuses to name the window until the algebra tells it which window to name. *That* is the bifurcation point: introducing ℓ as an unknown rather than guessing it. It is the same discipline as not choosing a substitution until you see which one clears the denominator, and it is worth stating as a law: when the estimate contains a free scale, carry the scale as a symbol and optimise at the end.

Layer 2: HOW

Block 1. **Cue.** The conclusion is "either P or Q", and Q is a statement that something is infinite. **Why natural.** A disjunction is proved as "not Q implies P", and you pick the side to negate by asking which negation is usable. "$\limsup = \infty$" is a statement of unboundedness; its negation is boundedness, which is an inequality with a constant, and inequalities with constants are the raw material of analysis. Negating P instead gives you only a sequence along which $|g'|$ stays above some ε_0, which is a much thinner object to work with. **Link to the next block.** You now hold two bounds near 0, one on g and one on g'', and a target concerning g'.

Block 2. **Cue.** The problem offers you two hypotheses; before using both, check whether one suffices. **Why natural.** If the hypothesis on g alone forced $g' \to 0$, the second alternative would be redundant and the problem would be misstated. It does not: $g(x) = x^{r+1}\sin(x^{-N})$ with $N > r$ is $o(x^r)$ with an unbounded derivative. Running this check costs two minutes and buys certainty about what the proof must contain, namely an essential use of the curvature bound. On a six mark boundary problem, knowing what the proof must contain is worth more than any single estimate. **Link to the next block.** The proof must link g, g' and g'' simultaneously, so you need an identity containing all three.

Block 3. **Cue.** Control on a function and on its second derivative, with the first derivative as the target. **Why natural.** There is exactly one elementary identity that contains a function, its derivative at a point, and its second derivative: Taylor's theorem to second order with Lagrange remainder, $g(x+\ell) = g(x) + g'(x)\ell + \frac{1}{2}g''(\xi)\ell^2$. Solving it for $g'(x)$ is not a manipulation, it is the definition of what interpolation means here: the derivative equals a difference quotient (controlled by the size of g) minus a curvature correction (controlled by g''). Landau's inequality is nothing but this identity plus an optimisation. **Link to the next block.** The two error terms move in opposite directions as the window grows, so the window length is a genuine degree of freedom.

Block 4. **Cue.** An upper bound of the form $A/\ell + B\ell/2$ with ℓ at your disposal. **Why natural.** Short windows make the difference quotient blow up; long windows make the curvature term blow up. Any bound of the shape $A/\ell + B\ell/2$ is minimised where the two terms are equal, at $\ell = \sqrt{2A/B}$, with minimum value $\sqrt{2AB}$: that is the arithmetic mean to geometric mean inequality, nothing more. Here $A = (2^r+1)\varepsilon x^r$ and $B = Mx^{-r}$, so $AB = (2^r+1)\varepsilon M$ is free of x, which is the design of the problem showing itself. Note the shape of the answer before you compute it: a constant times $\sqrt{\varepsilon}$, uniform in x. **Link to the next block.** Optimising has told you the window must have length proportional to x^r, so now you must check such a window is available.

Block 5. **Cue.** A window $[x, x+\ell]$ with $\ell = cx^r$, next to the singular point 0. **Why natural.** Both of your estimates were stated with constants valid at the scale x: $|g''| \le Mx^{-r}$ needs ξ to be comparable to x, and $|g(x+\ell)| \le \varepsilon(x+\ell)^r$ needs $x+\ell$ still inside the region where (2) holds. Requiring $\ell \le x$ delivers both at once, and $\ell = cx^r \le x$ is exactly $cx^{r-1} \le 1$, which is available for small x if and only if $r > 1$. Say this explicitly in the write up; it is the only line where the hypothesis $r > 1$ is consumed, and a grader will look for it.

Layer 3: WHY

The mathematical truth beneath the route is Landau's interpolation inequality. In its cleanest form: if f is twice differentiable on $[a, \infty)$ with $|f| \le A$ and $|f''| \le B$ throughout, then $|f'| \le 2\sqrt{AB}$ throughout. The proof is one line of Taylor plus one line of optimisation, exactly as above. The content is a statement about incompatible behaviours: a function cannot be simultaneously small, gently curved, and steep. Steepness at a point plus bounded curvature forces steepness on a whole

window of length proportional to $|f'|/B$; steepness over that window forces a displacement of order $|f'|^2/B$; and smallness caps the displacement at $2A$. Rearranging gives $|f'|^2 \le 2AB$ up to constants. Every proof of this problem, including the official ones, is that sentence in some packaging.

The second truth is scale invariance, and it is the discernment mechanism. The hypotheses are $|g| \le \varepsilon x^r$ and $|g''| \le Mx^{-r}$; their geometric mean is $\sqrt{\varepsilon M}$, free of x. When a problem's two hypotheses carry exponents whose product is scale free, the sharp mechanism is a geometric mean inequality and the conclusion will be uniform in the scale. That observation tells you the answer before you compute: $|g'|$ is bounded by a constant multiple of $\sqrt{\varepsilon}$ on a whole punctured neighbourhood, not merely along a sequence, and since ε is arbitrary the limit is 0. Conversely, if you compute and find an x dependent bound, you have chosen the wrong window and should go back to Block 4.

How do you train this? Two exercises, both cheap. First, dimensional analysis: give x the dimension of length and ask what length the problem provides. Here the only lengths available near the point x are x itself and x^r (through the ratio $\sqrt{A/B} = x^r\sqrt{\varepsilon/M}$), and since $r > 1$ these are genuinely different scales, so the problem is a two scale problem and the small scale is the one you must work at. Second, always leave the scale symbolic. Students lose this problem not because they cannot do Taylor but because they commit to a window in the first line and never revisit it.

What were the examiners nudging toward? Three nudges, all deliberate. The lim sup rather than lim in the second alternative is a nudge to negate that side, since only the lim sup has a clean finite negation. The identical exponent r on both sides is the scale invariance nudge. And the condition $r > 1$, which looks like a technical hypothesis, is the nudge that the window must be shorter than the distance to the singularity. Three cues, three decisions, one page of proof.

Revolving concepts

Limit superior. For h defined near 0^+, $\limsup_{x\to 0^+} h(x) = \lim_{\delta\to 0^+} \sup_{0<x<\delta} h(x)$, a limit of a nonincreasing function of δ, hence always defined in $[-\infty, +\infty]$. The negation used here: $\limsup_{x\to 0^+} h(x) < \infty$ if and only if there are M and $\delta_0 > 0$ with $h(x) \le M$ on $(0, \delta_0)$. Also $\limsup h = \infty$ if and only if there is a sequence $x_n \to 0^+$ with $h(x_n) \to \infty$. See Book 1, field: Real analysis, topic: limsup and liminf.

Taylor's theorem with Lagrange remainder. If f is n times differentiable on an open interval containing $[a, b]$, with $f^{(n-1)}$ continuous on $[a, b]$ and $f^{(n)}$ existing on (a, b), then there is $\xi \in (a, b)$ with $f(b) = \sum_{k=0}^{n-1} \frac{f^{(k)}(a)}{k!}(b-a)^k + \frac{f^{(n)}(\xi)}{n!}(b-a)^n$. The case $n = 1$ is the mean value theorem. The hypotheses matter here: we only know g is twice differentiable on the open interval $(0, 1)$, which is why the window is taken strictly inside. See Book 1, field: Real analysis, topic: Taylor's theorem.

Landau and Kolmogorov interpolation inequalities. Landau: on a half line, $\|f'\|_\infty^2 \le 4\|f\|_\infty\|f''\|_\infty$; on the whole line the constant improves to 2. Kolmogorov's general form: $\|f^{(k)}\|_\infty \le C_{k,n}\|f\|_\infty^{1-k/n}\|f^{(n)}\|_\infty^{k/n}$ for $0 < k < n$. The intermediate derivative is always controlled by a geometric mean of the two extremes, with weights given by the exponents. See Book 1, field: Real analysis, topic: interpolation inequalities.

The recursion hiding in interpolation, generalised. Apply Landau's inequality to $f^{(k-1)}$ instead of f: it gives $\|f^{(k)}\|_\infty^2 \le 4\|f^{(k-1)}\|_\infty\|f^{(k+1)}\|_\infty$ for every $k \ge 1$. Writing $L_k = \log\|f^{(k)}\|_\infty$, this is the recursion $2L_k \le L_{k-1} + L_{k+1} + \log 4$, that is, the sequence of logarithms of derivative norms is midpoint convex up to an additive constant. Iterating a midpoint convexity recursion of the form $2L_k \le L_{k-1} + L_{k+1} + c$ downward from the endpoints L_0 and L_n yields $L_k \le (1 - \frac{k}{n})L_0 + \frac{k}{n}L_n + C_{k,n}$, which is precisely Kolmogorov's inequality. The general lesson to install: any two term inequality that relates consecutive members of a family is a convexity recursion, and convexity recursions are solved by interpolating between the endpoints. See Book 1, field: Sequences and recurrences, topic: convexity recursions.

Two scale arguments and optimised windows. The general template: to estimate a quantity at a point x near a singularity, introduce a window of unspecified length ℓ, obtain a bound of the form

$A(x)/\ell^a + B(x)\ell^b$ with $a, b > 0$, and minimise over ℓ, giving $\ell \propto (aA/(bB))^{1/(a+b)}$ and a bound proportional to $A^{b/(a+b)}B^{a/(a+b)}$. Then check the optimal ℓ lies in the admissible range; that check is where the problem's structural hypotheses are consumed. See Book 1, field: Inequalities, topic: optimisation of a free parameter.

Circuit Bank

- **WHEN** the conclusion is a disjunction "P or Q" and Q asserts that something is infinite **DO** assume Q fails, convert that into an explicit inequality with a constant, and prove P **BECAUSE** the negation of an unboundedness statement is a usable quantitative bound, whereas the negation of a limit statement gives only a sequence
- **WHEN** you are given control of f and of f'' and asked about f' **DO** write Taylor to second order over a window and solve for f' **BECAUSE** this is the only elementary identity containing all three objects at once, and it is exactly Landau's interpolation inequality before optimisation
- **WHEN** an estimate contains a window length, a cutoff, or any other free scale **DO** carry it as a symbol and optimise at the very end, never guess it at the start **BECAUSE** the two error terms move in opposite directions, so the correct scale is the one that balances them, and guessing usually picks the scale that makes one term diverge
- **WHEN** two hypotheses carry exponents whose product is scale free (here x^r and x^{-r}) **DO** expect a geometric mean inequality and expect the final bound to be independent of position **BECAUSE** scale invariance of the data forces scale invariance of the sharp conclusion, so an x dependent answer is a signal that you optimised badly
- **WHEN** you are asked to prove a dichotomy **DO** first test whether either branch is a theorem on its own, using the cheapest oscillating counterexample you know, such as $x^a \sin(x^{-N})$ **BECAUSE** if one branch were always true the problem would be misstated, and the counterexample tells you which hypothesis the proof is obliged to use

Backtesting

1. First useful cue: the conclusion is a disjunction with a lim sup $= \infty$ on one side, so negate that side and read off $|g''(x)| \le Mx^{-r}$.
2. Method the expression suggested: interpolation. Control of g and g'' with g' as the target is Landau's inequality, realised as Taylor to second order over a window whose length you leave free and then optimise.
3. Where you would hesitate, and the thought to reinforce: the hesitation is choosing the window. Reinforce this sentence: do not choose it, carry ℓ as a symbol, and let the arithmetic mean to geometric mean balance point choose it for you; then check the chosen ℓ is admissible.
4. The trap the question sets: reading "either ... or" as exclusive, or believing that $g = o(x^r)$ already forces $g' \to 0$. Both cost the whole session, and both are refuted in two minutes by $x^a \sin(x^{-N})$ examples.
5. What makes you recognise it faster next time: the pair of exponents x^r and x^{-r} in the two hypotheses. Whenever the data are scale free in that way, the answer is a geometric mean and the bound is uniform in x.
6. The reusable decision rule: to bound an intermediate derivative, interpolate between the function and a higher derivative on an optimised window, and spend the structural hypothesis (here $r > 1$) on checking the window fits.

Mirror drills

1. Prove Landau's inequality: if f is twice differentiable on $[0,\infty)$ with $|f| \le A$ and $|f''| \le B$ everywhere, then $|f'(x)| \le 2\sqrt{AB}$ for all $x \ge 0$. *Answer:* Taylor gives $f(x+\ell) = f(x) + f'(x)\ell + \tfrac{1}{2}f''(\xi)\ell^2$, so $|f'(x)| \le 2A/\ell + B\ell/2$; minimise at $\ell = 2\sqrt{A/B}$ to get $2\sqrt{AB}$.

2. Show that $\lim_{x\to 0^+} g(x)/x^r = 0$ alone does not force $\lim_{x\to 0^+} g'(x) = 0$. *Answer:* take $g(x) = x^{r+1}\sin(x^{-N})$ with $N > r$ and $g(0) = 0$; then $g(x)/x^r = x\sin(x^{-N}) \to 0$, while along $x^{-N} = 2k\pi$ we get $g'(x) = -Nx^{r-N}$, which is unbounded.

3. Show the two alternatives in the problem can hold simultaneously. *Answer:* $g(x) = x^5\sin(x^{-3})$ with $r = 2$; then $g'(x) = 5x^4\sin(x^{-3}) - 3x\cos(x^{-3}) \to 0$, while $x^2 g''(x) = (20x^5 - 9x^{-1})\sin(x^{-3}) - 18x^2\cos(x^{-3})$ is unbounded along $x^{-3} = \tfrac{\pi}{2} + 2k\pi$.

7.7 B1. Counting squares in a Gaussian power of two lattice

Denote by $\mathbb{Z}^2$ the set of all points (x, y) in the plane with integer coordinates. For each integer $n \geq 0$, let P_n be the subset of $\mathbb{Z}^2$ consisting of the point $(0, 0)$ together with all points (x, y) such that $x^2 + y^2 = 2^k$ for some integer $k \leq n$. Determine, as a function of n, the number of four-point subsets of P_n whose elements are the vertices of a square.

Read it out loud

This is a lattice counting question whose real content is a factorisation question. Read the defining condition aloud: $x^2 + y^2 = 2^k$. You are not being asked about a circle. You are being asked which Gaussian integers have norm a power of two, because $x^2 + y^2$ is by definition the norm of $x + iy$ in $\mathbb{Z}[i]$. That is the whole cue. When a Diophantine condition on a pair (x, y) is exactly a norm form, you stop treating x and y as two unknowns and start treating $z = x + iy$ as one object, because norms are multiplicative and two unknowns are not.

The second structural feature is the range $k \leq n$. The exponent runs over an interval, so P_n is not a random point set: it is a geometric family, one level per exponent. Whatever the level m points are, the level $m + 1$ points ought to be their image under something of norm 2. Multiplication by $1 + i$ is a rotation by $\pi/4$ composed with a scaling by $\sqrt{2}$, and P_n is self-similar under it. Self-similarity plus a finite range is the signature of a descent argument, so expect the final classification to be proved by dividing by $1 + i$ and repeating.

The third feature is the word square. Squares are rigid: the four vertices of a square are $c + i^a w$ for $a = 0, 1, 2, 3$, where c is the centre and w a half diagonal. Rotation by a right angle is multiplication by i. So the geometric condition is also multiplicative, in the same ring as the arithmetic condition. Three multiplicative readings in one question is not a coincidence: the examiners built this problem on $\mathbb{Z}[i]$ and are waiting to see whether you notice.

Fields embedded: Gaussian integers and unique factorisation (number theory), plane geometry expressed through complex multiplication, and a small amount of careful counting. Within thirty seconds you should have written three lines: $N(z) = x^2 + y^2$; $2 = -i(1 + i)^2$ so $N(1 + i) = 2$; therefore $N(z) = 2^k$ forces $z = i^a(1 + i)^k$. Also note the one piece of small print: k is allowed to be negative, but 2^k is then not an integer, so negative k contributes nothing and the exponent range is really $0 \leq k \leq n$. State that, do not silently assume it.

Approaches, ranked worst to best

1. **Full coordinate case bash.** *Cue:* the set is finite and explicit for each n. *Circuit:* list the points, take all pairs as diagonals, impose integrality. You can list the $4n + 5$ points, take each of the $\binom{4n+5}{2}$ pairs as a diagonal, compute the other two vertices and test membership. It terminates, but it is $O(n^2)$ pairs with sign cases inside each, all done symbolically in n. It costs pages of ink and it teaches you nothing, because at the end you still cannot say why the answer is linear in n.

2. **Modulo four descent on coordinates.** *Cue:* $x^2 + y^2 \equiv 0 \pmod 4$ and squares are 0 or 1 mod 4. *Circuit:* parity descent to identify P_n, then a geometric case split. For $k \geq 2$ the relation $x^2 + y^2 \equiv 0 \pmod 4$ forces x and y both even, so $(x/2, y/2)$ lies two levels down, and induction identifies P_n as axis points at even levels and diagonal points at odd levels. This is honest and it is the standard route, but the description that comes out is split into two families, and the square classification then needs four separate cases (both vertices axial, both diagonal, one of each, and one at the origin). It works, it is slower, and the two families are an artefact of coordinates rather than a fact about the set.

3. **Convex hull recursion.** *Cue:* P_n is P_{n-1} plus exactly four new extreme points. *Circuit:* count the increment, not the total. The convex hull of P_n is a square whose vertices are the four

new points, and one shows each step adds exactly five squares. This is a good idea and gives $5n+1$ quickly, but it still needs the structure of P_n as an input and the hull argument requires care about which squares can touch an extreme point.

4. **Work in $\mathbb{Z}[i]$.** *Cue:* x^2+y^2 is the norm form; rotation by a right angle is multiplication by i. *Circuit:* unique factorisation plus a valuation descent. One lemma describes the entire set as $\{0\}\cup\{i^a(1+i)^m\}$. The vertex formula for a square becomes a formula about dividing by $1+i$. The classification collapses to a single dichotomy, whether the origin is a vertex or the centre, and the descent is two lines. This is best because every step is forced by the definition of the objects rather than by coordinates.

The ideal solution

Identify $\mathbb{Z}^2$ with the ring of Gaussian integers $\mathbb{Z}[i]$, writing $z=x+iy$ and $N(z)=z\bar{z}=x^2+y^2$. Set $u=1+i$, so $N(u)=2$ and $u^2=2i$.

Lemma 7.7.1. *For every $n\geq 0$,*

$$P_n=\{0\}\cup\{\, i^a u^m \;:\; a\in\{0,1,2,3\},\ 0\leq m\leq n\,\},$$

and the $4(n+1)$ listed nonzero points are pairwise distinct.

Proof. If $x^2+y^2=2^k$ with x,y integers, then 2^k is a nonnegative integer, so $k\geq 0$; negative k gives no points at all. Since $N(u)=2$ is a rational prime, u is prime in $\mathbb{Z}[i]$, and $\mathbb{Z}[i]$ is Euclidean, hence a unique factorisation domain whose units are $1, i, -1, -i$. From $N(z)=2^k$ and $2=-iu^2$ we get $z\bar{z}=(-i)^k u^{2k}$, so the only prime dividing z is u, and comparing norms gives $z=i^a u^k$ for some a. Conversely $N(i^a u^m)=2^m$. Distinctness is immediate: $|i^a u^m|=2^{m/2}$ separates the levels, and the four unit multiples at a fixed level are distinct. □

Call m the *level* of the nonzero point $i^a u^m$; it is the u-adic valuation $v(z)$, and $|P_n|=4n+5$.

Lemma 7.7.2. *If z and w are opposite vertices of a square, the other two vertices are*

$$\frac{iz+w}{u} \qquad \text{and} \qquad \frac{z+iw}{u}.$$

Proof. The centre is $c=(z+w)/2$ and the remaining vertices are $c\pm i(w-z)/2$, since a half diagonal rotates into the other half diagonal. Expanding, $c+i(w-z)/2=\frac{1}{2}\big((1-i)z+(1+i)w\big)$ and $c-i(w-z)/2=\frac{1}{2}\big((1+i)z+(1-i)w\big)$. Now $\frac{1-i}{2}=\frac{1}{u}$ and $\frac{1+i}{2}=\frac{i}{u}$, which gives the two stated expressions. □

Now count. Every square with vertices in P_n either has 0 as a vertex or does not.

Case A: the origin is a vertex. Let $w=i^a u^m$ be the opposite vertex. By Lemma 2 the other two vertices are $w/u=i^a u^{m-1}$ and $iw/u=i^{a+1}u^{m-1}$. If $m\geq 1$ these are level $m-1$ points of P_n, so the four points do lie in P_n and they do form a square. If $m=0$ then $w/u=w\bar{u}/2$ has norm $1/2$ and is not a Gaussian integer, so no square arises. Distinct choices of w give distinct squares, since w is recovered from the square as the vertex opposite 0. The count is therefore 4 choices of a times n choices of $m\in\{1,\dots,n\}$, that is $4n$ squares.

Case B: the origin is not a vertex. Then all four vertices are nonzero, so each has a level. I claim any such square is $\{i^a u^m : a=0,1,2,3\}$ for a single m, the square centred at the origin with its four vertices at one level.

First, a parity dichotomy. Reduction modulo the prime u gives $\mathbb{Z}[i]/(u)\cong\mathbb{F}_2$, in which every unit is congruent to 1 and every element of positive level is congruent to 0. If z,w are opposite vertices, Lemma 2 says $(iz+w)/u$ is a vertex, hence a Gaussian integer, so $iz+w\equiv 0 \pmod{u}$.

Since $i \equiv 1$, this reads $[v(z) = 0] + [v(w) = 0] \equiv 0 \pmod 2$: two opposite vertices have level zero together, or positive level together.

Second, suppose some pair of opposite vertices are both units, $z = i^a$ and $w = i^b$ with $b \neq a$. If $b = a + 1$ then $(z + iw)/u = i^a(1 + i^2)/u = 0$ and if $b = a + 3$ then $(iz + w)/u = i^{a+1}(1 + i^2)/u = 0$, both excluded because the origin is not a vertex. So $b = a + 2$, and then Lemma 2 gives the remaining vertices i^{a+1} and i^{a+3}: the square is $\{1, i, -1, -i\}$, the level zero square centred at the origin.

Third, descend. If some vertex has level 0, its opposite vertex has level 0 by the dichotomy, so by the previous paragraph the square is $\{1, i, -1, -i\}$. Otherwise all four vertices have level at least 1, hence all are divisible by u; dividing all four by u is a spiral similarity, so it produces another square, again with four nonzero vertices in $\{i^a u^m : m \geq 0\}$, and every level has dropped by exactly one. The minimum level is a nonnegative integer that strictly decreases, so after finitely many divisions some vertex has level 0 and the reduced square is $\{1, i, -1, -i\}$. Multiplying back by u^m, where m was the original minimum level, the original square is $\{i^a u^m : a = 0, 1, 2, 3\}$, as claimed.

Conversely each set $\{i^a u^m : a = 0, 1, 2, 3\}$ is a square, since multiplication by i rotates it by a right angle about 0, and it lies in P_n exactly when $0 \leq m \leq n$. That is $n + 1$ squares.

Adding the two cases, the number of four-point subsets of P_n forming a square is

$$4n + (n + 1) = \boxed{5n + 1}.$$

As a check, $n = 0$ gives 1 (only $\{1, i, -1, -i\}$, since P_0 has five points) and $n = 1$ gives 6 (the two centred squares plus the four unit squares with a vertex at the origin), both correct by direct inspection.

Layer 1: WHAT

Block 1. Recognise $x^2 + y^2 = 2^k$ as $N(z) = 2^k$ and move into $\mathbb{Z}[i]$.

Block 2. Factor: $2 = -iu^2$ with $u = 1 + i$ prime, so unique factorisation forces $z = i^a u^k$. The whole set is one geometric orbit, $P_n = \{0\} \cup \{i^a u^m : 0 \leq m \leq n\}$.

Block 3. Express the square condition multiplicatively: from opposite vertices z, w the other two are $(iz + w)/u$ and $(z + iw)/u$.

Block 4. Split on whether the origin is a vertex, because the origin is the only point of P_n that is not of the form $i^a u^m$ and the only one fixed by multiplication by i.

Block 5. Case A is a one line computation: the partner of w at level m lives at level $m - 1$, so the count is $4n$.

Block 6. Case B: reduce modulo u to force opposite vertices to share the level zero or not, then divide by u and descend. Only the centred squares survive: $n + 1$ of them.

Block 7. Add and sanity check small n.

Juxtaposition. The nominal route writes P_n as two coordinate families (axis points at even k, diagonal points at odd k), then takes all pairs of points as candidate diagonals and grinds through four configuration cases with sign analysis and triangle inequalities. It reaches the same $5n + 1$ after several pages. The bifurcation point is exactly the line where you first write the condition down. Either you write $x^2 + y^2 = 2^k$ as an equation in two integer unknowns and start reducing modulo 4, or you write $N(z) = 2^k$ and start factoring. Everything after that is downstream of that single choice, including whether you ever have to mention the words axis and diagonal at all.

Layer 2: HOW

Block 1. Cue. The expression $x^2 + y^2$ set equal to a prime power, with x, y ranging over integers. **Why natural.** $x^2 + y^2$ is not a random quadratic form: it is the norm form of $\mathbb{Z}[i]$, and the defining property of a norm is multiplicativity. A Diophantine condition that says a norm equals a prime power is a condition about factorisation, and factorisation questions are answered in the ring, not in coordinates. This is the same reflex that converts $a^2 + b^2 = c^2$ into Gaussian integers and $a^2 + 3b^2$

into Eisenstein integers. **Link to the next block.** Once you are in $\mathbb{Z}[i]$ you need the factorisation of the right hand side, so the next question asks itself: how does 2 factor in $\mathbb{Z}[i]$?

Block 2. **Cue.** The right hand side is a power of the single rational prime 2. **Why natural.** In $\mathbb{Z}[i]$ the prime 2 ramifies: $2 = -i(1+i)^2$, and $1+i$ has prime norm so it is prime. A number whose norm is 2^k can therefore have no prime factor other than $1+i$, and counting norms pins the exponent exactly. The four units $\pm 1, \pm i$ are the only remaining freedom, which is why there are exactly four points per level. **Link to the next block.** You now have a complete, uniform description of the point set with one integer parameter, the level. A one-parameter set invites a one-parameter answer, so you should expect the final count to be linear in n.

Block 3. **Cue.** The word square, and the fact that you have to decide membership of two unknown vertices. **Why natural.** A square is generated from any vertex by rotating about the centre by right angles, and rotation by a right angle in $\mathbb{C}$ is multiplication by i. Writing the two remaining vertices in terms of two opposite ones therefore produces an expression built from $1 \pm i$, and dividing by 2 turns into dividing by u because $\frac{1-i}{2} = \frac{1}{u}$. This is why the geometry and the arithmetic speak the same language: both are statements about divisibility by u. **Link to the next block.** The formula contains a division by u, and divisibility by u is exactly the level being positive. So the next move is to track levels.

Block 4. **Cue.** The set has one special point, 0, which has no level and is the fixed point of every rotation about it. **Why natural.** Any classification of configurations in a set with one distinguished point splits on whether the configuration uses that point. Here the split is genuinely structural rather than cosmetic, because the origin is the centre of symmetry of P_n: squares through it and squares around it are different animals. **Link to the next block.** Case A is finite and immediate; Case B needs an argument, so do Case A first to bank the easy count.

Block 5. **Cue.** A square with a vertex at 0 and opposite vertex w; Lemma 2 with $z = 0$ collapses to w/u and iw/u. **Why natural.** Dividing by u drops the level by one. So a square with a vertex at the origin exists exactly when the opposite vertex has a level to spare, that is $m \geq 1$, and the failure at $m = 0$ is not an accident but the statement that u does not divide a unit. **Link to the next block.** Case A used only divisibility by u. Case B should use the same tool, so reduce modulo u.

Block 6. **Cue.** Four unknown vertices, all nonzero, with a formula forcing $u \mid iz + w$. **Why natural.** The residue field $\mathbb{Z}[i]/(u)$ has two elements, so reduction modulo u can only see whether a point is a unit multiple of a power of u with exponent zero or positive. That is precisely the piece of information the formula constrains, and it yields the parity dichotomy for free. Once every vertex has positive level, every vertex is divisible by u, and dividing by u is a similarity of the plane, so it preserves squares. Any self-similar set forces this style of argument: strip a factor, repeat, terminate because the valuation is a nonnegative integer. **Link to the next block.** Two cases counted, so add them and test the answer on the smallest n you can enumerate by hand.

Block 7. **Cue.** A closed form in n that you have not yet stress tested. **Why natural.** $n = 0$ and $n = 1$ are cheap and independent of the argument, so they catch an off by one in the level ranges, which is where this problem punishes people. The two ranges to check are $1 \leq m \leq n$ in Case A and $0 \leq m \leq n$ in Case B, and mixing them up changes the constant.

Layer 3: WHY

The mathematical truth beneath the route is that P_n is not a set of points, it is a truncated orbit of a single multiplicative map. Once you know $P_n \setminus \{0\}$ is the set of associates of u^m for $0 \le m \le n$, the set is closed under multiplication by i and almost closed under multiplication by u: multiplying by u is a bijection from level m to level $m+1$. Any question about configurations inside such a set is a question about the group of similarities generated by these maps, and the answer must be an arithmetic progression in n because each new level contributes a fixed number of new configurations. The count $5n+1$ is linear for that reason, not by accident: four new squares through the origin, one new centred square, per level.

The discernment mechanism, stated as a rule: when the constraint defining your point set is a norm form of a quadratic ring, the coordinates are the wrong variables. Sums of two squares belong to $\mathbb{Z}[i]$; x^2+xy+y^2 and x^2+3y^2 belong to the Eisenstein integers $\mathbb{Z}[\omega]$; x^2-2y^2 belongs to $\mathbb{Z}[\sqrt{2}]$ with its unit group and Pell structure. The tell is that the form is multiplicative, so a product of two representable numbers is representable. If you catch yourself doing case analysis modulo 4 on x and y separately, you have already lost the multiplicative structure that the problem was built from.

The second truth is that descent by valuation is the correct tool for self-similar sets. The general shape is: a configuration all of whose members are divisible by a fixed prime π can be divided by π, producing a similar configuration in the same set with smaller valuation; therefore it is enough to classify configurations in which some member is a unit. That single sentence replaced an entire case analysis here, and it is the same sentence used in infinite descent proofs of the irrationality of $\sqrt{2}$, in the classification of Pythagorean triples, and in Fermat style arguments. Train it by asking, of any set you are given, whether it is invariant under some scaling, and if so by what.

The examiners nudged in three ways at once. They wrote x^2+y^2 rather than a general quadratic condition; they wrote a power of two rather than a general integer, which is the one case where the Gaussian prime is ramified and the answer is a single orbit; and they asked for the answer as a function of n, which tells you in advance that the structure is uniform across levels. Reading a question for what it has been made easy is part of reading it at all.

Revolving concepts

Gaussian integers. $\mathbb{Z}[i] = \{x+iy : x,y \in \mathbb{Z}\}$ with norm $N(x+iy) = x^2+y^2$, which is multiplicative: $N(zw) = N(z)N(w)$. It is Euclidean with respect to N, hence a principal ideal domain and a unique factorisation domain. Units are exactly the elements of norm 1, namely $1, i, -1, -i$. A rational prime p splits as a product of two conjugate Gaussian primes when $p \equiv 1 \pmod 4$, stays prime when $p \equiv 3 \pmod 4$, and ramifies for $p=2$ with $2 = -i(1+i)^2$. Any element of prime norm is prime. See Book 1, field: Number theory, topic: Gaussian integers.

Norm forms and sums of two squares. An integer m is a sum of two squares if and only if every prime $\equiv 3 \pmod 4$ occurs to an even power in m; the number of representations is $r_2(m) = 4(d_1(m) - d_3(m))$ where d_j counts divisors congruent to j modulo 4. For $m = 2^k$ this gives $r_2 = 4$, which is the count you proved by hand here. See Book 1, field: Number theory, topic: Sums of two squares.

Valuations and descent. For a prime π of a unique factorisation domain, $v_\pi(z)$ is the exponent of π in z, with $v_\pi(zw) = v_\pi(z) + v_\pi(w)$ and $v_\pi(z+w) \ge \min(v_\pi(z), v_\pi(w))$, with equality when the two valuations differ. Reduction modulo π lands in the residue field, here $\mathbb{Z}[i]/(1+i) \cong \mathbb{F}_2$. See Book 1, field: Number theory, topic: Valuations.

The recursion, generalised. The set here satisfies $P_n \setminus \{0\} = U \cup u\,(P_{n-1} \setminus \{0\})$ with $U = \{1, i, -1, -i\}$, a self-similar recursion with ratio u. The general statement worth installing: if a set X satisfies $X = F \cup \alpha X$ for a similarity α with $|\alpha| > 1$ and a finite base F, then any finite configuration $C \subseteq X$ which is closed under nothing in particular can be normalised by repeatedly dividing by α until $C \cap F \neq \emptyset$; hence configurations in X are exactly the α^m images of configurations

meeting F. Counting configurations then gives a count of the form (configurations meeting F) $\times$ (number of levels) plus boundary corrections, which is why linear answers in n appear. The same normalise then descend pattern solves questions about geometric sequences in lattices, about binary expansions, and about p-adic digit configurations. See Book 1, field: Sequences and recurrences, topic: Self-similar sets.

Squares via complex rotation. Four points z_1, z_2, z_3, z_4 form a square in this cyclic order if and only if $z_2 - z_1 = i(z_1 - z_4)$ and the quadrilateral closes, equivalently $z_1 + z_3 = z_2 + z_4$ and $z_3 - z_1 = -i(z_4 - z_2)$. Given opposite vertices, the other pair is $(iz + w)/(1 + i)$ and $(z + iw)/(1 + i)$. See Book 1, field: Complex numbers, topic: Rotations and similar figures.

Circuit Bank

- **WHEN** you see $x^2 + y^2$ constrained to a specific set of values **DO** rewrite it as $N(z)$ with $z = x + iy$ and factor in $\mathbb{Z}[i]$ **BECAUSE** $x^2 + y^2$ is the norm form of $\mathbb{Z}[i]$, and norms are multiplicative, so the condition is about factorisation, which coordinates hide
- **WHEN** you see a point set that is invariant under a scaling or spiral similarity **DO** classify configurations by minimal valuation, divide by the scaling factor, descend **BECAUSE** the valuation is a nonnegative integer, so the descent terminates and only the base level needs a case analysis
- **WHEN** you see squares or right angles with lattice constraints **DO** move to $\mathbb{C}$ and write rotation by a right angle as multiplication by i **BECAUSE** the rigid motion group of the plane is generated by complex multiplication and translation, so geometric conditions become algebraic identities with no coordinates
- **WHEN** you see a set with exactly one distinguished point, such as the centre of symmetry **DO** split the count on whether the configuration uses that point **BECAUSE** the distinguished point is the only one whose stabiliser differs, so the two families obey different formulas and merging them creates errors
- **WHEN** you finish with a closed form in n **DO** test $n = 0$ and $n = 1$ by hand **BECAUSE** the only realistic failure mode left is an off by one in an exponent range, and small cases expose it in seconds

Backtesting

1. First useful cue: $x^2 + y^2 = 2^k$ read as $N(z) = 2^k$, so the point set is the set of associates of powers of $1 + i$.
2. Method the expression suggested: unique factorisation in $\mathbb{Z}[i]$ to describe P_n, then complex rotation to describe squares, then a valuation descent to classify them.
3. Where you would hesitate, and the thought to reinforce: at Case B, when four unknown vertices appear at once. The thought is that you never need all four levels; you only need whether each is zero or positive, and reduction modulo $1 + i$ answers exactly that.
4. The trap the question sets: the condition is $k \leq n$, not $0 \leq k \leq n$, and the two exponent ranges in the two cases differ by one. A candidate who writes $4(n + 1)$ in Case A or n in Case B loses the problem while believing the argument is complete.
5. What makes you recognise it faster next time: the pairing of a norm form with a prime power right hand side. That pairing has exactly one meaning, and it appears every few years on the Putnam.
6. The reusable decision rule: norm form condition means move into the quadratic ring; self-similar set means descend by valuation; square means multiply by i.

Mirror drills

1. How many points $(x, y) \in \mathbb{Z}^2$ satisfy $x^2 + y^2 = 5^k$ for a fixed $k \geq 0$? *Answer:* $4(k+1)$. Since $5 = (2+i)(2-i)$ with the two factors non-associate primes, $z = i^a(2+i)^j(2-i)^{k-j}$ with $0 \leq j \leq k$.
2. Let $T_n = \{0\} \cup \{(x, y) : x^2 + y^2 = 3^k,\ k \leq n\}$. How many four-point subsets of T_n form a square? *Answer:* $\lfloor n/2 \rfloor + 1$. Here 3 is inert, so $N(z) = 3^k$ forces k even and $z = i^a 3^{k/2}$; every nonzero point has odd norm, so $1 + i$ divides no vertex and no square can use the origin. Only the centred squares survive.
3. Show that if all four vertices of a square lie in $\mathbb{Z}^2$, then its area is an integer. *Hint:* the side vector v satisfies $v \in \mathbb{Z}[i]$, and the area is $N(v)$.

7.8 B2. Telescoping a trigonometric sum of cubic growth

For all $n \geq 1$, let

$$a_n = \sum_{k=1}^{n-1} \frac{\sin\left(\frac{(2k-1)\pi}{2n}\right)}{\cos^2\left(\frac{(k-1)\pi}{2n}\right)\cos^2\left(\frac{k\pi}{2n}\right)}.$$

Determine

$$\lim_{n\to\infty} \frac{a_n}{n^3}.$$

Read it out loud

Say the summand aloud in words, not symbols. The denominator is the product of the squares of the cosines at two consecutive angles, $(k-1)\theta$ and $k\theta$, where $\theta = \pi/(2n)$. The numerator is the sine at the angle exactly halfway between the doubled angles, since $\frac{1}{2}\big(2(k-1)\theta + 2k\theta\big) = (2k-1)\theta$. A denominator built from consecutive values of one sequence, and a numerator built from the mean of the corresponding doubled angles, is not a random arrangement. It is the fingerprint of a difference. The examiners built this summand backwards from a telescoping identity, and your job is to run the construction in reverse.

The second reading is about size. There is a limit being asked for, and the normalisation is n^3, not n or n^2. A sum of $n-1$ terms that grows like n^3 cannot be an ordinary Riemann sum, because a Riemann sum grows like n times a bounded average. So either the individual terms are of size n^2, or a few terms near one end are enormous. Look at the last term: $\cos\big((n-1)\pi/(2n)\big) = \sin(\pi/(2n))$, which is of size $1/n$. Its square sits in the denominator alongside another cosine of size $1/n$, so the denominator is of size $1/n^4$ while the numerator is of size $1/n$, making that single term of size n^3 by itself. So the last few terms already carry the whole answer. That is a warning: the naive continuum approximation has a non integrable singularity at the right endpoint, and anyone who writes down $\int_0^1$ has already lost the problem.

Fields embedded: trigonometric identities (double angle, sum to product), telescoping sums, and one elementary limit. There is no analysis here beyond $\sin x/x \to 1$. What is really being tested is whether you look for exact structure before you reach for approximation. The Putnam rewards the candidate who computes a_n in closed form and then takes a limit in one line, and punishes the candidate who starts estimating.

Within thirty seconds you should have written $\theta = \pi/(2n)$, $c_k = \cos(k\theta)$, and the question: what is $\dfrac{1}{c_k^2} - \dfrac{1}{c_{k-1}^2}$?

Approaches, ranked worst to best

1. **Riemann sum in $t = k/n$.** *Cue:* a sum of $n-1$ terms with argument $k\pi/(2n)$. *Circuit:* recognise $\frac{1}{n}\sum f(k/n)$ as $\int_0^1 f$. Substituting $t = k/n$ turns the summand into roughly $2\sin(\pi t/2)/\cos^3(\pi t/2)$, so you would write $a_n/n^3 \approx \frac{1}{n}\int_0^1$ of something. It fails twice over. The integrand blows up like $(1-t)^{-3}$ at $t = 1$, so the integral diverges, and the powers of n do not even balance. This route is not merely inefficient, it produces a wrong answer with a confident face on it.

2. **Endpoint asymptotics after reversing the index.** *Cue:* the terms near $k = n$ dominate. *Circuit:* substitute $j = n-k$ and expand each term for fixed j. Putting $j = n-k$ turns the summand into $\sin((2j+1)\theta)/\big(\sin^2((j+1)\theta)\sin^2(j\theta)\big)$, which for fixed j and small θ is $\frac{2j+1}{j^2(j+1)^2}\theta^{-3}(1+O(\theta^2))$. Summing gives $\theta^{-3}\sum_{j\geq 1}\frac{2j+1}{j^2(j+1)^2} = \theta^{-3}$, and $\theta^{-3} = (2n/\pi)^3$. Correct, and it is the honest analytic route, but full marks demand a uniform error bound over the whole range of j, not just fixed j, which costs a paragraph of estimates. Notice too that the

final series telescopes, which is the problem telling you a second time that you should have telescoped from the start.

3. **Compute small cases, guess the closed form, prove by induction.** *Cue:* the answer is a clean constant, so a_n is probably clean. *Circuit:* conjecture and verify. From $a_2 = \sqrt{2}$ and a_3, a_4 you can guess $a_n = \cos^2\theta/\sin^3\theta$ and then prove it by induction on the partial sums. It gets there, but induction on a sum whose upper limit and whose angle both depend on n is awkward, because θ changes with n and the partial sums of different n are unrelated.
4. **Telescope exactly.** *Cue:* the denominator is a product of consecutive values of $\cos^2$. *Circuit:* write the summand as a difference of $1/\cos^2$ at consecutive indices. Compute $\cos^2((k-1)\theta) - \cos^2(k\theta)$ by double angle and sum to product; it equals $\sin((2k-1)\theta)\sin\theta$, which is the numerator times $\sin\theta$. The sum collapses to two boundary terms, a_n is exact, and the limit is immediate. Best because it uses the exact structure the setter built in, it needs no estimates at all, and it produces more than was asked, namely a closed form valid for every n.

The ideal solution

Write $\theta = \dfrac{\pi}{2n}$ and $c_k = \cos(k\theta)$, so that the summand is $\dfrac{\sin((2k-1)\theta)}{c_{k-1}^2 c_k^2}$.

By the double angle formula $\cos^2 x = \frac{1}{2}(1+\cos 2x)$,

$$c_{k-1}^2 - c_k^2 = \tfrac{1}{2}\Big(\cos\big(2(k-1)\theta\big) - \cos\big(2k\theta\big)\Big),$$

and by the sum to product identity $\cos A - \cos B = 2\sin\frac{A+B}{2}\sin\frac{B-A}{2}$ with $A = 2(k-1)\theta$, $B = 2k\theta$,

$$c_{k-1}^2 - c_k^2 = \sin\big((2k-1)\theta\big)\sin\theta.$$

For $1 \le k \le n-1$ every angle $k\theta$ lies in $[0, \pi/2)$, so $c_k \neq 0$ and we may divide by $c_{k-1}^2 c_k^2$:

$$\frac{1}{c_k^2} - \frac{1}{c_{k-1}^2} = \frac{c_{k-1}^2 - c_k^2}{c_{k-1}^2 c_k^2} = \sin\theta \cdot \frac{\sin((2k-1)\theta)}{c_{k-1}^2 c_k^2}.$$

Therefore each summand equals $\dfrac{1}{\sin\theta}\left(\dfrac{1}{c_k^2} - \dfrac{1}{c_{k-1}^2}\right)$, and the sum telescopes:

$$a_n = \frac{1}{\sin\theta}\left(\frac{1}{c_{n-1}^2} - \frac{1}{c_0^2}\right).$$

Now $c_0 = 1$ and $c_{n-1} = \cos\big(\frac{\pi}{2} - \theta\big) = \sin\theta$, so for every $n \ge 2$,

$$a_n = \frac{1}{\sin\theta}\left(\frac{1}{\sin^2\theta} - 1\right) = \frac{\cos^2\theta}{\sin^3\theta}, \qquad \theta = \frac{\pi}{2n}.$$

(For $n = 1$ the sum is empty and $a_1 = 0$, which does not affect a limit.)

Finally, $\lim\limits_{x\to 0}\dfrac{\sin x}{x} = 1$ gives $n\sin\theta = \frac{\pi}{2}\cdot\frac{\sin\theta}{\theta} \to \frac{\pi}{2}$, and $\cos\theta \to 1$. Hence

$$\frac{a_n}{n^3} = \cos^2\theta \cdot \frac{1}{(n\sin\theta)^3} \longrightarrow 1 \cdot \left(\frac{2}{\pi}\right)^3,$$

so

$$\lim_{n\to\infty}\frac{a_n}{n^3} = \boxed{\frac{8}{\pi^3}}.$$

As a check, $n = 2$ gives $\theta = \pi/4$ and $\cos^2\theta/\sin^3\theta = \frac{1}{2}/(\frac{\sqrt{2}}{2})^3 = \sqrt{2}$, which is the single term $\sin(\pi/4)/(1\cdot\cos^2(\pi/4)) = \sqrt{2}$.

Layer 1: WHAT

Block 1. Name the angle: $\theta = \pi/(2n)$, $c_k = \cos(k\theta)$. The summand is $\sin((2k-1)\theta)/(c_{k-1}^2 c_k^2)$.

Block 2. Read the denominator as a product of consecutive values of one sequence, which is the standing cue for telescoping, and therefore compute $c_{k-1}^2 - c_k^2$.

Block 3. Double angle turns squares of cosines into cosines of doubled angles; sum to product turns that difference into $\sin((2k-1)\theta)\sin\theta$, which is exactly the numerator times a constant.

Block 4. Divide: the summand is $\frac{1}{\sin\theta}\left(c_k^{-2} - c_{k-1}^{-2}\right)$. Check no denominator vanishes on the range.

Block 5. Telescope to the two endpoints, and use $c_{n-1} = \sin\theta$, which is the complementary angle identity and the reason the answer is clean.

Block 6. Closed form $a_n = \cos^2\theta/\sin^3\theta$, then divide by n^3 and use $n\sin\theta \to \pi/2$.

Juxtaposition. The nominal route is: this is a sum with k/n inside trigonometric functions, so it must be a Riemann sum, so approximate and integrate. That route dies on the singularity at the right endpoint. A slightly better zombie route notices the domination by the last terms, reverses the index and estimates term by term, arriving at the answer after a page of O notation. The bifurcation point is the very first decision after reading the summand: do you look at the denominator as a shape, or at the summand as a function of k/n? Looking at the shape gives an exact identity, looking at the function gives approximations. On a problem whose answer is a clean constant, the shape wins.

Layer 2: HOW

Block 1. Cue. Every angle in sight is an integer multiple of $\pi/(2n)$. **Why natural.** Naming θ costs one line and removes the n from the interior of every trigonometric function, so the summand becomes a statement about a sequence indexed by k with a parameter θ. Identities are found on sequences, not on cluttered fractions. Notation that hides the parameter is notation that lets you see the structure. **Link to the next block.** With the notation clean, the shape of the denominator becomes visible: $c_{k-1}^2 c_k^2$.

Block 2. Cue. The denominator is $g(k-1)g(k)$ for $g(k) = c_k^2$, a product of consecutive values of one sequence. **Why natural.** This is the exact algebraic signature of $\frac{1}{g(k-1)} - \frac{1}{g(k)} = \frac{g(k)-g(k-1)}{g(k-1)g(k)}$. Whenever a summand has consecutive values of one sequence multiplied in the denominator, the summand is a difference in disguise provided the numerator matches $g(k) - g(k-1)$. So you do not guess: you compute $g(k-1) - g(k)$ and compare. The same reading turns $\frac{1}{k(k+1)}$ into $\frac{1}{k} - \frac{1}{k+1}$ and $\frac{2k+1}{k^2(k+1)^2}$ into $\frac{1}{k^2} - \frac{1}{(k+1)^2}$. **Link to the next block.** The comparison requires simplifying a difference of squares of cosines, so reach for the identities that linearise squares.

Block 3. Cue. A difference of $\cos^2$ at two angles. **Why natural.** $\cos^2 x = \frac{1}{2}(1+\cos 2x)$ is the only identity that converts a square into something additive, and the additive constants cancel in a difference. Once you have a difference of two cosines, the sum to product identity is forced, since it is the identity that converts additive differences of cosines into products of sines. The numerator that emerges, sin of the mean of the two doubled angles, is precisely the numerator printed in the question. That is the confirmation that the setter constructed the summand this way. **Link to the next block.** The identity now reads: numerator times $\sin\theta$ equals the difference of the denominators' factors. Divide through.

Block 4. Cue. A proposed identity involving division by $c_{k-1}^2 c_k^2$. **Why natural.** Division needs the divisor to be nonzero, and here k runs only to $n-1$, so $k\theta \le (n-1)\pi/(2n) < \pi/2$ and every cosine is strictly positive. The upper limit $n-1$ rather than n is not decoration: at $k = n$ the cosine would vanish and the sum would not exist. Saying this in one clause is what separates a full-marks

write-up from a nearly right one. **Link to the next block.** With the identity established termwise, sum it.

Block 5. Cue. A sum of consecutive differences. **Why natural.** Telescoping is the discrete fundamental theorem of calculus: $\sum_{k=1}^{m} \big(G(k) - G(k-1)\big) = G(m) - G(0)$. The only work left is evaluating the two boundary values. Here $c_0 = 1$ is trivial and $c_{n-1} = \cos(\pi/2 - \theta) = \sin\theta$ by the complementary angle identity, which is why the closed form involves only θ. **Link to the next block.** You now have an exact formula, so the limit is a routine calculation rather than an estimate.

Block 6. Cue. A closed form with $\theta = \pi/(2n) \to 0$ and a division by n^3. **Why natural.** The only asymptotic input is $\sin x \sim x$. Group the expression so that each factor has an obvious limit: $\cos^2\theta \to 1$, and $n\sin\theta \to \pi/2$ because $n\theta = \pi/2$ exactly. Grouping before taking limits is what stops you from writing ∞/∞ and losing control of the constant.

Layer 3: WHY

The truth underneath is that this sum is a telescoping sum by construction, and telescoping is the discrete antiderivative. In the continuous world, $\int f$ is easy when $f = G'$. In the discrete world, $\sum_k t_k$ is easy when $t_k = G(k) - G(k-1)$. Everything in the ideal solution is the search for G. The setter chose $G(k) = \sec^2(k\theta)$, computed $G(k) - G(k-1)$, tidied it with two standard identities, and printed the result as the question. Reading a summand as the output of that process is a trainable skill, and the trigger is structural: consecutive indices multiplied in the denominator.

The discernment mechanism for choosing telescoping over approximation is a two part test. First, is the requested answer exact or asymptotic in a clean form? A clean constant such as $8/\pi^3$ suggests an exact closed form is available. Second, is the sum dominated by a bounded number of terms, or spread evenly? If a handful of terms carry the whole sum, a Riemann sum is meaningless and you should be looking for exact cancellation instead. Both tests point the same way here. Train the reflex by taking any sum you meet and asking the single question: is the denominator a product of consecutive values of one sequence? If yes, compute the difference of those values before doing anything else.

There is a second, deeper reason the problem is clean. The function $x \mapsto \sec^2 x$ is the derivative of $\tan x$, and the identity used is the discrete shadow of $\frac{d}{dx}\tan x = \sec^2 x$. In fact the general identity behind the whole problem is

$$\sum_{k=1}^{m} \frac{\sin((2k-1)x)}{\cos^2((k-1)x)\cos^2(kx)} = \frac{\tan^2(mx)}{\sin x},$$

valid whenever no cosine vanishes, and the problem is the case $m = n-1$, $x = \pi/(2n)$, chosen so that mx is the complement of x and the answer becomes a function of x alone. The examiners hid a one parameter identity by tying the two parameters together. Recognising a specialised identity, and asking what the free version looks like, is exactly how you convert one Putnam problem into a piece of permanent equipment.

The nudges are visible once you know they are there: the upper limit $n-1$ instead of n (which keeps the cosines nonzero and makes the last term the dominant one), the argument $(2k-1)\pi/(2n)$ in the numerator (which is sin of the mean of the doubled denominator angles, the sum to product signature), and the normalisation n^3 (which announces that the sum is not an average but is driven by a small number of large terms).

Revolving concepts

Telescoping. If $t_k = G(k) - G(k-1)$ then $\sum_{k=a}^{b} t_k = G(b) - G(a-1)$. This is the discrete fundamental theorem of calculus and the discrete counterpart of an exact differential. The search for G is

the discrete analogue of antidifferentiation, and it is decidable for hypergeometric summands by Gosper's algorithm, whose creative telescoping extension (Zeilberger) settles most binomial identities mechanically. Knowing that such an algorithm exists tells you that hunting for G is a legitimate first move rather than a hopeful one. See Book 1, field: Sequences and recurrences, topic: Telescoping and summation by parts.

The generalised recursion. Set $G(k) = \sec^2(k\theta)$ and the problem is the first order recursion $G(k) = G(k-1) + \sin\theta \cdot t_k$, whose solution is $G(m) = G(0) + \sin\theta \sum_{k\le m} t_k$. Every telescoping sum is exactly this: a first order linear recursion with unit coefficient, solved by summing. The general version worth carrying is: for $t_k = \dfrac{g(k) - g(k-1)}{g(k-1)g(k)}$ the partial sums are $\dfrac{1}{g(a-1)} - \dfrac{1}{g(b)}$, so any summand whose denominator is a product of consecutive values of g and whose numerator is the corresponding difference collapses. Special cases include $\sum \frac{1}{k(k+1)}$, $\sum \frac{2k+1}{k^2(k+1)^2}$, and $\sum \frac{1}{\sin(kx)\sin((k+1)x)}$ via $\sin x = \sin((k+1)x - kx)$.

Sum to product and product to sum. $\cos A - \cos B = 2\sin\frac{A+B}{2}\sin\frac{B-A}{2}$, $\sin A - \sin B = 2\cos\frac{A+B}{2}\sin\frac{A-B}{2}$, and the double angle forms $\cos^2 x = \frac{1+\cos 2x}{2}$, $\sin^2 x = \frac{1-\cos 2x}{2}$. These are the standard toolkit for converting between additive and multiplicative trigonometric structure, and telescoping needs the additive direction. See Book 1, field: Calculus and integrals, topic: Trigonometric identities.

Small angle asymptotics. $\sin x = x + O(x^3)$, $\cos x = 1 + O(x^2)$, and $\lim_{x\to 0}\frac{\sin x}{x} = 1$. For sums where the answer is only asymptotic, the uniform version $\frac{\sin x}{x} = 1 + O(x^2)$ on $[0, \pi]$ is what licenses termwise replacement inside a sum, and the error must be summed, not waved at. See Book 1, field: Real analysis, topic: Asymptotic expansions.

Domination by boundary terms. A positive sum $\sum_{k=1}^{n-1} f(k/n)$ where f has a pole of order $p > 1$ at the endpoint grows like n^p times a convergent series, not like n times an integral. The correct normalisation is read off from the order of the pole, and the constant comes from the convergent series in the reversed index. See Book 1, field: Real analysis, topic: Sums with endpoint singularities.

Circuit Bank

- **WHEN** you see a summand whose denominator is a product of consecutive values of one sequence **DO** compute the difference of those consecutive values and compare it with the numerator **BECAUSE** such a summand is $\frac{g(k)-g(k-1)}{g(k-1)g(k)} = \frac{1}{g(k-1)} - \frac{1}{g(k)}$, so the sum telescopes and no estimation is needed

- **WHEN** you see a difference of squares of sines or cosines **DO** apply the double angle formula first, then sum to product **BECAUSE** squares are multiplicative objects and differences are additive, so you must linearise before you can factor a difference

- **WHEN** you are asked for an asymptotic limit with a clean closed constant **DO** look for an exact closed form of the finite sum before estimating **BECAUSE** clean constants are the residue of exact identities, and an exact formula converts the limit into one line with no error control

- **WHEN** you see a sum whose terms blow up at one end of the range **DO** reverse the index so the blow up is at $j = 1$ and check the resulting series converges **BECAUSE** the growth rate in n is then read off the order of the pole, and no Riemann sum is available since the limiting integral diverges

- **WHEN** you divide by a trigonometric expression inside a sum **DO** state the range of angles that keeps it nonzero **BECAUSE** the upper limit $n - 1$ was chosen precisely to avoid a zero cosine, and a grader reads that clause as the difference between an identity and an assertion

Backtesting

1. First useful cue: the denominator is $\cos^2((k-1)\theta)\cos^2(k\theta)$, consecutive values of one sequence multiplied together.
2. Method the expression suggested: build the difference $\sec^2(k\theta) - \sec^2((k-1)\theta)$, confirm by double angle and sum to product that it reproduces the numerator times $\sin\theta$, and telescope.
3. Where you would hesitate, and the thought to reinforce: the temptation to treat the sum as a Riemann sum because $k\pi/(2n)$ looks like a sampled variable. The thought is that a Riemann sum grows like n, and you were handed n^3, so the analogy is dead on arrival.
4. The trap the question sets: the n^3 normalisation invites approximation, and the approximation that first comes to hand diverges. The problem is built so that the lazy analytic route is not merely long but wrong.
5. What makes you recognise it faster next time: the numerator being the sine of the mean of the doubled denominator angles. That is the sum to product identity read backwards, and it can only have been put there deliberately.
6. The reusable decision rule: consecutive values in a denominator means telescoping; verify by computing the difference of those values, never by hoping.

Mirror drills

1. Evaluate $\displaystyle\sum_{k=1}^{m} \frac{\sin((2k-1)x)}{\cos^2((k-1)x)\cos^2(kx)}$ for $0 < x < \frac{\pi}{2m}$. *Answer:* $\dfrac{\tan^2(mx)}{\sin x}$, by the same telescoping; the problem is the case $m = n-1$, $x = \pi/(2n)$.
2. Evaluate $\displaystyle\sum_{k=1}^{m} \frac{1}{\sin(kx)\sin((k+1)x)}$. *Answer:* $\dfrac{\cot x - \cot((m+1)x)}{\sin x}$, since $\sin x = \sin\big((k+1)x - kx\big)$ expands to $\sin((k+1)x)\cos(kx) - \cos((k+1)x)\sin(kx)$, giving $\cot(kx) - \cot((k+1)x)$ after dividing.
3. Show $\displaystyle\sum_{k=1}^{n-1} \frac{2k+1}{k^2(k+1)^2} = 1 - \frac{1}{n^2}$, and say in one sentence which feature of the summand told you so. *Answer:* the numerator is $(k+1)^2 - k^2$ and the denominator is the product of the corresponding consecutive squares, so the summand is $\frac{1}{k^2} - \frac{1}{(k+1)^2}$. This is the algebraic shadow of the trigonometric identity in the problem.

7.9 B3. A reflection restores the eigenvalue one

Let Q be an n-by-n real orthogonal matrix, and let $u \in \mathbb{R}^n$ be a unit column vector (that is, $u^T u = 1$). Let $P = I - 2uu^T$, where I is the n-by-n identity matrix. Show that if 1 is not an eigenvalue of Q, then 1 is an eigenvalue of PQ.

Read it out loud

Three objects, each of which must be translated from matrix language into geometric language before you write anything. Q is orthogonal, so it preserves lengths and inner products. The hypothesis that 1 is not an eigenvalue of Q says Q has no nonzero fixed vector, and equivalently that $Q - I$ is invertible. Say the equivalent form out loud, because an invertible matrix is something you can divide by, and a hypothesis you can divide by is a hypothesis you should use as a division. $P = I - 2uu^T$ is a rank one update of the identity, and rank one updates are never mysterious: P fixes everything orthogonal to u and sends u to $-u$, so P is the reflection in the hyperplane $u^\perp$, with $P^2 = I$ and $\det P = -1$. The conclusion, 1 is an eigenvalue of PQ, says PQ has a nonzero fixed vector.

Now read the whole statement as one sentence of geometry: composing a fixed-point-free orthogonal map with a reflection always produces a map with a fixed direction. That is a statement about parity, and it should smell like one, because reflections flip orientation and fixed-point-free orthogonal maps are exactly those of a definite determinant sign. Two proofs are therefore available in principle: a parity proof by determinants, and a constructive proof that produces the fixed vector. On the Putnam the constructive proof is worth more per line, because a produced vector cannot be wrong.

The decisive structural fact is that P differs from I by rank one. If $PQw = w$ then, multiplying by P and using $P^2 = I$, we get $Qw = Pw$, and Pw differs from w by a multiple of u. So the equation to solve is $(Q - I)w \in \operatorname{span}(u)$. Since $Q - I$ is invertible, that determines w up to scale immediately: there is exactly one candidate line, spanned by $(Q - I)^{-1}u$. There is no search here and no cleverness required. The rank one structure leaves exactly one place for the answer to be.

Fields embedded: the real orthogonal group, eigenvalues as fixed vectors, rank one perturbations, and (in the alternative route) the spectrum of real orthogonal matrices and the Cayley transform. Within thirty seconds you should have written $P^2 = I$, $Pw = w - 2(u^T w)u$, and $w = (Q - I)^{-1}u$.

Approaches, ranked worst to best

1. **Expand the characteristic polynomial of PQ.** *Cue:* eigenvalue questions are about characteristic polynomials. *Circuit:* compute $\det(PQ - \lambda I)$ in coordinates. There is nothing to expand: Q is an arbitrary orthogonal matrix of arbitrary size. Any attempt to write entries produces symbols with no relations you can exploit. This is zombie maths in its purest form, doing the thing the words suggest with no reading of the structure.

2. **Test $n = 2$ and $n = 3$.** *Cue:* small cases build intuition. *Circuit:* specialise and look for the mechanism. For $n = 2$, Q is a rotation by $\theta \neq 0$ and P is a reflection, so PQ is a reflection and every reflection of the plane fixes a line. That is genuinely informative, because it shows the mechanism is orientation and not size. It is not a proof, and generalising the two-dimensional picture directly does not work, because in higher dimensions PQ is not a reflection.

3. **Determinant parity.** *Cue:* orthogonal, fixed-point-free, and a reflection all point at det. *Circuit:* spectrum of a real orthogonal matrix, then a contradiction. The eigenvalues of a real orthogonal matrix lie on the unit circle and the non-real ones occur in conjugate pairs of product 1. If 1 is not an eigenvalue, then $\det Q = (-1)^k$ where k is the multiplicity of -1, and $k \equiv n$

(mod 2) since the remaining eigenvalues pair up. Hence $\det Q = (-1)^n$. If PQ also had no eigenvalue 1, the same applies to the orthogonal matrix PQ, giving $\det(PQ) = (-1)^n$, while $\det(PQ) = \det P \det Q = -(-1)^n$. Contradiction. This is a complete and memorable proof; it costs you the spectral lemma and it yields no eigenvector.

4. **Matrix determinant lemma.** *Cue:* P is a rank one update, and rank one updates have a determinant formula. *Circuit:* $\det(A + vw^T) = \det A\,(1 + w^T A^{-1} v)$. Since $P^{-1} = P$, $\det(PQ - I) = \det P \det(Q - P) = -\det\big((Q - I) + 2uu^T\big) = -\det(Q - I)\big(1 + 2u^T(Q - I)^{-1}u\big)$, and the bracket vanishes because $u^T(Q - I)^{-1}u = -\frac{1}{2}$. Short and structural, but it imports a lemma and proves only that something is singular.

5. **Construct the fixed vector.** *Cue:* $Pw - w$ is always a multiple of u, and $Q - I$ is invertible. *Circuit:* solve $(Q - I)w \in \operatorname{span}(u)$, then normalise. The candidate $w = (Q - I)^{-1}u$ is forced, not guessed, and the single scalar that must come out right, $u^T w$, is pinned by the one property of Q you have not yet used: it preserves norms. Best because it is four lines, uses no lemma beyond the definition of orthogonality, produces the eigenvector explicitly, and even shows the eigenspace is exactly one dimensional.

The ideal solution

Since $u^T u = 1$,

$$P^2 = (I - 2uu^T)^2 = I - 4uu^T + 4u(u^T u)u^T = I,$$

so P is invertible with $P^{-1} = P$, and for every w,

$$Pw = w - 2(u^T w)\,u.$$

Because 1 is not an eigenvalue of Q, the matrix $Q - I$ is invertible. Define

$$w = (Q - I)^{-1}u.$$

Then $w \neq 0$ (as $u \neq 0$), and by construction

$$Qw = w + u.$$

Now use the only property of Q not yet used: Q preserves the Euclidean norm, so $\|Qw\| = \|w\|$. Squaring $Qw = w + u$,

$$\|w\|^2 = \|Qw\|^2 = \|w + u\|^2 = \|w\|^2 + 2u^T w + \|u\|^2 = \|w\|^2 + 2u^T w + 1,$$

and therefore

$$u^T w = -\tfrac{1}{2}.$$

Consequently

$$Pw = w - 2\left(-\tfrac{1}{2}\right)u = w + u = Qw,$$

and applying P to both sides,

$$PQw = P(Pw) = P^2 w = w.$$

Since $w \neq 0$, the number 1 is an eigenvalue of PQ, with eigenvector $(Q - I)^{-1}u$. ■

Remark 7.9.1. The eigenvector is unique up to scale. Indeed $PQw = w$ is equivalent to $Qw = Pw$, that is to $(Q - I)w = -2(u^T w)u \in \operatorname{span}(u)$, so any such w lies in $(Q - I)^{-1}\operatorname{span}(u)$, a one dimensional space. Hence the eigenvalue 1 of PQ has geometric multiplicity exactly 1.

Remark 7.9.2. The scalar identity proved above is worth isolating: for every real orthogonal Q without eigenvalue 1 and every unit vector u,

$$u^T(Q - I)^{-1}u = -\tfrac{1}{2}.$$

Since this holds for every unit u, the symmetric part of $(Q - I)^{-1}$ is exactly $-\frac{1}{2}I$, that is, $(Q - I)^{-1} + \frac{1}{2}I$ is skew-symmetric. Equivalently $(Q + I)(Q - I)^{-1}$ is skew-symmetric, which is the Cayley transform.

Layer 1: WHAT

Block 1. Translate: P is the reflection in $u^\perp$; $P^2 = I$; $Pw = w - 2(u^T w)u$; 1 is an eigenvalue of M means M has a nonzero fixed vector.

Block 2. Rewrite the target: $PQw = w$ if and only if $Qw = Pw$, because P is its own inverse.

Block 3. Read the right hand side: Pw differs from w by a multiple of u, so the equation says $(Q - I)w \in \text{span}(u)$.

Block 4. Use the hypothesis as a division: $Q - I$ is invertible, so the candidate is forced to be $w = (Q - I)^{-1}u$ up to scale.

Block 5. Test the candidate. It satisfies $Qw = w + u$ by construction, so everything reduces to the single scalar $u^T w$.

Block 6. Pin the scalar with the unused hypothesis: $\|Qw\| = \|w\|$ gives $u^T w = -\frac{1}{2}$, exactly the value that makes $Pw = w + u$.

Block 7. Conclude, and note the eigenspace is one dimensional.

Juxtaposition. The nominal route treats the conclusion as a determinant statement and goes hunting for $\det(PQ - I) = 0$: either by expanding, or by the spectral parity argument, or by importing the matrix determinant lemma. All three are proofs by contradiction or by formula, and all three tell you only that a fixed vector exists. The bifurcation point is the sentence you write after reading the conclusion. If you write $\det(PQ - I) = 0$, you are committed to determinants and to whichever lemma you can remember. If you write $PQw = w$ for some $w \neq 0$, then the next line is $Qw = Pw$, and from there the rank one structure of P does the rest. Eigenvalue equals fixed vector is the more useful translation whenever the matrix has any explicit structure at all.

Layer 2: HOW

Block 1. **Cue.** $P = I - 2uu^T$ with u a unit vector, a rank one update of the identity. **Why natural.** A rank one update acts as the identity on a hyperplane, so its whole content is what it does to one direction. Computing $Pu = u - 2u(u^T u) = -u$ and $Pv = v$ for $v \perp u$ identifies P instantly as a reflection, and $P^2 = I$ follows either from that description or from one line of algebra. Knowing $P^{-1} = P$ is what lets you move P across an equation later without introducing an inverse you would have to analyse. **Link to the next block.** Since P is its own inverse, the fixed vector equation for PQ can be rearranged into a comparison of Q and P directly.

Block 2. **Cue.** The conclusion names an eigenvalue, and the eigenvalue is 1. **Why natural.** Eigenvalue 1 has a coordinate-free meaning: a nonzero fixed vector. That reading is superior here because you are being asked to prove existence, and existence proofs are cheapest when you can exhibit the object. Rewriting $PQw = w$ as $Qw = Pw$ removes the composition and turns the problem into a question about where the two maps agree. **Link to the next block.** You now have two explicit expressions to compare, and one of them, Pw, has a very restricted form.

Block 3. **Cue.** $Pw = w - 2(u^T w)u$, so $Pw - w$ always lies on the fixed line $\text{span}(u)$. **Why natural.** This is the definition-level consequence of rank one. Whatever w is, P can only move it parallel to u. So the equation $Qw = Pw$ can only hold if Q also moves w parallel to u, that is $(Q - I)w \in \text{span}(u)$. The unknown vector has been reduced from n degrees of freedom to a one dimensional condition without any computation. **Link to the next block.** A membership condition of the form $(Q - I)w \in \text{span}(u)$ is solved by inverting $Q - I$, and the hypothesis has just handed you that inverse.

Block 4. **Cue.** The hypothesis says 1 is not an eigenvalue of Q, which is the same as $\det(Q - I) \neq 0$. **Why natural.** A negative hypothesis is useless until you turn it into a positive tool. Not an eigenvalue means invertible means you may divide. So the hypothesis is not a condition to check at the end, it

is the engine that produces the candidate. Applying $(Q-I)^{-1}$ to u gives the unique line on which the equation can possibly hold, so the candidate is forced rather than guessed. **Link to the next block.** You have a candidate. All that remains is a consistency check on one scalar.

Block 5. Cue. The candidate satisfies $Qw = w + u$ exactly, and the requirement is $Qw = w - 2(u^T w)u$. **Why natural.** Comparing the two gives the single scalar equation $-2(u^T w) = 1$. Everything vectorial has already matched. Reducing an n dimensional problem to one scalar identity is the normal outcome of a rank one structure, and the moment you see it you should ask which hypothesis has not yet been spent, because that hypothesis must be what makes the scalar come out right. **Link to the next block.** The unused hypothesis is that Q is orthogonal, in the sense of preserving norms.

Block 6. Cue. $Qw = w + u$ and $\|Qw\| = \|w\|$. **Why natural.** Orthogonality is most usable in its metric form. Squaring an equation whose two sides have equal norms kills the $\|w\|^2$ terms and leaves a linear relation between $u^T w$ and $\|u\|^2$. Geometrically this is the statement that $0, w, Qw$ is an isosceles triangle, so the chord $Qw - w$ is perpendicular to the mean direction $Qw + w$; the value $-\frac{1}{2}$ is the projection of that isosceles condition onto the chord. Note that it is exactly here that u being a unit vector is used, and if u had norm c the same computation would give $u^T w = -c^2/2$, matching the rescaled reflection. **Link to the next block.** The scalar is correct, so substitute back and finish.

Block 7. Cue. A verified identity $Qw = Pw$ with $w \neq 0$. **Why natural.** Applying P to both sides and using $P^2 = I$ converts the agreement into the required eigenvector equation with no further work. Recording that the solution set was forced also gives the multiplicity for free, which costs one sentence and shows the grader you understood why the vector was unique.

Layer 3: WHY

The route is ideal because it uses each hypothesis exactly once, in its most usable form: P rank one gives the direction, $Q - I$ invertible gives the vector, Q orthogonal gives the scalar. When a proof consumes each hypothesis exactly once and in a different way, you can be confident it is the intended route and that nothing has been wasted.

Underneath, the identity $u^T(Q-I)^{-1}u = -\frac{1}{2}$ is doing all the work, and it is not an accident about u. It says the symmetric part of $(Q-I)^{-1}$ equals $-\frac{1}{2}I$ for every fixed-point-free orthogonal Q. Equivalently $A = (Q+I)(Q-I)^{-1}$ is skew-symmetric, which is the Cayley transform: the map $A \mapsto (I-A)(I+A)^{-1}$ is a bijection from skew-symmetric matrices onto orthogonal matrices without eigenvalue -1, and it is the rational parametrisation of the orthogonal group, the matrix analogue of the tangent half angle substitution. Recognising that the scalar identity is a shadow of the Cayley transform is what upgrades this problem from a one-off to a piece of equipment.

The parity explanation is the other half of the truth, and you should hold both. A real orthogonal matrix has all eigenvalues on the unit circle, with non-real ones in conjugate pairs whose product is 1; if 1 is not among them then the multiplicity of -1 has the same parity as n, so $\det Q = (-1)^n$. Fixed-point-free orthogonal maps therefore have a forced determinant, and multiplying by a reflection breaks that forcing, so the product must acquire a fixed vector. In the language of topology, an orthogonal map with no eigenvalue 1 has no fixed point on the sphere S^{n-1}, and a fixed-point-free self map of the sphere is homotopic to the antipodal map, whose degree is $(-1)^n$. The determinant is the degree. That is why the statement is really about orientation.

Discernment mechanism: when a conclusion is of the form some specific number is an eigenvalue, ask whether the matrix has structure that makes the eigenvector constructible. Rank one updates, projections, reflections, permutation-like structure, and circulants all do. If yes, construct.

If not, fall back on determinants, traces or parity. Train it by rewriting every eigenvalue statement you meet as a statement about a vector, and every non-eigenvalue hypothesis as an invertibility statement you are allowed to divide by.

The examiners nudged clearly: they wrote P in the explicit form $I - 2uu^T$ rather than saying let P be a reflection, which is an invitation to use the algebraic rank one form; and they gave the hypothesis as a negative statement about an eigenvalue, which is an invitation to convert it into invertibility.

Revolving concepts

Householder reflections. For a unit u, $P = I - 2uu^T$ satisfies $P = P^T$, $P^2 = I$, $Pu = -u$, $Pv = v$ for $v \perp u$, and $\det P = -1$. Every orthogonal matrix is a product of at most n Householder reflections; the minimum number needed is $n - \dim\ker(Q - I)$, so Q needs exactly n precisely when it has no eigenvalue 1. This gives a third proof: if neither Q nor PQ had eigenvalue 1, each would be a product of exactly n reflections and so both would have determinant $(-1)^n$, which contradicts $\det(PQ) = -\det Q$. See Book 1, field: Linear algebra, topic: Householder reflections and QR.

Spectrum of a real orthogonal matrix. All eigenvalues have modulus 1; non-real eigenvalues come in conjugate pairs; the real canonical form is a block diagonal matrix of 2×2 rotation blocks together with ± 1 entries. Consequences: $\det Q = \pm 1$; if n is odd and $\det Q = 1$ then 1 is an eigenvalue (Euler's rotation theorem); if 1 is not an eigenvalue then $\det Q = (-1)^n$. See Book 1, field: Linear algebra, topic: Orthogonal group and normal forms.

Rank one updates. $\det(A + vw^T) = \det A\,(1 + w^T A^{-1} v)$ (matrix determinant lemma) and $(A + vw^T)^{-1} = A^{-1} - \frac{A^{-1} v w^T A^{-1}}{1 + w^T A^{-1} v}$ (the Sherman and Morrison formula). Both say the same thing: a rank one perturbation changes everything through a single scalar $w^T A^{-1} v$. Recognising that scalar in a problem is usually the whole problem. See Book 1, field: Matrices and determinants, topic: Rank one updates.

Cayley transform. If A is skew-symmetric then $I + A$ is invertible and $Q = (I - A)(I + A)^{-1}$ is orthogonal without eigenvalue -1; conversely if Q is orthogonal without eigenvalue -1 then $A = (I - Q)(I + Q)^{-1}$ is skew. The version used here is the reflection of that statement about the eigenvalue 1: for Q orthogonal without eigenvalue 1, $(Q + I)(Q - I)^{-1}$ is skew, equivalently $(Q - I)^{-1} + \frac{1}{2} I$ is skew. See Book 1, field: Linear algebra, topic: Cayley transform.

Fixed vectors and iteration. There is no recursion in this problem, but the associated generalisation is worth recording: for any invertible M and rank one update $P = I - 2uu^T$, the fixed vectors of PM are exactly the solutions of $(M - I)w \in \operatorname{span}(u)$ together with the normalisation $u^T w = -\frac{1}{2} \cdot$ (a factor determined by M). The general principle is that composing with a rank one update reduces an n dimensional existence question to a single scalar equation, and the scalar is $u^T (M - I)^{-1} u$. See Book 1, field: Linear algebra, topic: Fixed vectors of perturbed maps.

Circuit Bank

- **WHEN** you see the hypothesis that some number is not an eigenvalue **DO** immediately rewrite it as the corresponding matrix being invertible, and plan to divide by it **BECAUSE** a negative spectral statement is unusable, an invertibility statement is a tool that constructs vectors
- **WHEN** you are asked to show that 1 is an eigenvalue **DO** try to exhibit a nonzero fixed vector rather than to show a determinant vanishes **BECAUSE** a produced vector is a complete proof with no lemma imported, and it also delivers the eigenspace dimension
- **WHEN** you see $I + vw^T$ or $I - 2uu^T$ **DO** note that the map moves every vector only in the direction v, and reduce the problem to one scalar **BECAUSE** rank one means the entire perturbation is carried by a single scalar, usually $w^T A^{-1} v$

- **WHEN** you have used all the structure except orthogonality and one scalar remains **DO** square the vector identity and use $\|Qx\| = \|x\|$ **BECAUSE** norm preservation is the metric form of orthogonality and is the cheapest way to extract a scalar relation from a vector equation
- **WHEN** you see a reflection composed with something **DO** think determinant and orientation as a sanity check on whether the claim can be true **BECAUSE** reflections have determinant -1, so any claim about a composition with a reflection is usually a parity statement in disguise

Backtesting

1. First useful cue: P is a rank one update, so $Pw - w$ is always parallel to u.
2. Method the expression suggested: rewrite $PQw = w$ as $Qw = Pw$, deduce $(Q - I)w \in \text{span}(u)$, invert $Q - I$, and check the one scalar with norm preservation.
3. Where you would hesitate, and the thought to reinforce: after writing $w = (Q - I)^{-1}u$, whether the normalisation can be arranged by scaling w. It cannot, because scaling w scales both sides of $(Q - I)w = -2(u^T w)u$ equally; the scalar identity is a genuine constraint and is exactly what orthogonality supplies.
4. The trap the question sets: pushing you toward determinants. The determinant route needs the spectral structure of real orthogonal matrices, which is fine if you know it and fatal if you half remember it, and it never produces the vector.
5. What makes you recognise it faster next time: the pairing of a rank one update with an invertibility hypothesis. That pairing always means the answer is a specific vector obtained by inverting the invertible part and applying it to the rank one direction.
6. The reusable decision rule: eigenvalue statements become fixed vector statements; not an eigenvalue becomes invertible; rank one becomes one scalar.

Mirror drills

1. Prove Euler's rotation theorem: if n is odd and Q is orthogonal with $\det Q = 1$, then 1 is an eigenvalue of Q. *Answer:* $\det(Q - I) = \det(Q - QQ^T) = \det Q \det(I - Q^T) = \det Q(-1)^n \det(Q - I)$, so for n odd and $\det Q = 1$ we get $\det(Q - I) = -\det(Q - I) = 0$.
2. Show that for real orthogonal Q without eigenvalue 1, the matrix $(Q + I)(Q - I)^{-1}$ is skew-symmetric. *Hint:* the problem proved $u^T(Q - I)^{-1}u = -\frac{1}{2}$ for every unit u, so the symmetric part of $(Q - I)^{-1}$ is $-\frac{1}{2}I$; now write $(Q + I)(Q - I)^{-1} = I + 2(Q - I)^{-1}$.
3. Let M be any real matrix with 1 not an eigenvalue, let u be a unit vector, and set $P = I - 2uu^T$. Show that 1 is an eigenvalue of PM if and only if $u^T(M - I)^{-1}u = -\frac{1}{2}$. *Answer:* the fixed vectors of PM are the nonzero w with $(M - I)w \in \text{span}(u)$, hence $w = c(M - I)^{-1}u$, and substituting into $Mw = w - 2(u^T w)u$ gives the stated scalar condition. Orthogonality of M is exactly what guarantees it.

7.10 B4. Manufacturing a mixed partial with Euler operators

Let $\mathcal{F}$ be the set of functions $f(x,y)$ that are twice continuously differentiable for $x \geq 1$, $y \geq 1$ and that satisfy the following two equations (where subscripts denote partial derivatives):

$$xf_x + yf_y = xy\ln(xy),$$
$$x^2 f_{xx} + y^2 f_{yy} = xy.$$

For each $f \in \mathcal{F}$, let

$$m(f) = \min_{s \geq 1} \left(f(s+1,s+1) - f(s+1,s) - f(s,s+1) + f(s,s)\right).$$

Determine $m(f)$, and show that it is independent of the choice of f.

Read it out loud

Read the quantity being minimised first, because it is the only thing you actually need. The expression $f(s+1,s+1) - f(s+1,s) - f(s,s+1) + f(s,s)$ is the mixed second difference of f over the unit square $[s,s+1]^2$. For a twice continuously differentiable f it equals $\iint_{[s,s+1]^2} f_{xy}$, by applying the fundamental theorem of calculus once in each variable. So the entire problem is: find f_{xy}. Nothing else about f matters, and in particular the mixed second difference annihilates every function of the form $u(x) + v(y)$, which is exactly why the answer can be independent of f.

Now read the two given equations and notice what is missing. You are given f_x, f_y combined with coefficients x and y, and f_{xx}, f_{yy} combined with coefficients x^2 and y^2. You are not given anything mixed. So the problem has a single mechanical task at its heart: manufacture f_{xy} out of pure derivatives. There is only one way to make a mixed derivative from first order data, namely to differentiate the first equation again, once in x and once in y, and to arrange the algebra so that the pure second derivatives cancel against the second equation.

The coefficients tell you which derivative to use. A first derivative multiplied by x and a second derivative multiplied by x^2 is the signature of the Euler operator $D = x\frac{\partial}{\partial x}$, which in the variable $u = \ln x$ is simply $\partial/\partial u$. That is the same signature you meet in the Cauchy and Euler differential equation $ax^2y'' + bxy' + cy = 0$, and the response is identical: pass to logarithms and the operators become plain derivatives with constant coefficients. Once you are in that language, the algebra to perform is the completed square $2DE = (D+E)^2 - D^2 - E^2$, and the two given equations supply precisely $D + E$ and (after correction) $D^2 + E^2$.

Fields embedded: multivariable calculus (mixed partials, Clairaut, iterated integrals), linear differential operators and their algebra, and a one line optimisation at the end. Within thirty seconds you should have written: target $= \iint f_{xy}$; $D = x\partial_x$, $E = y\partial_y$; $x^2 f_{xx} = D(D-1)f$; and the plan, apply $D + E$ to the first equation.

Approaches, ranked worst to best

1. **Solve the system for all f.** *Cue:* two partial differential equations and a family $\mathcal{F}$. *Circuit:* find the general solution, then compute. You can do it: the general element is $\frac{1}{2}(xy\ln(xy) - xy) + a\ln(x/y) + b$. But finding the general solution of a coupled system is a much bigger job than the question asks, and if you fail to prove you have found all of them you cannot conclude independence of f. Maximum ink, maximum risk.

2. **Guess a particular solution, then prove independence separately.** *Cue:* both equations are symmetric in x and y and involve xy. *Circuit:* posit $f = h(xy)$, solve for h, then classify the difference of two solutions. Substituting $f = h(xy)$ into the first equation gives $2xyh'(xy) = xy\ln(xy)$, hence $h(t) = \frac{1}{2}(t\ln t - t)$, which does satisfy both equations. Then show any two members of $\mathcal{F}$ differ by something with vanishing mixed second difference. This is a

genuinely good route and it has the bonus of proving $\mathcal{F}$ is nonempty, but it is two jobs instead of one.

3. **The magic linear combination.** *Cue:* you need f_{xy}, so differentiate. *Circuit:* form $x\partial_x(1) + y\partial_y(1) - (1) - (2)$ and watch the pure terms cancel. This is the shortest route in raw lines, and it works, but presented as a combination pulled out of the air it is unrepeatable. If you cannot say why those four terms with those signs, you have memorised an answer rather than installed a circuit.

4. **Euler operators, then complete the square.** *Cue:* coefficients x with f_x and x^2 with f_{xx}. *Circuit:* $D = x\partial_x$, $x^2\partial_{xx} = D(D-1)$, and $2DE = (D+E)^2 - D^2 - E^2$. The two given equations become $(D+E)f$ known and $D^2f + E^2f$ known. Applying $D+E$ to the first gives $(D+E)^2 f$, and subtracting delivers $2DEf = 2xyf_{xy}$. Every step is forced by the algebra of operators, and the same manipulation is exactly why the combination in the previous approach works. Best because it is short, motivated, and reusable.

The ideal solution

Write $D = x\dfrac{\partial}{\partial x}$ and $E = y\dfrac{\partial}{\partial y}$, and label the given equations

$$(1)\ \ Df + Ef = xy\ln(xy), \qquad (2)\ \ x^2 f_{xx} + y^2 f_{yy} = xy.$$

Since $D(Df) = x\partial_x(xf_x) = xf_x + x^2 f_{xx}$, we have the operator identity

$$x^2 f_{xx} = D^2 f - Df, \qquad \text{and similarly} \qquad y^2 f_{yy} = E^2 f - Ef.$$

Also $DEf = x\partial_x\big(yf_y\big) = xy\, f_{yx}$, and $EDf = xy\, f_{xy}$; since f is twice continuously differentiable, Clairaut's theorem gives $f_{xy} = f_{yx}$, so $DEf = EDf = xyf_{xy}$. All the expressions written here involve only first and second derivatives of f, so every step below is legitimate for $f \in \mathcal{F}$; no third derivative is ever required.

Substituting the operator identity into (2) and then using (1),

$$D^2 f + E^2 f = xy + \big(Df + Ef\big) = xy + xy\ln(xy). \tag{2′}$$

Now apply the operator $D+E$ to both sides of (1). On the left, $(D+E)(Df+Ef) = D^2f + E^2f + 2DEf$. On the right,

$$D\big(xy\ln(xy)\big) = x\big(y\ln(xy) + y\big) = xy\ln(xy) + xy,$$

and by the symmetry of $xy\ln(xy)$ in x and y the operator E gives the same, so

$$D^2 f + E^2 f + 2DEf = 2xy\ln(xy) + 2xy. \tag{1′}$$

Subtracting (2′) from (1′),

$$2DEf = xy\ln(xy) + xy, \qquad \text{that is} \qquad 2xy\, f_{xy} = xy\big(\ln(xy) + 1\big).$$

Since $x, y \geq 1$ we may divide by xy:

$$f_{xy}(x,y) = \tfrac{1}{2}\big(\ln x + \ln y + 1\big) \qquad \text{for all } x, y \geq 1.$$

This is the same for every $f \in \mathcal{F}$, which is where the independence of f comes from.

Now evaluate the mixed second difference. Fix $s \geq 1$ and put

$$\Delta(s) = f(s+1, s+1) - f(s+1, s) - f(s, s+1) + f(s, s).$$

For each fixed x, the fundamental theorem of calculus applied to $y \mapsto f(x,y)$ gives $f(x,s+1) - f(x,s) = \int_s^{s+1} f_y(x,y)\,dy$. Applying it again to $x \mapsto f_y(x,y)$ and using continuity of f_{xy} to interchange the (proper, continuous) iterated integrals,

$$\Delta(s) = \int_s^{s+1}\int_s^{s+1} f_{xy}(x,y)\,dx\,dy = \frac{1}{2}\int_s^{s+1}\int_s^{s+1} \big(\ln x + \ln y + 1\big)\,dx\,dy.$$

The square has unit area, and by symmetry the two logarithm terms contribute equally, so

$$\Delta(s) = \frac{1}{2}\left(2\int_s^{s+1} \ln x\,dx + 1\right) = \frac{1}{2} + \int_s^{s+1} \ln x\,dx.$$

Differentiating, $\Delta'(s) = \ln(s+1) - \ln s > 0$ for $s \geq 1$, so Δ is strictly increasing on $[1,\infty)$ and its minimum there is attained at $s = 1$. Since $\int_1^2 \ln x\,dx = \big[x\ln x - x\big]_1^2 = 2\ln 2 - 1$,

$$m(f) = \frac{1}{2} + 2\ln 2 - 1 = \boxed{2\ln 2 - \tfrac{1}{2}}$$

for every $f \in \mathcal{F}$, independently of f. (Numerically $m(f) \approx 0.8863$.)

Remark 7.10.1. $\mathcal{F}$ is nonempty: $f_0(x,y) = \frac{1}{2}\big(xy\ln(xy) - xy\big)$ satisfies $xf_{0,x} = yf_{0,y} = \frac{1}{2}xy\ln(xy)$ and $x^2 f_{0,xx} = y^2 f_{0,yy} = \frac{1}{2}xy$. Moreover $\mathcal{F} = \{f_0 + a\ln(x/y) + b : a,b \in \mathbb{R}\}$: if $f_0 + g \in \mathcal{F}$ then $g_{xy} = 0$, so $g = u(x) + v(y)$, and $xg_x + yg_y = 0$ says $xu'(x) = -yv'(y)$, a function of x equal to a function of y, hence a constant a. Every such g is a sum of a function of x and a function of y, so its mixed second difference vanishes, which is a second and completely explicit reason for the independence of f.

Layer 1: WHAT

Block 1. Read the target as a mixed second difference, hence as $\iint f_{xy}$ over the unit square. Conclude that only f_{xy} matters.

Block 2. Notice the data are pure derivatives with Euler coefficients, so introduce $D = x\partial_x$, $E = y\partial_y$ and record $x^2\partial_{xx} = D(D-1)$, $DE = xy\partial_{xy}$.

Block 3. Rewrite equation (2) as $D^2 f + E^2 f = xy + xy\ln(xy)$, using equation (1) to absorb the first order correction.

Block 4. Apply $D + E$ to equation (1) to obtain $(D+E)^2 f$, which is $D^2 f + E^2 f + 2DEf$.

Block 5. Subtract. The pure squares cancel by construction and $2xyf_{xy} = xy(\ln(xy) + 1)$ falls out. Independence of f is now proved, since f_{xy} is determined.

Block 6. Integrate over the unit square: $\Delta(s) = \frac{1}{2} + \int_s^{s+1} \ln x\,dx$.

Block 7. $\Delta' = \ln(s+1) - \ln s > 0$, so minimise at $s = 1$ and evaluate.

Juxtaposition. The nominal route reads the words let $\mathcal{F}$ be the set of functions satisfying, and starts solving the system for f. That is the consumption reflex: the question mentioned a family, so describe the family. It works, eventually, and it is three times the length. The bifurcation point is the first line you write after reading the definition of $m(f)$. If you write out the four values of f and start hunting for f itself, you are solving the wrong problem. If you write $\iint f_{xy}$, you have converted the entire question into a single unknown function and the rest is forced.

Layer 2: HOW

Block 1. **Cue.** Four values of f at the corners of a unit square with alternating signs. **Why natural.** That pattern is the definition of a second mixed difference, and the second mixed difference is the discrete analogue of $\partial^2/\partial x\partial y$. Applying the fundamental theorem of calculus in each variable turns it into $\iint f_{xy}$ exactly, not approximately. The immediate structural payoff is that any additively separable part of f contributes nothing, which is the mechanism that will make $m(f)$ independent of f. **Link to the next block.** You now need f_{xy} and nothing else, so look at the data and ask how to produce a mixed derivative.

Block 2. **Cue.** First derivatives carrying a factor x, second derivatives carrying a factor x^2. **Why natural.** That is the fingerprint of the Euler operator $D = x\partial_x$, whose powers are $D^2 = x^2\partial_{xx} + x\partial_x$. Equivalently, in the variable $u = \ln x$ the operator D is ∂_u: the substitution that makes a Cauchy and Euler differential equation constant coefficient is the same substitution that makes this system translation invariant. Introducing D and E costs one line and converts the two equations into statements about a commutative algebra of operators, where you can do ordinary algebra. **Link to the next block.** In that algebra you want DE, and you have $D + E$ and, after a correction, $D^2 + E^2$.

Block 3. **Cue.** Equation (2) contains $D^2 - D$ and $E^2 - E$, while equation (1) contains $D + E$. **Why natural.** The correction terms $-Df - Ef$ are already known from equation (1), so you can eliminate them and get a clean expression for $D^2f + E^2f$. Always normalise your data into the same basis before combining them; here the basis is $\{D + E, D^2 + E^2, DE\}$. **Link to the next block.** With $D + E$ and $D^2 + E^2$ both known, the identity $2DE = (D + E)^2 - D^2 - E^2$ tells you exactly what to do next.

Block 4. **Cue.** You possess $(D + E)f$ as an explicit function and you want $(D + E)^2 f$. **Why natural.** Applying $D + E$ to a known function is just differentiation of the right hand side, which is elementary. This is the standard move for extracting higher information from a first order equation: differentiate the equation, not the unknown. Note that only second derivatives of f appear on the left, so the C^2 hypothesis is enough and no regularity is being assumed that you were not given. **Link to the next block.** The two expressions now share the terms $D^2f + E^2f$, so subtract.

Block 5. **Cue.** Two equations whose difference isolates $2DEf$. **Why natural.** This is completing the square in operator form, the same identity as $2ab = (a + b)^2 - a^2 - b^2$. The reason the setter's system is solvable at all is that they gave you the two symmetric functions of D and E that determine the product. Dividing by xy is legal because the domain is $x, y \geq 1$, and saying so is worth a clause. **Link to the next block.** You have f_{xy} explicitly; feed it into the integral from Block 1.

Block 6. **Cue.** $\iint$ of $\frac{1}{2}(\ln x + \ln y + 1)$ over a unit square. **Why natural.** The integrand is separable, so the double integral splits into single integrals, and the square has unit side so the constant term contributes $\frac{1}{2}$ and each logarithm contributes $\frac{1}{2}\int_s^{s+1} \ln$. Symmetry in x and y means you compute one integral, not two. **Link to the next block.** You have a closed form in s; minimise it.

Block 7. **Cue.** A minimum over the closed unbounded interval $s \geq 1$. **Why natural.** Differentiating under the integral sign is unnecessary here since $\frac{d}{ds}\int_s^{s+1} \ln = \ln(s + 1) - \ln s$ by the fundamental theorem, and this is positive because ln is strictly increasing. A strictly increasing continuous function on $[1, \infty)$ attains its minimum at the left endpoint, so the minimum exists and equals $\Delta(1)$. Say that the minimum is attained; a question that writes min rather than inf expects you to notice.

Layer 3: WHY

The route is ideal because it identifies the single invariant of the family. The problem hands you a set $\mathcal{F}$ and asks for a quantity that turns out not to depend on which member you take. Whenever that happens, the honest question is: which functional of f is pinned down by the data? Here the data pin down f_{xy} exactly, and the quantity asked for depends only on f_{xy}. Once those two facts are in place the independence is not a surprise to be verified at the end but the reason the question was posed. Contrast with the route that solves for all of $\mathcal{F}$: it reaches the same conclusion by describing a two parameter family and then observing that the two parameters happen to cancel. Same answer, far less understanding.

Underneath sits the algebra of the operators $D = x\partial_x$ and $E = y\partial_y$. They commute, they generate scalings, and under $x = e^u$, $y = e^v$ they become ∂_u and ∂_v. In those coordinates the

problem reads: given $F_u + F_v$ and $F_{uu} + F_{vv}$, find F_{uv}; and the answer is the identity $2F_{uv} = (\partial_u + \partial_v)(F_u + F_v) - (F_{uu} + F_{vv})$. That is why the problem is well posed with exactly two equations: the two symmetric functions $p = D + E$ and $q = D^2 + E^2$ determine the elementary symmetric product DE through $2DE = p^2 - q$, exactly as $2ab = (a+b)^2 - (a^2 + b^2)$ recovers a product from a sum and a sum of squares. A setter who wants to hide f_{xy} behind two innocent equations has essentially no other choice.

The second truth is the exactness of the discrete to continuous translation. The second mixed difference over $[s, s+1]^2$ is not approximately f_{xy} at some point, it is the exact double integral of f_{xy} over the square, by two applications of the fundamental theorem of calculus. That exactness is what lets you compute $m(f)$ in closed form rather than estimate it. The same reflex applies whenever you see an alternating sum of function values at the corners of a box: in one dimension a difference is $\int f'$, in two a mixed second difference is $\iint f_{xy}$, in n dimensions an alternating sum over 2^n corners is the integral of $\partial^n f / \partial x_1 \cdots \partial x_n$.

Discernment mechanism: read the objective before the data. The objective told you that only f_{xy} matters; the data then had exactly one job. Candidates who read the data first spend their time on the family $\mathcal{F}$ because that is what the first half of the question talks about. Train this by making it a rule: on any problem that defines a set and then asks for a number, find out which feature of the set members the number depends on before you study the set.

The examiners nudged with the coefficients. They could have written the first equation as $f_x + f_y = \ldots$, and they did not; the factors x, y, x^2, y^2 are there to tell you to use D and E, and the perfect symmetry of both equations in x and y is there to tell you that only the symmetric combinations matter.

Revolving concepts

Mixed second differences. For f of class C^2, $f(a+h, b+k) - f(a+h, b) - f(a, b+k) + f(a, b) = \int_a^{a+h} \int_b^{b+k} f_{xy}$. Consequences: the mixed second difference vanishes identically if and only if f is additively separable, $f = u(x) + v(y)$; it is the model case of the inclusion and exclusion pattern over the 2^n vertices of a box, which for n variables computes $\int \partial^n f / \partial x_1 \cdots \partial x_n$. See Book 1, field: Calculus and integrals, topic: Mixed partials and differences.

Clairaut's theorem. If f_{xy} and f_{yx} exist and are continuous near a point then they are equal there. This is what licenses $DEf = EDf$ and the interchange of the order of integration in the iterated integral (both integrands being continuous on a compact square, so Fubini for continuous functions applies). See Book 1, field: Real analysis, topic: Equality of mixed partials.

Euler operators and the Cauchy and Euler equation. With $D = x\frac{d}{dx}$ one has $x^k \frac{d^k}{dx^k} = D(D-1)\cdots(D-k+1)$, and under $x = e^u$, $D = \frac{d}{du}$. Hence any equation whose kth derivative carries the coefficient x^k becomes constant coefficient in logarithmic variables. The archetype is $ax^2y'' + bxy' + cy = 0$, solved by $y = x^r$ with $ar(r-1) + br + c = 0$, which is the indicial equation. Recognising the pattern is the trigger for the substitution. See Book 1, field: Sequences and recurrences, topic: Euler operators and equidimensional equations.

Symmetric functions of commuting operators. For commuting D, E one has $2DE = (D+E)^2 - D^2 - E^2$, and more generally the power sums $p_k = D^k + E^k$ determine the elementary symmetric functions through Newton's identities. The generalised statement worth carrying: if a problem gives you p_1 and p_2 for two commuting objects, it has given you their product, and if it gives you $p_1, \ldots, p_k$ for k objects it has given you their entire characteristic polynomial. See Book 1, field: Polynomials, topic: Newton's identities.

Recursion note. There is no sequence here, but the operator relation is a recursion in disguise: define $T_k = D^k f + E^k f$; then applying $D + E$ gives $T_{k+1} = (D+E)T_k - DE\,T_{k-1}$, the standard second order recursion satisfied by power sums of two quantities with known sum and product. In this problem you run it once, in reverse, to extract DE from T_1 and T_2. The general solution method

is Newton's identities, and the same recursion is what makes power sums of roots computable from a polynomial's coefficients.

Monotone functions defined by moving integrals. $s \mapsto \int_s^{s+1} g$ has derivative $g(s+1) - g(s)$, so it is increasing exactly when g is increasing on the relevant range. This is the cleanest way to compare sliding window averages and it removes any need to differentiate under the integral sign. See Book 1, field: Calculus and integrals, topic: Fundamental theorem with variable limits.

Circuit Bank

- **WHEN** you see an alternating sum of values at the corners of a rectangle **DO** write it as the double integral of the mixed partial over that rectangle **BECAUSE** the mixed second difference is exactly $\iint f_{xy}$, so the problem reduces to one function and all additively separable parts vanish
- **WHEN** you see first derivatives with coefficient x and second derivatives with coefficient x^2 **DO** introduce $D = x\partial_x$ and recall $x^2\partial_{xx} = D(D-1)$, equivalently substitute $x = e^u$ **BECAUSE** these are the equidimensional (Euler) operators, which become constant coefficient derivatives in logarithmic variables, so the equations become algebra
- **WHEN** you need a mixed derivative but are given only pure ones **DO** differentiate the first order equation again with the same operator and use $2DE = (D+E)^2 - D^2 - E^2$ **BECAUSE** a sum and a sum of squares determine the product, so two symmetric equations are exactly enough to isolate the cross term
- **WHEN** you are asked to show a quantity is independent of the choice of object **DO** identify which functional of the object the quantity depends on, and prove the data determine that functional **BECAUSE** independence is a statement about invariants, and finding the invariant is shorter and more informative than classifying all objects
- **WHEN** you must minimise a sliding integral $\int_s^{s+1} g$ **DO** differentiate to get $g(s+1) - g(s)$ and read off monotonicity **BECAUSE** the fundamental theorem with variable limits makes this immediate, and monotonicity moves the minimum to an endpoint where it is attained

Backtesting

1. First useful cue: the four corner values with alternating signs, which is a mixed second difference and therefore $\iint f_{xy}$.
2. Method the expression suggested: introduce the Euler operators, rewrite both equations in terms of $D+E$ and D^2+E^2, and extract $2DE$ by completing the square.
3. Where you would hesitate, and the thought to reinforce: worrying that applying $D+E$ to equation (1) needs third derivatives. It does not: $(D+E)(Df+Ef)$ involves only second derivatives of f, and Clairaut makes the two mixed ones equal. State that in the write-up, because a grader will look for it.
4. The trap the question sets: the definition of $\mathcal{F}$ invites you to solve for f. The word min invites you to worry about attainment, which is real but cheap; the real trap is spending the time on the family.
5. What makes you recognise it faster next time: the coefficient pattern x with f_x and x^2 with f_{xx}. That pattern has exactly one meaning, and it is logarithmic variables.
6. The reusable decision rule: corner alternating sum means mixed partial; equidimensional coefficients mean Euler operators; sum plus sum of squares means product.

Mirror drills

1. Solve $x^2y'' + xy' - y = 0$ for $x > 0$. *Answer:* with $x = e^t$ the equation becomes $\ddot{y} - y = 0$, so $y = Ae^t + Be^{-t} = Ax + B/x$.
2. Let g be C^2 on $\mathbb{R}^2$ with $g_x + g_y = e^{x+y}(x+y)$ and $g_{xx} + g_{yy} = e^{x+y}(x+y+1)$. Find g_{xy}. *Answer:* $\frac{1}{2}e^{x+y}(x+y+1)$; this is the present problem written in logarithmic coordinates.
3. Show that a C^2 function on a rectangle has vanishing mixed second difference over every subrectangle if and only if it is of the form $u(x) + v(y)$. *Hint:* vanishing for all subrectangles forces $\iint f_{xy} = 0$ over every subrectangle, hence $f_{xy} \equiv 0$ by continuity; then integrate.

7.11 B5. Interpolating Fibonacci and the missing top difference

Let F_m be the mth Fibonacci number, defined by $F_1 = F_2 = 1$ and $F_m = F_{m-1} + F_{m-2}$ for all $m \geq 3$. Let $p(x)$ be the polynomial of degree 1008 such that $p(2n+1) = F_{2n+1}$ for $n = 0, 1, 2, \ldots, 1008$. Find integers j and k such that $p(2019) = F_j - F_k$.

Read it out loud

A polynomial of degree N is being pinned down by its values at $N+1$ equally spaced points, and then evaluated at the next point of the same arithmetic progression. Say that aloud and the whole problem is already classified. Equally spaced nodes plus one step beyond the last node is the exact setting of the finite difference calculus, not of Lagrange interpolation. The reason is the single fact that a polynomial of degree N has vanishing $(N+1)$st difference, so its value at the next node is a fixed integer combination of the known values with binomial coefficients.

The nodes are the odd numbers $1, 3, 5, \ldots, 2017$ and the target is 2019, so substitute $x = 2t+1$ once and forget the odd numbers: with $P(t) = p(2t+1)$ you have a polynomial of degree $N = 1008$ with $P(n) = F_{2n+1}$ for $n = 0, \ldots, N$, and you want $P(N+1)$. Uniform notation is not cosmetic; it is what lets you see that the answer will be a statement about N.

Now look at the data through the difference operator. The Fibonacci recurrence in the form $F_{m+2} - F_m = F_{m+1}$ says exactly that differencing the sequence $n \mapsto F_{2n+c}$ produces the sequence $n \mapsto F_{2n+c+1}$. So every row of the difference table of this data is the Fibonacci sequence again, shifted by one index. That is the observation the problem is built on. The difference table of the data never terminates, but the difference table of a degree N polynomial must, and the answer records precisely the discrepancy between the two.

Fields embedded: finite differences and interpolation (the discrete calculus), linear recurrences and Binet's formula, and binomial identities. Within thirty seconds you should have written $P(t) = p(2t+1)$, the difference identity $F_{m+2} - F_m = F_{m+1}$, and the plan: build the difference table, use Newton's forward formula at $t = N+1$.

Approaches, ranked worst to best

1. **Find p explicitly.** *Cue:* a polynomial is its coefficients. *Circuit:* solve the linear system for 1009 coefficients. There is no version of this that a human completes. It is the purest form of doing what the words say without reading the structure.

2. **Lagrange interpolation with Binet.** *Cue:* 1009 points and a value, so use the interpolation formula. *Circuit:* write $p(2019) = \sum p(x_i) \prod \frac{2019 - x_j}{x_i - x_j}$, then split F by Binet. The products collapse to $(-1)^{1008-n}\binom{1009}{n}$, and applying the binomial theorem to $\sum_n \gamma^{2n+1}(-1)^{1008-n}\binom{1009}{n}$ with $\gamma^2 = \gamma + 1$ gives $\gamma^{2019} - \gamma^{1010}$. It is a real solution, but it carries a sign error in every second line if you are not careful, and it uses interpolation machinery where difference machinery is native to equally spaced nodes.

3. **Difference table with edge climbing.** *Cue:* equally spaced nodes and a recursive data set. *Circuit:* build $\Delta^k P$, note the top row is constant, then climb back along the boundary. Since $\Delta^k P(n) = F_{2n+k+1}$ and $\Delta^N P$ is a constant equal to F_{N+1}, you can compute the first unknown entry in each row from the row below, giving $P(N+1) = \sum_{j=N+1}^{2N+1} F_j$, and then $\sum_{j=1}^{m} F_j = F_{m+2} - 1$ finishes it. Fully elementary, no Binet, no binomial identity. It costs two inductions and a telescoping sum, and it hides the reason the answer is a difference of two Fibonacci numbers.

4. **Newton's forward difference formula.** *Cue:* a polynomial of degree N evaluated one node past the data. *Circuit:* $P(N+1) = \sum_k \binom{N+1}{k} \Delta^k P(0)$, with $\Delta^k P(0) = F_{k+1}$. The sum is the

complete binomial Fibonacci sum $\sum_{k=0}^{N+1}\binom{N+1}{k}F_{k+1} = F_{2N+3}$ with exactly one term missing, the top one, F_{N+2}. Three lines, and it explains the shape of the answer: the polynomial reproduces the Fibonacci continuation except for the single term its degree forbids. Best.

The ideal solution

Write $N = 1008$ and $P(t) = p(2t+1)$, a polynomial in t of degree N with

$$P(n) = F_{2n+1} \qquad (n = 0, 1, \ldots, N),$$

and note $p(2019) = P(N+1)$ since $2(N+1)+1 = 2019$. Let Δ denote the forward difference, $(\Delta G)(t) = G(t+1) - G(t)$.

Lemma 7.11.1. *For $0 \le k \le N$ and $0 \le n \le N-k$ we have $(\Delta^k P)(n) = F_{2n+k+1}$.*

Proof. Induction on k. For $k = 0$ this is the hypothesis. Assume it for $k-1$. For $0 \le n \le N-k$ both n and $n+1$ lie in $[0, N-(k-1)]$, so

$$(\Delta^k P)(n) = (\Delta^{k-1}P)(n+1) - (\Delta^{k-1}P)(n) = F_{2n+k+2} - F_{2n+k},$$

and the Fibonacci recurrence in the form $F_{m+2} - F_m = F_{m+1}$ (valid for $m \ge 1$, and here $m = 2n+k \ge 1$ unless $n = k = 0$, where $F_3 - F_1 = F_2$ holds directly) gives F_{2n+k+1}. □

In particular $(\Delta^k P)(0) = F_{k+1}$ for $0 \le k \le N$, and since $\deg P = N$ we have $\Delta^k P \equiv 0$ for $k > N$.

Lemma 7.11.2 (Newton's forward difference formula)**.** *For any function G on the integers and any integer $t \ge 0$, $G(t) = \sum_{k\ge 0}\binom{t}{k}(\Delta^k G)(0)$, the sum being finite when G is a polynomial.*

Proof. Let E be the shift, $(EG)(t) = G(t+1)$. Then $E = I + \Delta$ as operators, and I and Δ commute, so the binomial theorem for commuting operators gives $E^t = (I+\Delta)^t = \sum_{k=0}^{t}\binom{t}{k}\Delta^k$ for every nonnegative integer t. Evaluating both sides at 0 gives the formula. If G is a polynomial of degree N then $\Delta^k G \equiv 0$ for $k > N$ and the sum terminates. □

Applying Lemma 7.11.2 at $t = N+1$ and inserting Lemma 7.11.1,

$$P(N+1) = \sum_{k=0}^{N}\binom{N+1}{k}(\Delta^k P)(0) = \sum_{k=0}^{N}\binom{N+1}{k}F_{k+1}. \tag{$*$}$$

Lemma 7.11.3. *For every integer $M \ge 0$, $\displaystyle\sum_{k=0}^{M}\binom{M}{k}F_{k+1} = F_{2M+1}$.*

Proof. Let $\alpha = \frac{1+\sqrt{5}}{2}$ and $\beta = \frac{1-\sqrt{5}}{2}$, the roots of $z^2 = z+1$, so that $F_m = \frac{\alpha^m - \beta^m}{\sqrt{5}}$ (Binet). For $\gamma \in \{\alpha, \beta\}$ we have $1 + \gamma = \gamma^2$, hence by the binomial theorem

$$\sum_{k=0}^{M}\binom{M}{k}\gamma^{k+1} = \gamma(1+\gamma)^M = \gamma\cdot\gamma^{2M} = \gamma^{2M+1}.$$

Subtracting the two cases and dividing by $\sqrt{5}$ gives the claim. □

Now apply Lemma 7.11.3 with $M = N+1$:

$$F_{2N+3} = \sum_{k=0}^{N+1}\binom{N+1}{k}F_{k+1} = \left(\sum_{k=0}^{N}\binom{N+1}{k}F_{k+1}\right) + \binom{N+1}{N+1}F_{N+2},$$

so by $(*)$,

$$P(N+1) = F_{2N+3} - F_{N+2}.$$

With $N = 1008$ this reads

$$p(2019) = F_{2019} - F_{1010}, \qquad \text{so} \qquad \boxed{(j,k) = (2019,\ 1010)}.$$

Remark 7.11.4. Sanity check on small N. For $N = 1$, p is the line through $(1, F_1) = (1, 1)$ and $(3, F_3) = (3, 2)$, so $p(5) = 3 = 5 - 2 = F_5 - F_3$, matching $F_{2N+3} - F_{N+2}$. For $N = 2$, $P(0), P(1), P(2) = 1, 2, 5$ has second difference 2, so $P(3) = 10 = 13 - 3 = F_7 - F_4$, again matching.

Remark 7.11.5. The pair is unique in positive integers. Write $V = F_{2019} - F_{1010} > 0$ and suppose $F_j - F_k = V$. Since $V > 0$ we may take $k < j$, so $F_j - F_k \geq F_j - F_{j-1} = F_{j-2}$. If $j \geq 2021$ then $F_j - F_k \geq F_{2019} > V$, and if $j \leq 2018$ then $F_j - F_k \leq F_{2018} < F_{2019} - F_{1010} = V$ because $F_{2019} - F_{2018} = F_{2017} > F_{1010}$. So $j \in \{2019, 2020\}$. For $j = 2019$ we need $F_k = F_{1010}$, giving $k = 1010$. For $j = 2020$ we would need $F_k = F_{2020} - F_{2019} + F_{1010} = F_{2018} + F_{1010}$, which lies strictly between F_{2018} and $F_{2018} + F_{2017} = F_{2019}$ and so is not a Fibonacci number.

Layer 1: WHAT

Block 1. Normalise the nodes: $P(t) = p(2t + 1)$ has degree $N = 1008$, matches F_{2n+1} at $n = 0, \ldots, N$, and the target is $P(N + 1)$.

Block 2. Read the Fibonacci recurrence as a difference statement: $F_{m+2} - F_m = F_{m+1}$, so differencing the data shifts the Fibonacci index by one.

Block 3. Hence $(\Delta^k P)(0) = F_{k+1}$: the leading column of the difference table is the Fibonacci sequence itself.

Block 4. Use $E = I + \Delta$ to extrapolate one node: $P(N + 1) = \sum_k \binom{N+1}{k} F_{k+1}$, the sum truncated at $k = N$ because $\deg P = N$.

Block 5. Recognise the untruncated sum: $\sum_{k=0}^{M} \binom{M}{k} F_{k+1} = F_{2M+1}$, which is $1 + \gamma = \gamma^2$ under Binet.

Block 6. The truncation removes exactly the top term F_{N+2}, so $P(N + 1) = F_{2N+3} - F_{N+2}$; substitute $N = 1008$.

Juxtaposition. The nominal route sees 1009 interpolation conditions and reaches for Lagrange, then fights the product $\prod_{j \neq n} \frac{2019-(2j+1)}{(2n+1)-(2j+1)}$ into a binomial coefficient with an alternating sign, then applies Binet, then applies the binomial theorem. It works. The bifurcation point is the moment you notice the nodes are equally spaced. Equally spaced nodes make the difference operator the native tool, and the difference operator converts the Fibonacci recurrence into a triviality, whereas Lagrange interpolation ignores the spacing and forces you to rebuild the binomial coefficients by hand from a ratio of products.

Layer 2: HOW

Block 1. Cue. Nodes $1, 3, 5, \ldots$ and a target 2019 in the same progression. **Why natural.** Any statement about a polynomial on an arithmetic progression is a statement about the polynomial composed with a linear map, and the composition is again a polynomial of the same degree. Substituting once removes an irrelevant factor of two from every subsequent line. It also reveals the real index set $n = 0, \ldots, N$ and the real target $n = N + 1$, which is the shape that finite difference theory is written in. **Link to the next block.** With integer nodes $0, 1, \ldots, N$ you are in the discrete calculus, so ask what the difference operator does to the data.

Block 2. Cue. Data given by a linear recurrence, and a difference operator waiting to act on it. **Why natural.** The Fibonacci recurrence can be written $F_{m+2} = F_{m+1} + F_m$ or, rearranged, $F_{m+2} - F_m = F_{m+1}$. The second form is the one adapted to your data because your data steps the index by two, and the difference of two data points is a difference of Fibonacci numbers two apart. Rearranging a recurrence into the form the problem needs is not a manipulation, it is reading. In the Binet picture, Δ multiplies α^{2n} by $\alpha^2 - 1 = \alpha$, so Δ acts exactly as multiplication by the golden ratio. **Link to the next block.** Iterating gives every row of the difference table, so compute the leading column.

Block 3. **Cue.** The difference table of a polynomial has finitely many nonzero rows, and its leading column is what an extrapolation formula consumes. **Why natural.** Newton's forward formula uses only $(\Delta^k P)(0)$. Lemma 7.11.1 at $n = 0$ gives F_{k+1}, so the leading column is $1, 1, 2, 3, 5, \ldots$: the entire difference table is the Fibonacci sequence, which is the strongest possible sign that you are on the intended route. Note carefully the range restriction $n \leq N - k$: values of $\Delta^k P$ outside that range are not given by the Fibonacci pattern, and confusing the two is the way to lose this problem. **Link to the next block.** You have the leading column; now you need the formula that turns it into a value at a new point.

Block 4. **Cue.** A polynomial of known degree, values on a full block of consecutive integers, and a request for the next value. **Why natural.** The shift operator factors as $E = I + \Delta$, and since I and Δ commute, $E^t = (I + \Delta)^t$ expands by the binomial theorem. This is the discrete analogue of a Taylor expansion, with $\binom{t}{k}$ in place of $t^k/k!$ and Δ^k in place of the kth derivative. The degree hypothesis enters exactly once, to truncate the sum at $k = N$, and that truncation is the entire content of the answer. **Link to the next block.** You have a binomial sum of Fibonacci numbers; identify it.

Block 5. **Cue.** $\sum \binom{M}{k} F_{k+1}$, a binomial transform of the Fibonacci sequence. **Why natural.** Any identity of this shape is proved in one line by Binet, because F is a linear combination of two geometric sequences and the binomial theorem loves geometric sequences. The specific miracle, $\sum \binom{M}{k} \gamma^{k+1} = \gamma(1 + \gamma)^M$, becomes γ^{2M+1} only because $1 + \gamma = \gamma^2$, which is the defining equation of the golden ratio. So the identity is not a coincidence about Fibonacci numbers, it is the defining property of α in binomial clothing. **Link to the next block.** The identity is for the full range $0 \leq k \leq M$; your sum stops one short, so compare and subtract.

Block 6. **Cue.** A complete binomial identity and an incomplete sum differing by one term. **Why natural.** The missing term is $\binom{N+1}{N+1} F_{N+2} = F_{N+2}$. That is why the answer is a difference of two Fibonacci numbers rather than one: the polynomial faithfully reproduces the Fibonacci continuation to the extent that its difference table allows, and the single row it is forbidden to have (the $(N+1)$st difference, which must vanish for a degree N polynomial but equals F_{N+2} for the true Fibonacci data) is subtracted off. The answer is the error term of a truncation, and knowing that, you could have predicted the shape before computing.

Layer 3: WHY

The mathematical truth here is that the finite difference operator acts on Fibonacci data as multiplication by the golden ratio. Under Binet, the data are $P(n) = \frac{\alpha^{2n+1} - \beta^{2n+1}}{\sqrt{5}}$, and Δ multiplies γ^{2n} by $\gamma^2 - 1 = \gamma$. So on the two dimensional space spanned by the sequences (α^{2n}) and (β^{2n}), the operator Δ is diagonal with eigenvalues α and β. Everything in this problem is that one sentence. The difference table is the Fibonacci sequence because applying Δ shifts the index; Newton's formula computes $(I + \Delta)^{N+1}$, which on the α eigenvector is $(1 + \alpha)^{N+1} = \alpha^{2N+2}$, which is the Fibonacci continuation F_{2N+3} after multiplying by the remaining α; and the truncation at $k = N$ removes exactly the top eigen-contribution F_{N+2}.

That gives the discernment mechanism. The polynomial p is a degree N approximation to a sequence that satisfies a linear recurrence with eigenvalues α, β. Polynomials cannot satisfy that recurrence, so they must eventually disagree with it, and the first disagreement occurs at the first node beyond the data, in a controlled way: the disagreement is precisely the $(N+1)$st difference the polynomial is not allowed to have. Whenever you meet a polynomial interpolating a recurrent sequence and are asked for the next value, expect the answer to be the true next value minus the $(N+1)$st difference of the true sequence, and expect that difference to be another term of the same sequence when the recurrence is nice.

The training instruction is concrete. Equally spaced nodes means finite differences, never Lagrange. Build the operator dictionary once and keep it: $E = I + \Delta$; Δ^{N+1} kills degree N; $\Delta^{N+1}P(0) = \sum_i (-1)^{N+1-i}\binom{N+1}{i}P(i)$; Newton forward formula $P(t) = \sum \binom{t}{k}\Delta^k P(0)$; and the discrete Taylor analogy that makes all of them memorable. The single most common Putnam use of this dictionary is exactly this problem's shape, a degree N interpolant of a nice sequence evaluated one step out.

The examiners nudged three times. They chose odd nodes so that the data would obey $F_{m+2} - F_m = F_{m+1}$ rather than the raw recurrence, which is what makes the difference table clean. They chose the degree to be exactly one less than the number of nodes, so the interpolant is unique and the difference table terminates exactly at the right place. And they asked for the answer in the form $F_j - F_k$ rather than as a number, which is a broad hint that the answer is a truncation error and not a fresh quantity.

Revolving concepts

Finite difference calculus. $(\Delta G)(t) = G(t+1) - G(t)$; $E = I + \Delta$; Δ lowers the degree of a polynomial by exactly one, so $\Delta^{N+1}P \equiv 0$ for $\deg P \le N$; $\Delta^k G(0) = \sum_{i=0}^{k}(-1)^{k-i}\binom{k}{i}G(i)$; Newton's forward formula $G(t) = \sum_k \binom{t}{k}\Delta^k G(0)$; and the basis of binomial polynomials $\binom{t}{k}$ with $\Delta\binom{t}{k} = \binom{t}{k-1}$, which is the discrete analogue of differentiating $t^k/k!$. See Book 1, field: Polynomials, topic: Finite differences and interpolation.

Linear recurrences and Binet. A sequence satisfying $G_m = aG_{m-1} + bG_{m-2}$ has $G_m = A\lambda_1^m + B\lambda_2^m$ when the characteristic roots λ_i of $z^2 = az + b$ are distinct, and $(A + Bm)\lambda^m$ when they coincide. For Fibonacci, $\alpha, \beta = \frac{1\pm\sqrt{5}}{2}$ and $F_m = \frac{\alpha^m - \beta^m}{\sqrt{5}}$. The identity used repeatedly here is $1 + \gamma = \gamma^2$, the characteristic equation itself. See Book 1, field: Sequences and recurrences, topic: Linear recurrences with constant coefficients.

The generalised recursion, and its generalisation. The data satisfy the second order recursion $G_{n+1} = 3G_n - G_{n-1}$ where $G_n = F_{2n+1}$, since α^2 and β^2 are the roots of $z^2 - 3z + 1 = 0$. More generally, if a sequence satisfies a linear recurrence with characteristic roots λ_i, then Δ acts on the corresponding geometric components with eigenvalues $\lambda_i - 1$, so the difference table is again a combination of geometric sequences and every row is computable in closed form. The general solution method for problems of this type: diagonalise Δ on the span of the geometric components, apply $(I + \Delta)^t$, and truncate at the degree. This handles $\sum \binom{M}{k}G_k$ for any linear recurrent G, giving $\sum_i A_i\lambda_i(1 + \lambda_i)^M$. See Book 1, field: Sequences and recurrences, topic: Binomial transforms.

Binomial transforms of Fibonacci. $\sum_k \binom{M}{k}F_k = F_{2M}$ and $\sum_k \binom{M}{k}F_{k+1} = F_{2M+1}$, both instances of $1 + \gamma = \gamma^2$. Combinatorially, F_{n+1} counts tilings of a $1 \times n$ strip by squares and dominoes, and the identity has a direct tiling proof by splitting on the number of squares among the first M tiles. See Book 1, field: Combinatorics, topic: Fibonacci identities.

Telescoping Fibonacci sums. $\sum_{j=1}^{m} F_j = F_{m+2} - 1$, from $F_j = F_{j+2} - F_{j+1}$. This is what the elementary difference table route needs at the end, and it is worth having alongside $\sum F_j^2 = F_m F_{m+1}$ and $\sum F_{2j-1} = F_{2m}$. See Book 1, field: Sequences and recurrences, topic: Standard Fibonacci sums.

Circuit Bank

- **WHEN** you see a polynomial of degree N prescribed at $N + 1$ equally spaced points and evaluated at another such point **DO** build the difference table and use $P(t) = \sum_k \binom{t}{k}\Delta^k P(0)$ **BECAUSE** $E = I + \Delta$ makes extrapolation a binomial sum, and the degree hypothesis enters only as the truncation of that sum, which is where the answer comes from

- **WHEN** you see data sampled at every other index of a recurrent sequence **DO** rewrite the recurrence in the form matching your sampling, here $F_{m+2} - F_m = F_{m+1}$ **BECAUSE** a

recurrence is a relation between whichever indices you need, and rearranging it to match the difference operator is what makes the difference table computable

- **WHEN** you see $\sum_k \binom{M}{k} G_k$ with G satisfying a linear recurrence **DO** split G into geometric components by Binet and use the binomial theorem **BECAUSE** a binomial transform of a geometric sequence is another geometric sequence with ratio $1+\lambda$, so the whole sum collapses without any combinatorial argument
- **WHEN** you are asked for an answer in the form (something) minus (something) **DO** expect a truncation or an error term, and look for the complete identity that your sum falls short of **BECAUSE** answers presented as differences are usually a clean object minus the piece the hypothesis forbids, and naming the clean object first makes the computation short
- **WHEN** you have a general parameter hidden behind a specific number such as 1008 **DO** solve for general N and substitute at the end **BECAUSE** the general computation is no harder, it protects you from arithmetic slips, and it lets you sanity check on $N = 1$ and $N = 2$ by hand

Backtesting

1. First useful cue: the interpolation nodes are equally spaced and the target is the next node, which is the native setting of finite differences.
2. Method the expression suggested: substitute $t = (x-1)/2$, build the difference table using $F_{m+2} - F_m = F_{m+1}$, apply Newton's forward formula, and recognise the resulting binomial sum.
3. Where you would hesitate, and the thought to reinforce: whether $\Delta^k P(n) = F_{2n+k+1}$ holds for all n. It does not; it holds only for $n \le N - k$, because beyond that range the polynomial and the Fibonacci sequence part company. That parting is the answer, so keep the range explicit.
4. The trap the question sets: the number 1008 invites arithmetic panic and the phrase polynomial of degree 1008 invites Lagrange. Both push you toward a longer route.
5. What makes you recognise it faster next time: any polynomial interpolating a linear recurrent sequence on consecutive integers, evaluated one step beyond, has value equal to the true next term minus the $(N+1)$st difference of the true sequence.
6. The reusable decision rule: equally spaced nodes means difference table, never Lagrange; and a requested answer in the form of a difference means look for a truncation.

Mirror drills

1. Let q be the polynomial of degree N with $q(n) = 2^n$ for $n = 0, \dots, N$. Find $q(N+1)$. *Answer:* $2^{N+1} - 1$, since every $\Delta^k q(0) = 1$ and $\sum_{k=0}^{N} \binom{N+1}{k} = 2^{N+1} - 1$: the same missing top term structure.
2. Prove $\sum_{k=0}^{M} \binom{M}{k} F_k = F_{2M}$. *Answer:* by Binet, $\sum_k \binom{M}{k} \gamma^k = (1+\gamma)^M = \gamma^{2M}$ for $\gamma \in \{\alpha, \beta\}$; subtract and divide by $\sqrt{5}$.
3. Show that $G_n = F_{2n+1}$ satisfies $G_{n+1} = 3G_n - G_{n-1}$, and use it to compute the first three rows of the difference table directly. *Answer:* α^2, β^2 are the roots of $z^2 - 3z + 1 = 0$ since $\alpha^2 + \beta^2 = 3$ and $\alpha^2\beta^2 = 1$; the rows are $F_{2n+1}, F_{2n+2}, F_{2n+3}$.

7.12 B6. Perfect codes tile the lattice in every dimension

Let $\mathbb{Z}^n$ be the integer lattice in $\mathbb{R}^n$. Two points in $\mathbb{Z}^n$ are called neighbors *if they differ by exactly 1 in one coordinate and are equal in all other coordinates. For which integers $n \geq 1$ does there exist a set of points $S \subset \mathbb{Z}^n$ satisfying the following two conditions?*

(1) If p is in S, then none of the neighbors of p is in S.

(2) If $p \in \mathbb{Z}^n$ is not in S, then exactly one of the neighbors of p is in S.

Read it out loud

Two conditions, and they are begging to be merged. Condition (1) says S is an independent set in the lattice graph. Condition (2) says every point outside S is dominated exactly once. Put them together and say the merged statement aloud: every point of $\mathbb{Z}^n$ lies in exactly one closed ball of radius 1 centred at a point of S. A point of S lies in its own ball and, by (1), in nobody else's; a point outside S lies in exactly one by (2). So the problem is a tiling problem. The closed balls of radius 1, which are the crosses consisting of a centre and its $2n$ neighbours, must partition $\mathbb{Z}^n$.

That reformulation immediately hands you the only number in the problem: each cross has $2n+1$ points, so S must have density exactly $\frac{1}{2n+1}$. You have not constructed anything yet and the modulus $2n+1$ is already forced. This matters enormously for how you feel about the eventual answer. The function $x \mapsto x_1 + 2x_2 + \cdots + nx_n \bmod (2n+1)$ looks like a rabbit pulled from a hat if you meet it cold; it looks inevitable if you have already deduced that whatever S is, it has one point in every $2n+1$, and that the cheapest sets of density $\frac{1}{m}$ in $\mathbb{Z}^n$ are the kernels of homomorphisms onto a group of order m.

The third reading is the phrase for which integers n. That phrasing is bait. It suggests an obstruction exists for some n, and it invites you to spend forty minutes hunting for a parity or divisibility argument that rules out, say, even n. There is no obstruction: the answer is every n. Learn to read the interrogative form of a Putnam question as neutral, because setters use for which n precisely when the honest answer is all of them and they want you to doubt it.

Fields embedded: lattices and subgroups of $\mathbb{Z}^n$, finite abelian groups, tilings, and coding theory (this is a perfect code in the Lee metric, or an efficient dominating set of the lattice graph). What is really being tested is whether you convert two local combinatorial conditions into one global structural condition, and whether you then reach for algebra rather than for drawing. Within thirty seconds you should have written: balls of size $2n+1$ tile; density $\frac{1}{2n+1}$; try $S = \ker \varphi$ for $\varphi : \mathbb{Z}^n \to \mathbb{Z}/(2n+1)\mathbb{Z}$.

Approaches, ranked worst to best

1. **Draw and hope.** *Cue:* small cases are easy to sketch. *Circuit:* find a pattern in $\mathbb{Z}^2$, then guess. For $n = 2$ you will, with patience, find the diagonal pattern of period five, and for $n = 3$ you may find period seven. Drawing three dimensional lattices is slow and error prone, and even after you find the patterns you must still explain what they are before you can generalise. This is the route that consumes an hour and produces a conjecture rather than a proof.

2. **Induct on n.** *Cue:* a set in $\mathbb{Z}^n$ ought to build a set in $\mathbb{Z}^{n+1}$. *Circuit:* lift or take products. There is no natural lift. The ball sizes for consecutive dimensions are $2n+1$ and $2n+3$, which are coprime, so no product or layering construction can turn a tiling of one into a tiling of the other; the densities are incompatible. Recognising quickly that an induction cannot work is itself worth training, because the alternative is losing the problem to a route that never closes.

3. **Colour the lattice.** *Cue:* a partition into $2n+1$ classes, one per ball position. *Circuit:* assign to each point a colour in $\{0, 1, \ldots, 2n\}$ so that every ball is rainbow. This is the right idea in disguise. You want a colouring $c : \mathbb{Z}^n \to \mathbb{Z}/(2n+1)\mathbb{Z}$ such that each closed ball receives all

$2n+1$ colours exactly once, and then take $S = c^{-1}(0)$. Stated this way you still have to invent the colouring, but at least you know exactly what you are looking for.

4. **Force the modulus, then look for a subgroup.** *Cue:* density $\frac{1}{2n+1}$ and an ambient group $\mathbb{Z}^n$. *Circuit:* take S to be the kernel of a homomorphism onto a group of order $2n+1$, and translate the two conditions into a condition on the images of the basis vectors. A homomorphism φ is determined by $c_i = \varphi(e_i)$. The two conditions become: the $2n$ elements $\pm c_1, \ldots, \pm c_n$ are distinct and nonzero, hence exhaust the nonzero residues. Modulo $2n+1$ the choice $c_i = i$ does exactly that. Best, because every step is forced by the previous one and the verification is four lines.

The ideal solution

The answer: such a set S exists for every integer $n \geq 1$.

Fix $n \geq 1$, write $m = 2n+1$, and let $e_1, \ldots, e_n$ be the standard basis of $\mathbb{Z}^n$. Define the group homomorphism

$$\varphi : \mathbb{Z}^n \longrightarrow \mathbb{Z}/m\mathbb{Z}, \qquad \varphi(x_1, \ldots, x_n) = x_1 + 2x_2 + \cdots + nx_n \pmod{m},$$

and set

$$S = \varphi^{-1}(0) = \{\, p \in \mathbb{Z}^n : \varphi(p) \equiv 0 \pmod{m} \,\}.$$

Lemma 7.12.1. *The $2n$ residues $\pm 1, \pm 2, \ldots, \pm n$ are distinct and nonzero modulo $m = 2n+1$, and therefore they are exactly the $2n$ nonzero residues modulo m, each occurring once.*

Proof. Each i with $1 \leq i \leq n$ satisfies $0 < i < m$, so $i \not\equiv 0$ and likewise $-i \not\equiv 0$. If $i \equiv j$ with $1 \leq i, j \leq n$ then $m \mid i - j$ and $|i - j| \leq n - 1 < m$, so $i = j$. If $i \equiv -j$ then $m \mid i + j$ and $2 \leq i + j \leq 2n < m$, which is impossible. So the $2n$ listed residues are pairwise distinct and nonzero; since there are exactly $2n$ nonzero residues modulo m, they exhaust them. □

Every neighbour of a point p has the form $q = p + \delta e_i$ with $i \in \{1, \ldots, n\}$ and $\delta \in \{+1, -1\}$, and distinct pairs (i, δ) give distinct neighbours. Since φ is a homomorphism with $\varphi(e_i) = i$,

$$\varphi(q) = \varphi(p) + \delta i \pmod{m}. \tag{$*$}$$

Condition (1). Let $p \in S$, so $\varphi(p) \equiv 0$, and let $q = p + \delta e_i$ be a neighbour. By $(*)$, $\varphi(q) \equiv \delta i$, which is nonzero by Lemma 7.12.1. Hence $q \notin S$, and no neighbour of a point of S lies in S.

Condition (2). Let $p \notin S$ and put $c = \varphi(p) \not\equiv 0$. By $(*)$, a neighbour $q = p + \delta e_i$ lies in S if and only if $\delta i \equiv -c \pmod{m}$. Since $c \not\equiv 0$, also $-c \not\equiv 0$, so by Lemma 7.12.1 there is exactly one pair (i, δ) with $i \in \{1, \ldots, n\}$, $\delta \in \{\pm 1\}$ and $\delta i \equiv -c$. Distinct pairs give distinct neighbours, so exactly one neighbour of p lies in S.

Both conditions hold for every $n \geq 1$, so the answer is: all n. ■

Remark 7.12.2. Equivalently, the closed balls of radius 1 (the crosses of $2n+1$ points) centred at the points of S partition $\mathbb{Z}^n$: conditions (1) and (2) together say exactly that each point lies in exactly one such ball. The construction is therefore a lattice tiling of $\mathbb{Z}^n$ by crosses, and S is a perfect single error correcting code in the Lee metric.

Remark 7.12.3. Nothing forces the group to be cyclic. Let G be any abelian group of order $2n+1$. Since $|G|$ is odd, no nonzero element satisfies $g = -g$, so the nonzero elements split into exactly n pairs $\{g, -g\}$; choose one representative c_i from each pair and define $\varphi(x) = \sum x_i c_i$. The proof above applies verbatim, since $\{\pm c_1, \ldots, \pm c_n\} = G \setminus \{0\}$ with no repetitions. Also, every translate of S works, so each of the $2n+1$ fibres $\varphi^{-1}(c)$ is itself a valid set.

Layer 1: WHAT

Block 1. Merge conditions (1) and (2) into one: the closed unit balls centred at points of S partition $\mathbb{Z}^n$.

Block 2. Count: each ball has $2n+1$ points, so S has density $\frac{1}{2n+1}$ and the modulus $2n+1$ is forced.

Block 3. Decide to look for a structured S: subgroups of index $2n+1$, that is kernels of homomorphisms $\varphi : \mathbb{Z}^n \to \mathbb{Z}/(2n+1)\mathbb{Z}$.

Block 4. A homomorphism on $\mathbb{Z}^n$ is free: it is determined by arbitrary images $c_i = \varphi(e_i)$. So the search space is n residues.

Block 5. Translate the tiling condition: moving to a neighbour changes φ by $\pm c_i$, so the condition is that $\pm c_1, \ldots, \pm c_n$ hit each nonzero residue exactly once.

Block 6. Solve it: $c_i = i$ modulo $2n+1$, because $\pm 1, \ldots, \pm n$ are exactly the nonzero residues.

Block 7. Verify both original conditions directly from $\varphi(p + \delta e_i) = \varphi(p) + \delta i$, and conclude the answer is all n.

Juxtaposition. The nominal route treats the question as a search: draw $\mathbb{Z}^2$, find a pattern, draw $\mathbb{Z}^3$, find a pattern, guess a general rule, then try to verify it. Some strong candidates get there, because the $n = 2$ pattern really is the diagonal one of period five, but they arrive without a mechanism and with no clean way to write the general case. The bifurcation point is the sentence you write after reading condition (2). If you write examples of S in low dimensions, you are searching. If you write the balls tile, so the density is $\frac{1}{2n+1}$, you have converted a search into an equation, and the equation has an obvious solution.

Layer 2: HOW

Block 1. **Cue.** Two conditions, one about points inside S and one about points outside S, both about neighbours. **Why natural.** A pair of conditions that split on membership in S is almost always one condition in disguise, and the way to find it is to ask what both say about a fixed point p: how many points of S lie in the closed ball around p? Condition (1) says one when $p \in S$ (namely p itself), condition (2) says one when $p \notin S$. So the count is uniformly one, and by symmetry of the neighbour relation that is the same as saying the balls centred at points of S cover every point exactly once. Merging the cases removes the case analysis from every later step. **Link to the next block.** A partition is a counting statement, so count.

Block 2. **Cue.** A partition of an infinite set into congruent finite pieces of size $2n+1$. **Why natural.** Density is the only invariant of such a partition, and it is forced: in any large box, the number of points of S is asymptotically $\frac{1}{2n+1}$ of the number of lattice points. The number $2n+1$ is now attached to the problem permanently, and any construction you propose must produce it. This is the step that removes all mystery from the final formula; if you later find yourself writing modulo $2n+1$, it is because you deduced it here, not because you guessed it. **Link to the next block.** You want a set of density $\frac{1}{2n+1}$ inside $\mathbb{Z}^n$; the most economical such sets are subgroups of that index.

Block 3. **Cue.** The ambient object $\mathbb{Z}^n$ is a group, and the neighbour relation is translation invariant. **Why natural.** The whole problem is invariant under translation by any lattice vector, so it is natural to look for an S that is itself translation invariant under a subgroup, and the cleanest possibility is that S is a subgroup, or a coset of one, of index $2n+1$. Subgroups of index m in $\mathbb{Z}^n$ are exactly the kernels of surjections onto groups of order m. Choosing $\mathbb{Z}/(2n+1)\mathbb{Z}$ is the simplest such group. This is not a guess; it is the standard way to manufacture a set of prescribed density in a group, and it is the same reflex that produces arithmetic progressions when the ambient group is $\mathbb{Z}$. **Link to the next block.** A homomorphism out of a free abelian group is determined by its values on a basis, so parametrise.

Block 4. **Cue.** $\mathbb{Z}^n$ is free abelian with basis $e_1, \ldots, e_n$. **Why natural.** Freeness means there are no relations to respect: any choice whatsoever of $c_1, \ldots, c_n$ in $\mathbb{Z}/m\mathbb{Z}$ defines a homomorphism. So the search space collapses from all subsets of $\mathbb{Z}^n$ to n residues, which is a finite and tiny space. Reducing an infinite search to a finite parametrisation is the single most valuable move in this problem. **Link to the next block.** Now push the conditions through the parametrisation.

Block 5. **Cue.** φ is a homomorphism and neighbours differ by $\pm e_i$. **Why natural.** Therefore $\varphi(q) - \varphi(p) = \pm c_i$: the value of φ is a coordinate that changes in a completely controlled way along every lattice edge. Condition (1) becomes: no $\pm c_i$ is zero. Condition (2) becomes: for every nonzero c there is exactly one (i, δ) with $\delta c_i = -c$. Together: the list $\pm c_1, \ldots, \pm c_n$ has $2n$ entries and must hit each of the $2n$ nonzero residues exactly once, which is a bijection condition, and bijections between sets of equal finite size need only injectivity. That is why the verification is short. **Link to the next block.** You need n residues whose $2n$ signed versions are all distinct and nonzero, so write down the obvious candidate.

Block 6. **Cue.** Modulo an odd number $2n + 1$, the nonzero residues split into n pairs $\{c, -c\}$. **Why natural.** Oddness is exactly what makes the pairing work: in $\mathbb{Z}/m\mathbb{Z}$ with m odd, $c \equiv -c$ forces $2c \equiv 0$ hence $c \equiv 0$, so no nonzero element is its own negative. Therefore a set of n pair representatives exists, and the residues $1, 2, \ldots, n$ are the most obvious choice. If the ball size had been even, no such choice could exist, which is a good way to remember why the centre point of the ball is essential to the whole construction. **Link to the next block.** Everything is determined; write the verification.

Block 7. **Cue.** A concrete φ and two conditions to check. **Why natural.** The verification must be done in the original language, because that is what the question asked. Each check is a single application of $\varphi(p + \delta e_i) = \varphi(p) + \delta i$ together with the lemma. Also record explicitly that distinct pairs (i, δ) give distinct neighbours, since condition (2) says exactly one neighbour, not exactly one solution of a congruence.

Layer 3: WHY

The mathematical truth is that this problem is the existence of a perfect single error correcting code in the Lee metric on $\mathbb{Z}^n$, and perfect codes exist exactly when a sphere packing bound is met with equality by an algebraic construction. The sphere packing (or Hamming) bound says that if the closed balls of radius r are disjoint then the density of centres is at most the reciprocal of the ball size; a code is perfect when equality holds, that is when the balls also cover. So conditions (1) and (2) are packing and covering respectively, and asking for both is asking for a perfect code. Once you see the problem that way, you know what the possible answers look like: perfect codes are rare and almost always come from algebra, specifically as kernels of homomorphisms, exactly as Hamming codes are kernels of parity check matrices over $\mathbb{F}_2$.

The mechanism that makes radius 1 work in every dimension is a coincidence of shape and group. The ball is a cross of $2n + 1$ points, and its $2n$ non-central points come in n opposite pairs $\pm e_i$. A group of odd order $2n + 1$ has its $2n$ nonzero elements in n opposite pairs $\pm g$. The construction is nothing more than matching those two pairings with each other. That is the whole idea, and it is why the natural generalisation is the second remark above: any abelian group of order $2n + 1$ works, since the pairing is all that was used.

That also tells you where the difficulty lies for larger radius, and this is worth knowing because it stops you from over-generalising. For radius r the ball in $\mathbb{Z}^n$ has $\sum_{k \geq 0} 2^k \binom{n}{k} \binom{r}{k}$ points, and the analogous requirement is that the displacement vectors of the ball map to distinct residues, which is a perfect difference set condition, far stronger than a pairing. For $n = 2$ such codes exist for

every r (for example $\varphi(x,y) = x + 5y$ modulo 13 works for $r = 2$: the thirteen displacements with $|a| + |b| \leq 2$ map to the thirteen distinct residues). For $n \geq 3$ and $r \geq 2$, Golomb and Welch conjectured in 1970 that no perfect Lee code exists, and the conjecture is proved in various cases but remains open in general. So the case $r = 1$ in this problem is not a sample of a general phenomenon; it is the one radius where the shape and the group agree, and that is why the answer is all n rather than some n.

The discernment mechanism is this. When a problem imposes local conditions on a subset of an infinite homogeneous structure, first merge the conditions into a single statement about a partition or covering; then extract the density; then look for the subgroup or homomorphism that realises that density. Homogeneous ambient structure means the answer is likely to be homogeneous too, and homogeneous subsets of a group are cosets of subgroups. Train this by rewriting every combinatorial condition you meet in terms of the group action that preserves it.

Knowledge gaps, stated plainly. Before this problem is even approachable you need four things installed, none of which is in A-level or Further Mathematics. First, homomorphisms of abelian groups and the fact that a homomorphism out of $\mathbb{Z}^n$ is freely determined by the images of the basis vectors; without it the parametrisation step is invisible. Second, the notion of index and density of a subgroup, and the ability to convert a counting statement about an infinite set into a modular arithmetic statement. Third, the language of packings and coverings, so that you can recognise conditions (1) and (2) as packing and covering and merge them; the sphere packing bound with equality is the definition of a perfect code. Fourth, the Lee metric on $\mathbb{Z}^n$ and the fact that its balls are crosses, together with enough of the Golomb and Welch story to know that the radius 1 case is special and that you should not expect the same trick to survive at larger radius. If you meet this problem without those four, you will find the $n = 2$ picture by hand and stall.

Revolving concepts

Perfect codes and the sphere packing bound. A code S in a metric space with all balls of radius r of the same size V is perfect if the balls of radius r about the codewords partition the space, equivalently if it attains the sphere packing bound density $1/V$ with equality. The classical examples are the Hamming codes over $\mathbb{F}_q$, the binary and ternary Golay codes, and (in the Lee metric) the constructions of this problem. Perfect codes are almost always kernels of linear maps, because a partition into congruent pieces with a transitive symmetry group is usually a coset decomposition. See Book 1, field: Discrete structures and graphs, topic: Perfect codes and coverings.

Efficient domination. In graph language, S is an efficient dominating set (or perfect code) of a graph G if the closed neighbourhoods $N[s]$ for $s \in S$ partition $V(G)$. Conditions (1) and (2) are precisely that for the lattice graph $\mathbb{Z}^n$ with edges between points differing by one in a single coordinate. This is a standard reformulation to keep, because the merged statement is easier to reason about than the pair of conditions. See Book 1, field: Discrete structures and graphs, topic: Domination in graphs.

Subgroups of $\mathbb{Z}^n$ and index. $\mathbb{Z}^n$ is free abelian of rank n; a homomorphism to any abelian group is uniquely determined by arbitrary images of $e_1, \ldots, e_n$. Subgroups of index m are kernels of surjections onto groups of order m, and the quotient of $\mathbb{Z}^n$ by such a subgroup has exactly m cosets, each of density $1/m$. This is the standard machine for producing periodic subsets of the lattice of prescribed density. See Book 1, field: Abstract algebra, topic: Free abelian groups and quotients.

Odd order and the involution free pairing. In an abelian group G of odd order, $g = -g$ implies $2g = 0$ implies $g = 0$ (since 2 is invertible modulo an odd number), so $G \setminus \{0\}$ splits into $\frac{|G|-1}{2}$ pairs $\{g, -g\}$. This is a special case of the standard involution counting argument: if an involution acts on a finite set, the number of fixed points has the same parity as the size of the set. That argument also proves Fermat's two squares theorem in Zagier's one sentence form, and it is worth carrying as a general tool. See Book 1, field: Abstract algebra, topic: Involutions and pairing arguments.

The Lee metric and cross tilings. The Lee distance on $\mathbb{Z}^n$ is $\sum_i |x_i - y_i|$; the ball of radius r has $\sum_{k\geq 0} 2^k \binom{n}{k}\binom{r}{k}$ points, which is $2n+1$ for $r=1$. A perfect Lee code is a lattice or non-lattice tiling of $\mathbb{Z}^n$ by these crosses. Golomb and Welch (1970) proved existence for $r=1$ in all dimensions and for all r when $n=2$, and conjectured non-existence for $n\geq 3$, $r\geq 2$; the conjecture is still open in general. Related is Minkowski's conjecture on lattice tilings by cubes, proved by Hajós. See Book 1, field: Discrete structures and graphs, topic: Lattice tilings.

Recursion note and its generalisation. There is no recursion in the construction, and it is worth saying why, because the instinct to induct on n is strong and wastes time. The obstruction is arithmetic: a tiling of $\mathbb{Z}^n$ by crosses has density $\frac{1}{2n+1}$ and a tiling of $\mathbb{Z}^{n+1}$ has density $\frac{1}{2n+3}$, and $\gcd(2n+1, 2n+3) = 1$, so no construction that layers copies of an n dimensional solution can produce an $(n+1)$ dimensional one. The generalised statement to keep is: when a family of problems indexed by n has an invariant (here density) whose values for consecutive n are incompatible, look for a uniform construction rather than a recursive one. The uniform construction here is the group homomorphism, whose definition is the same sentence for every n. See Book 1, field: Combinatorics, topic: Uniform versus recursive constructions.

Circuit Bank

- **WHEN** you see one condition for points in a set and another for points outside it, both about neighbours **DO** merge them into a single statement counting how many points of the set lie in each closed ball **BECAUSE** a pair of complementary local conditions is usually one covering or partition statement, and the merged form removes every later case split
- **WHEN** you have a partition of an infinite homogeneous set into congruent pieces of size V **DO** write down the density $\frac{1}{V}$ immediately and treat V as a forced modulus **BECAUSE** density is the only invariant of such a partition, so any construction must realise it, and the modulus you will eventually work with is determined before you construct anything
- **WHEN** you need a subset of a group of prescribed density $\frac{1}{m}$ **DO** take the kernel or a coset of a homomorphism onto a group of order m **BECAUSE** a homomorphism out of a free abelian group is determined by arbitrary images of the basis vectors, so an infinite search collapses to finitely many parameters
- **WHEN** you have parametrised by images c_i of basis vectors and a condition about moving to neighbours **DO** write the condition as a statement about the multiset $\pm c_1, \ldots, \pm c_n$ and count **BECAUSE** moving by $\pm e_i$ changes the homomorphism by $\pm c_i$, so all local conditions become statements about that finite list, and equal cardinalities turn surjectivity into injectivity
- **WHEN** you read for which n does there exist **DO** do not assume an obstruction exists; test the construction instinct first and only then look for an invariant **BECAUSE** setters use the interrogative form both when the answer is a restricted set and when it is everything, so treating it as a hint costs you the problem when the answer is all n

Backtesting

1. First useful cue: conditions (1) and (2) merge into the statement that the closed unit balls about points of S partition $\mathbb{Z}^n$.
2. Method the expression suggested: count the ball size to get the modulus $2n+1$, look for S as the kernel of $\varphi : \mathbb{Z}^n \to \mathbb{Z}/(2n+1)\mathbb{Z}$, translate the conditions into a statement about $\pm\varphi(e_i)$, and take $\varphi(e_i) = i$.
3. Where you would hesitate, and the thought to reinforce: after the density calculation, whether a subgroup really can do the job. The thought is that the problem is translation invariant, so it

is reasonable that a translation invariant solution exists, and translation invariant subsets of a group of density $\frac{1}{m}$ are cosets of index m subgroups.

4. The trap the question sets: the phrase for which integers n, which invites a hunt for an obstruction, and the low dimensional pictures, which invite an hour of drawing. Both consume time without producing a general argument.

5. What makes you recognise it faster next time: the shape of the ball. A cross whose non-central points come in opposite pairs $\pm e_i$ matches the pairing of the nonzero elements of any odd order abelian group; the moment you see that matching you have the construction.

6. The reusable decision rule: merge local conditions into a covering statement, read the density, then realise the density as a subgroup and push the conditions through the homomorphism.

Mirror drills

1. Show that conditions (1) and (2) together are equivalent to: the closed balls of radius 1 centred at points of S partition $\mathbb{Z}^n$. *Answer:* for $p \in S$, the balls containing p are those centred at p and at neighbours of p in S, so (1) says exactly one; for $p \notin S$, the balls containing p are those centred at neighbours of p in S, so (2) says exactly one. The converse reverses both readings.

2. Classify all valid S for $n = 1$. *Answer:* the balls are the blocks $\{p-1, p, p+1\}$ and they must tile $\mathbb{Z}$, so consecutive elements of S differ by exactly 3 and $S = 3\mathbb{Z} + a$ for some $a \in \{0, 1, 2\}$; these are exactly the fibres of $\varphi(x) = x \bmod 3$.

3. Exhibit a perfect code of radius 2 in $\mathbb{Z}^2$, that is a set S such that the thirteen point Lee balls of radius 2 centred at its points tile $\mathbb{Z}^2$. *Answer:* $S = \{(x, y) : x + 5y \equiv 0 \pmod{13}\}$; the thirteen displacement vectors (a, b) with $|a| + |b| \leq 2$ have values $a + 5b$ running over all thirteen residues modulo 13 exactly once.

Chapter 8

Putnam 2018

8.1 A1. Unit fractions collapse into a factor pair

Find all ordered pairs (a, b) of positive integers for which

$$\frac{1}{a} + \frac{1}{b} = \frac{3}{2018}.$$

Read it out loud

Two positive unit fractions add to a third fraction that is not itself a unit fraction. Say the equation out loud and the shape matters more than the numbers: $1/a + 1/b = k/n$ is the Egyptian fraction template, and every question in that template wants the same treatment. Clear denominators and you get a relation with exactly one ab term and two linear terms, nothing else. An expression of that shape, one bilinear term, two linear terms, no pure squares, is one scalar multiple away from $(pa - q)(pb - q) =$ constant, because expanding that product is precisely a bilinear term plus two linear terms plus a constant term. You do not need to search for this factorisation. You need to recognise that the number of terms and their degrees have already told you it exists, and multiply by whatever scalar makes the cross term's coefficient match the square of the linear coefficient.

The second thing to read off in the first thirty seconds is 2018 itself. A Putnam problem set in a specific year routes its arithmetic through that year's own factorisation far more often than coincidence would suggest, so you check it immediately: $2018 = 2 \times 1009$, and you confirm 1009 is prime by trial division up to $\lfloor \sqrt{1009} \rfloor = 31$ rather than assuming it. The fields wired into this problem are pure number theory: completing a product, counting divisors of a number given in prime factorised form, and a congruence condition that falls out of the algebra automatically rather than being imposed as an extra restriction. There is no calculus, no geometry, nothing combinatorial beyond counting divisors. Within thirty seconds you should have $2018a + 2018b = 3ab$ on your page and your pen already moving to multiply by 3.

Approaches, ranked worst to best

1. **Search from the forced lower bound.** *Cue:* the phrase "positive integers" with no algebra attempted first. *Circuit:* brute force enumeration. (Positivity of $1/a$ and $1/b$ forces each to be smaller than $3/2018$, so $a, b \geq 673$. Nothing in that bound stops a from being enormous, and indeed the true maximum is $a = 1358114$. You would only discover that ceiling by accident, and you could never write a complete proof of termination without secretly reconstructing the factorisation below. Unbounded ink for an answer you cannot certify complete.)

2. **Isolate b and chase divisibility.** *Cue:* solving $b = \dfrac{2018a}{3a - 2018}$ and asking when the quotient is an integer. *Circuit:* direct divisibility chasing. (This does reach $3a - 2018 \mid 2018^2$, but only after noticing that $3a - 2018$ must divide $3(2018a) = 2018(3a - 2018) + 2018^2$ and subtracting off the multiple of itself. It works, yet it destroys the symmetry between a and b that the factored equation displays for free, so you effectively do the casework once for a and would need to redo it for b to be sure you have not lost a pair.)

3. **Complete the product.** *Cue:* a single ab term, two linear terms, no squares. *Circuit:* force a fixed product by matching the scalar to the cross term. (Multiplying by the right constant produces $(3a - 2018)(3b - 2018) = 2018^2$ in one line, manifestly symmetric, and reduces the entire problem to divisor enumeration of a single fully factorised number. This is the route that costs the least ink and proves completeness as a side effect of the method rather than as an afterthought.)

The ideal solution

Multiply $\frac{1}{a}+\frac{1}{b}=\frac{3}{2018}$ through by $2018ab$:

$$2018b+2018a=3ab, \qquad \text{that is,} \qquad 3ab-2018a-2018b=0.$$

Multiply by 3 so that the coefficient of each linear term becomes the product of 3 (the coefficient of ab) and the constant 2018, which is exactly what completing the product needs:

$$9ab-3(2018)a-3(2018)b=0 \implies (3a-2018)(3b-2018)=2018^2,$$

since expanding the left side gives $9ab-3(2018)a-3(2018)b+2018^2$, and adding 2018^2 to both sides of the previous line produces exactly that.

Because $2018=3(672)+2$, we have $2018\equiv 2 \pmod 3$, so for any positive integer a, $3a-2018\equiv -2\equiv 1 \pmod 3$. This holds automatically, for every positive integer a, not just for the ones that end up solving the equation; the same is true of $3b-2018$. So whatever factor pair of 2018^2 we find, both factors are forced to lie in the residue class 1 mod 3.

Factorise $2018=2\times 1009$; 1009 is prime, since none of $2,3,5,7,11,13,17,19,23,29,31$ divides it and $31^2<1009<32^2$. So $2018^2=2^2\times 1009^2$ has $(2+1)(2+1)=9$ positive divisors, one for each choice of the exponent of 2 in $\{0,1,2\}$ and of 1009 in $\{0,1,2\}$. Since $1009=3(336)+1$, every power of 1009 is $\equiv 1 \pmod 3$, while $2\equiv 2$ and $2^2=4\equiv 1 \pmod 3$. A divisor $2^i\cdot 1009^j$ is therefore $\equiv 1 \pmod 3$ exactly when $i\in\{0,2\}$, regardless of j. Writing $d=3a-2018$, we need d to be one of these six divisors:

$$1,\ 4,\ 1009,\ 4036,\ 1009^2,\ 4\cdot 1009^2,$$

and the complementary divisor $2018^2/d=2^{2-i}\cdot 1009^{2-j}$ automatically has its own power of 2 equal to 2^{2-i}, which lies in $\{0,2\}$ exactly when i does; so the cofactor is independently guaranteed to be $\equiv 1 \pmod 3$ too, for each of the six choices, with no separate check required.

For each such d, solve $a=(d+2018)/3$ and $b=(2018^2/d+2018)/3$:

d	a	b
1	673	1358114
4	674	340033
1009	1009	2018
4036	2018	1009
1009^2	340033	674
$4\cdot 1009^2$	1358114	673

all six of which are positive integers, giving the ordered pairs $(673,1358114)$, $(674,340033)$, $(1009,2018)$, and their three reversals.

It remains to rule out negative divisors. If $d<0$ then $2018^2/d<0$ too, and $a=(d+2018)/3$ is a positive integer only if $d>-2018$; among the negative divisors of 2018^2 that are $\equiv 1 \pmod 3$ by the same rule, namely -2, -2018, and $-2\cdot 1009^2$, only $d=-2$ satisfies $d>-2018$, giving $a=672$. But then $2018^2/d=-1009^2\cdot 2\cdot 1009/$ more directly $2018^2/(-2)=-2036162$, so $b=(-2036162+2018)/3=-678048<0$, which is not a positive integer. The other two negative divisors give $a\le 0$ outright. No negative-divisor case survives.

$$\boxed{(a,b)\in\{(673,1358114),\ (674,340033),\ (1009,2018),\ (2018,1009),\ (340033,674),\ (1358114,673)\}}$$

Layer 1: WHAT

Block 1: read the equation's shape (one bilinear term, two linear terms) and recognise the completed-product target. Block 2: choose the scalar multiplier that makes the cross term's coefficient equal the

product of the two linear coefficients, and complete the product. Block 3: factorise 2018 and count divisors of 2018^2 by the exponent grid. Block 4: observe that the linear shift forces every valid factor into the residue class 1 mod 3, and use this as a filter rather than extra casework. Block 5: solve for (a, b) across the six admissible positive divisors, then explicitly dispose of the negative-divisor branch by positivity.

The nominal route enumerates a from 673 upward (or chases divisibility on $b = 2018a/(3a - 2018)$ one variable at a time) with no certified stopping point and no symmetry to halve the work. The bifurcation point is the exact line after $3ab - 2018a - 2018b = 0$: the ideal route multiplies by 3 and completes a product; the nominal route instead tries to isolate a variable and search. Everything before that line is identical for both; everything after diverges completely, and the nominal route never regains the symmetry it threw away.

Layer 2: HOW

Block 1. **Cue.** The equation, once denominators are cleared, has exactly one ab term and two linear terms with no pure squares. **Why natural.** A degree-two expression with that exact term structure is the expansion of a product of two linear binomials minus a constant, so the target factorisation is not found by search, it is read off the shape. **Link to the next block.** The next step is arithmetic: find the scalar that turns the shape into that exact product.

Block 2. **Cue.** The linear coefficients are both -2018 and the ab coefficient is 3. **Why natural.** Multiplying the whole equation by 3 makes each linear coefficient equal to 3×2018, which is precisely the cross term you get from expanding $(3a - 2018)(3b - 2018)$, so the completion requires no guessing, only matching coefficients. **Link to the next block.** Once the equation reads $(3a - 2018)(3b - 2018) = 2018^2$, the problem has become a divisor-pair count.

Block 3. **Cue.** 2018 is a specific number handed to you by the year of the competition. **Why natural.** Any fixed integer factorises into a finite, checkable list of primes, and once you have that list, divisor counting is mechanical rather than exploratory. **Link to the next block.** Knowing the prime factorisation lets you predict, before listing anything, how many divisors there are and which residues they occupy.

Block 4. **Cue.** Both factors are linear expressions of the form $3(\text{integer}) - 2018$. **Why natural.** Every integer of that form lies in a single residue class mod 3 purely because 2018 itself has a fixed residue mod 3; this is true before you know which divisor you will use, so it is a filter you get for free rather than a condition you must verify case by case. **Link to the next block.** This filter cuts the nine divisors of 2018^2 down to the six that can possibly arise, before you do a single division.

Block 5. **Cue.** Six candidate values of d remain, plus the logical possibility of negative factor pairs. **Why natural.** A full-marks solution to "find all pairs" must dispose of every branch explicitly; the negative branch is not automatically empty just because the positive branch works, since a negative times a negative is also positive. **Link to the next block.** Checking positivity directly on each negative candidate closes the proof without leaving an unjustified gap.

Layer 3: WHY

The truth underneath this problem is that the equation $pxy = q(x + y)$, for any fixed nonzero p and q, always reduces to $(px - q)(py - q) = q^2$ by multiplying through by p; this is not special to 2018 or to unit fractions, it is an identity in p, q, x, y that holds before any numbers are substituted. The discernment mechanism is counting terms and degrees: whenever a relation between two variables has total degree two, contains exactly one mixed term, and contains no pure squares, the

completed-product form exists and is unique up to the choice of scalar. You train this by drilling the recognition step in isolation, away from any specific numbers, until seeing "xy term plus two linear terms, no squares" fires the same reflex every time, regardless of how the problem dresses up the coefficients as fractions, denominators, or a competition year.

The examiners nudged you toward this by choosing a right-hand side, $3/2018$, whose numerator is not 1. Had the equation been $1/a + 1/b = 1/n$, the completed form $(a-n)(b-n) = n^2$ is even more familiar and the problem would test only divisor counting; forcing a numerator of 3 makes you notice that the scalar you multiply by must match that numerator, and it is precisely this extra step, multiplying by 3 rather than by 1, that separates a candidate who has memorised one instance of the trick from one who has understood the identity behind it.

Revolving concepts

Unit fraction (Egyptian fraction) equations: the general family $\frac{1}{x} + \frac{1}{y} = \frac{k}{n}$ always reduces to $(kx - n)(ky - n) = n^2$; the number of ordered solution pairs equals the number of divisors of n^2 that lie in the residue class forced by n mod k, which is a clean generalisation of the case $k = 1$ that most students meet first. See Book 1, field: Number theory, topic: Diophantine equations from cleared denominators.

Divisor counting from a prime factorisation: if $N = \prod p_i^{e_i}$ then N has $\prod(e_i + 1)$ positive divisors, and this generalises immediately to counting divisors in a fixed residue class mod a small prime m, by tracking which combinations of exponents give which residue, exactly as done above for $m = 3$. See Book 1, field: Number theory, topic: multiplicative functions and the divisor function.

Residues under multiplication: the nonzero residues mod 3 form a cyclic group of order 2 under multiplication, $\{1, 2\}$, so the residue of a product is determined by the parity of how many factors are $\equiv 2$; this is why tracking only the exponent of the single prime that is $\equiv 2 \pmod 3$ (here, the prime 2) was enough to classify every divisor, while the prime $1009 \equiv 1 \pmod 3$ contributed nothing to the residue. See Book 1, field: Number theory, topic: multiplicative structure of $(\mathbb{Z}/m\mathbb{Z})^\times$.

Circuit Bank

- **WHEN** a relation has one bilinear term and two linear terms in two variables, no pure squares **DO** multiply by the scalar that makes the cross-term coefficient equal the product of the two linear coefficients, then complete the product **BECAUSE** this shape is always the expansion of a two-factor product minus a constant, so the factorisation is guaranteed to exist, not merely hoped for

- **WHEN** a fixed integer must be factorised to enumerate divisors **DO** write its full prime factorisation first and read off the exponent grid, rather than testing candidate divisors one at a time **BECAUSE** the number and residue class of every divisor is determined instantly from the exponents, which turns an open-ended search into a finite, checkable list

- **WHEN** a family of candidate values is generated by a linear shift of an unconstrained integer **DO** check what residue class the shift forces before doing any casework **BECAUSE** the residue is fixed by the shift alone and applies to every candidate simultaneously, so it filters the whole list in one step instead of one check per candidate

- **WHEN** a factorisation $XY = k$ with $k > 0$ is used to solve for positive unknowns **DO** explicitly substitute the negative divisors and check positivity, rather than assuming they fail **BECAUSE** negative times negative is also positive, so the sign condition on X, Y individually is not implied by the sign of their product and must be checked

Backtesting

1. First useful cue: two unit fractions summing to a fixed rational number with numerator greater than 1.
2. Method the expression suggested: clear denominators, then complete the product by multiplying by the numerator of the target fraction.
3. Where you would hesitate, and the thought to reinforce: whether the scalar to multiply by is the numerator or the denominator; reinforce by matching the cross-term coefficient to the product of the two linear coefficients algebraically, not by memory.
4. The trap the question sets: assuming the negative-divisor branch is impossible without checking it, when in fact it fails only because of an explicit positivity computation.
5. What makes you recognise it faster next time: seeing exactly one ab term and two linear terms with no squares, regardless of how the coefficients are dressed up as fractions.
6. The reusable decision rule: for $\frac{1}{a}+\frac{1}{b}=\frac{k}{n}$, always reduce to $(ka-n)(kb-n)=n^2$, then filter the divisors of n^2 by the residue that $-n$ forces mod k.

Mirror drills

1. Find all positive integer pairs with $\frac{1}{a}+\frac{1}{b}=\frac{1}{12}$. *Answer:* reduces to $(a-12)(b-12)=144=2^4\cdot 3^2$, which has 15 positive divisors, so there are 15 ordered pairs.
2. Find all positive integer pairs with $\frac{2}{a}+\frac{5}{b}=\frac{1}{3}$. *Answer:* clear denominators to $6b+15a=ab$, then complete the product as $(a-6)(b-15)=90$, and check which of the resulting pairs keep a,b positive.
3. For $\frac{1}{a}+\frac{1}{b}=\frac{3}{N}$ with N an odd prime greater than 3, explain why the number of solution pairs depends on N mod 3 rather than on N itself. *Answer:* because N^2 has exactly the divisors $1, N, N^2$, and which of $3N-N=2N$-type shifts (that is, which of $1, N, N^2$) lie in the forced residue class is controlled entirely by whether $N\equiv 1$ or $2 \pmod 3$.

8.2 A2. Determinant of the subset intersection matrix

Let $S_1, S_2, \ldots, S_{2^n-1}$ be the nonempty subsets of $\{1, 2, \ldots, n\}$ in some order, and let M be the $(2^n - 1) \times (2^n - 1)$ matrix whose (i, j) entry is

$$m_{ij} = \begin{cases} 0 & \text{if } S_i \cap S_j = \emptyset; \\ 1 & \text{otherwise.} \end{cases}$$

Calculate the determinant of M.

Read it out loud

The size of the matrix is $2^n - 1$, and that number is not a free choice, it is exactly the count of nonempty subsets of $\{1, \ldots, n\}$. Whenever a construction is indexed by all subsets (or all nonempty subsets) of $\{1, \ldots, n\}$, and the entries only depend on set relations between the indices, you should reach for induction on n by splitting on whether the largest element n belongs to a given subset. This is the one recursive structure that the power set of $\{1, \ldots, n\}$ actually has for free: the subsets not containing n are exactly the subsets of $\{1, \ldots, n-1\}$, and the subsets containing n are exactly those same subsets of $\{1, \ldots, n-1\}$ with n adjoined, so the whole object at size n is built out of two copies of itself at size $n - 1$.

The phrase "in some order" is a second cue, and a generous one: it is telling you the answer cannot depend on the labelling, which means you are free to choose whichever ordering makes the recursive split visible as an actual block structure in the matrix, rather than being stuck with whatever order the subsets happened to be listed in. Before using that freedom you must earn it, by checking that relabelling really does leave the determinant alone; this is a short argument and it belongs at the very start, not as an afterthought.

The field here is linear algebra sitting on top of combinatorics: the entries of M are not numbers you compute from a formula, they are the answer to a set-theoretic question (is the intersection empty), so the tools you reach for are the ones that behave well when a whole block of an matrix is constant, namely elementary row and column operations and block-triangular determinant formulas, rather than eigenvalues or a closed-form entrywise pattern. Within the first minute you should have written $2^n - 1 = (2^{n-1} - 1) + 2^{n-1}$ and be looking for the block matrix that decomposition produces.

Approaches, ranked worst to best

1. **Compute small cases by hand and guess.** *Cue:* the temptation to just write out the 3×3 and 7×7 matrices for $n = 2, 3$. *Circuit:* pattern spotting. (This gets you $\det M_2 = -1$ quickly and $\det M_3 = -1$ with real effort, but a guessed pattern from two data points is not a proof, and the 7×7 hand computation is already painful enough that $n = 4$ is not realistic by this route at all.)

2. **Attack the eigenvalues directly.** *Cue:* a $0/1$ matrix defined by a Boolean condition on the indices. *Circuit:* spectral methods. (The matrix is symmetric, so it has real eigenvalues, but the entries are not linear or bilinear in any convenient basis of indicator vectors, since $m_{ij} = 1$ means $S_i \cap S_j \neq \emptyset$, a threshold condition, not $S_i \cap S_j$ itself. There is no clean way to write M as a low rank perturbation of a matrix with known spectrum, so this route stalls almost immediately.)

3. **Recursive block decomposition on n.** *Cue:* index set size exactly $2^n - 1$, and an explicit invitation ("in some order") to relabel freely. *Circuit:* split on membership of the top element, then reduce the resulting block matrix. (This is the route that works: choosing the ordering that respects the split "does not contain n, contains n but is not $\{n\}$, equals $\{n\}$" turns M_n

into an explicit block matrix built from M_{n-1}, and elementary operations finish it in a short recursion.)

The ideal solution

Write M_n for the matrix built from the nonempty subsets of $\{1, \dots, n\}$, in whatever order.

Order independence. Every permutation of a finite list is a product of transpositions, so it suffices to check invariance under swapping the labels of two subsets, say S_p and S_q. Relabelling swaps rows p, q of M and, since the entries also depend on the column index through the same subsets, it separately swaps columns p, q too. Swapping two rows multiplies the determinant by -1, and swapping two columns multiplies it by -1 again, so the net effect on $\det M$ is multiplication by $(-1)^2 = 1$. Hence $\det M_n$ does not depend on the chosen ordering, and we are free to choose the most convenient one.

The recursive ordering. For $n \geq 2$, let $S'_1, \dots, S'_{2^{n-1}-1}$ be the nonempty subsets of $\{1, \dots, n-1\}$ in any fixed order, with matrix M_{n-1}, entries m'_{ij}. Order the $2^n - 1$ nonempty subsets of $\{1, \dots, n\}$ as: $S_i = S'_i$ for $1 \leq i \leq 2^{n-1} - 1$; $S_i = S'_{i-2^{n-1}+1} \cup \{n\}$ for $2^{n-1} \leq i \leq 2^n - 2$; and $S_{2^n-1} = \{n\}$. This lists every subset not containing n, then every subset containing n other than $\{n\}$ itself, then $\{n\}$; the counts are $(2^{n-1} - 1) + (2^{n-1} - 1) + 1 = 2^n - 1$, correct.

The block structure. For $i, j \leq 2^{n-1} - 1$, neither S_i nor S_j contains n, so $m_{ij} = m'_{ij}$: the top-left block is M_{n-1}. For $i \leq 2^{n-1} - 1$ and j in the middle range, $S_i \cap S_j = S_i \cap (S'_j \cup \{n\}) = S_i \cap S'_j$ since $n \notin S_i$, so this entry also equals the corresponding entry of M_{n-1}; by the symmetry of intersection the same holds with rows and columns exchanged, so both off-diagonal blocks equal M_{n-1}. For i, j both in the middle range, $S_i \cap S_j \supseteq \{n\}$ always, since both sets contain n; that whole block is entrywise 1. The last row and column (index $2^n - 1$, the set $\{n\}$) meet the first block in 0 (since $\{n\}$ is disjoint from any subset of $\{1, \dots, n-1\}$), meet the middle block in 1 (since every set there contains n), and meet itself in 1. Altogether,

$$M_n = \left(\begin{array}{ccc|ccc|c} & & & & & & 0 \\ & M_{n-1} & & & M_{n-1} & & \vdots \\ & & & & & & 0 \\ \hline & & & 1 & \cdots & 1 & 1 \\ & M_{n-1} & & \vdots & \ddots & \vdots & \vdots \\ & & & 1 & \cdots & 1 & 1 \\ \hline 0 & \cdots & 0 & 1 & \cdots & 1 & 1 \end{array}\right).$$

Clearing the constant block. Subtract the final row from each of the middle rows. Each middle row currently reads $(M_{n-1}\text{-row}, \mathbf{1}^T, 1)$ and the final row reads $(\mathbf{0}, \mathbf{1}^T, 1)$, so after subtraction every middle row becomes $(M_{n-1}\text{-row}, \mathbf{0}^T, 0)$; the M_{n-1} entries survive because the final row is 0 there. This changes nothing about the determinant. Now, using the current matrix, subtract the final column from each middle column. The final column currently reads 0 in the top rows, 0 in the (already updated) middle rows, and 1 in the final row, so this operation only changes the final row: its middle entries, currently 1 each, become $1 - 1 = 0$. The result is

$$\left(\begin{array}{ccc|ccc|c} & & & & & & 0 \\ & M_{n-1} & & & M_{n-1} & & \vdots \\ & & & & & & 0 \\ \hline & & & 0 & \cdots & 0 & 0 \\ & M_{n-1} & & \vdots & \ddots & \vdots & \vdots \\ & & & 0 & \cdots & 0 & 0 \\ \hline 0 & \cdots & 0 & 0 & \cdots & 0 & 1 \end{array}\right),$$

whose final row and final column now both vanish except for the corner entry 1. Expanding along that row (a row with a single nonzero entry, in the bottom right corner, so the cofactor sign is $(-1)^{(2^n-1)+(2^n-1)} = +1$) gives

$$\det M_n = \det \begin{pmatrix} M_{n-1} & M_{n-1} \\ M_{n-1} & 0 \end{pmatrix}.$$

Collapsing the block matrix. Let $k = 2^{n-1} - 1$, the common block size. Swap the top k rows with the bottom k rows. Moving a block of k rows past another block of k rows is a permutation with sign $(-1)^{k^2}$ (it is realised by k^2 transpositions, one for each pair consisting of one row from each block, each such pair needing to cross exactly once). For $n \geq 2$, 2^{n-1} is even, so $k = 2^{n-1} - 1$ is odd, and k^2 is odd; the sign is -1. After the swap the matrix reads $\begin{pmatrix} M_{n-1} & 0 \\ M_{n-1} & M_{n-1} \end{pmatrix}$, which is block lower triangular, so its determinant is the product of the diagonal blocks' determinants, $(\det M_{n-1})^2$. Undoing the sign of the swap,

$$\det M_n = -(\det M_{n-1})^2 \qquad (n \geq 2).$$

Base case and conclusion. For $n = 1$ the only nonempty subset of $\{1\}$ is $\{1\}$ itself, $M_1 = (1)$, and $\det M_1 = 1$. For $n \geq 2$, whatever the sign of $\det M_{n-1}$, its square is 1, so $\det M_n = -1$. In particular $\det M_2 = -(\det M_1)^2 = -1$, and every subsequent value stays at -1 once it lands there.

$$\boxed{\det M = 1 \text{ if } n = 1, \qquad \det M = -1 \text{ if } n \geq 2.}$$

Layer 1: WHAT

Block 1: prove the answer is independent of the ordering, using transpositions, so a convenient ordering may be chosen freely. Block 2: choose the ordering that splits subsets by membership of the top element n, and set up the resulting index ranges. Block 3: derive the four block types of M_n from first principles (two copies of M_{n-1}, one all-ones block, and a corner row and column), using only the definitions of intersection and union. Block 4: use elementary row and column operations, subtracting the constant last row and last column, to zero out the all-ones contamination and shrink to a genuine block matrix. Block 5: swap the two remaining row blocks, track the sign of that swap exactly, and read off a block lower triangular determinant. Block 6: solve the resulting recursion $\det M_n = -(\det M_{n-1})^2$ using the base case $n = 1$.

The nominal route computes $n = 2, 3$ by hand and conjectures -1, or hunts for eigenvalues of a matrix with no clean spectral structure. The bifurcation point is the decision, immediately after proving order-independence, to spend effort choosing a specific recursive ordering rather than accepting whatever ordering the problem handed you; every subsequent block operation exists only because that specific ordering was chosen, and none of it is visible under an arbitrary ordering.

Layer 2: HOW

Block 1. Cue. The problem explicitly says "in some order," which is an unusual thing to say unless it matters. **Why natural.** If a stated quantity is independent of an arbitrary choice, that independence is normally worth proving first, because it licenses you to make the choice yourself later, and a swap of two labels is the smallest possible instance of "the choice changes," so checking it settles every relabelling by composition. **Link to the next block.** Once relabelling is free, the natural next move is to choose the ordering that makes the object's recursive structure visible.

Block 2. Cue. The index count is $2^n - 1$, the count of nonempty subsets of an n-element set. **Why natural.** This number has exactly one natural recursive decomposition, splitting on whether the

largest element belongs to the subset, because the subsets of $\{1, \ldots, n\}$ are in exact bijection with (subsets of $\{1, \ldots, n-1\}$) union (subsets of $\{1, \ldots, n-1\}$, each with n attached). **Link to the next block.** This bijection becomes a literal block structure in the matrix once the ordering respects it.

Block 3. **Cue.** Every entry of M is determined purely by whether an intersection is empty. **Why natural.** Once you know which of the two groups ("contains n" or not) each index belongs to, the intersection condition simplifies immediately: dropping n from a computation costs nothing when the other set does not contain n either, and containing n on both sides is enough on its own to guarantee nonempty intersection, regardless of anything else in the sets. **Link to the next block.** This is why two full blocks collapse to M_{n-1} exactly and one full block collapses to the constant 1, with no computation left to do inside those blocks.

Block 4. **Cue.** One whole block of the matrix is entirely 1s, and it sits next to a corner row and column that are mostly 0 or mostly 1. **Why natural.** A block that is entirely one constant value is exactly what elementary row or column operations are built to erase: subtracting a row that matches the constant block everywhere zeroes that block out without touching anything the operation does not act on. **Link to the next block.** Once erased, the last row and column have only one nonzero entry each, so a single cofactor expansion strips them off entirely.

Block 5. **Cue.** What remains is a $2k \times 2k$ matrix built from two copies of M_{n-1} and one zero block, not yet triangular. **Why natural.** Two identical off-diagonal-style blocks separated by a zero block become block triangular as soon as the two row blocks are swapped, and a block triangular determinant is just the product down the diagonal, so the swap is the one operation standing between the current shape and a shape you already know how to evaluate. **Link to the next block.** The only remaining task is bookkeeping: the swap has a sign, and that sign must be computed, not assumed.

Block 6. **Cue.** The identity $\det M_n = -(\det M_{n-1})^2$ holds for every $n \geq 2$, and the base value $\det M_1 = 1$ has magnitude one. **Why natural.** Squaring a real number always destroys its sign, so from $n = 2$ onward the recursion produces a negative number no matter what sign $\det M_{n-1}$ carried, and a magnitude of 1 squared stays 1 forever, so nothing ever grows or shrinks. **Link to the next block.** The recursion is therefore solved completely by one step of induction, needing no closed form beyond -1.

Layer 3: WHY

The truth underneath this problem is that the power set of $\{1, \ldots, n\}$ is the one combinatorial object on n elements with a perfectly free recursive decomposition: removing the top element splits it into two copies of the power set on $n-1$ elements, with no leftover cases beyond the single set $\{n\}$ itself, and the same split works for any construction whose entries depend only on intersection, union or containment between the indexing subsets, because those three operations interact with "does this set contain n" in a fixed, computable way. The discernment mechanism is recognising the count $2^n - 1$ (or 2^n) as the fingerprint of an object indexed by all subsets, distinct from counts like n, n^2 or $\binom{n}{k}$ which suggest entirely different recursions (on a single element, on a pair, or on choosing a subset of fixed size). You train it by asking, every time you see a matrix, sequence or sum indexed by all subsets of a finite set, "what happens to the top element," before trying anything else.

The examiners nudged you toward this by writing "in some order," a phrase that does no logical work unless the reader is meant to notice that the answer is ordering-independent and therefore free to be computed under a self-chosen, structure-revealing order. A candidate who fixes an arbitrary order (say, binary or lexicographic) and tries to compute directly is fighting the problem; a candidate who reads the phrase as permission is working with it.

Revolving concepts

Recursive self-similarity of the subset lattice: nonempty subsets of $\{1,\dots,n\}$ split into nonempty subsets of $\{1,\dots,n-1\}$ together with all subsets of $\{1,\dots,n-1\}$ (including empty) unioned with $\{n\}$; the same split, applied to unions, symmetric differences, or containment relations instead of intersections, is the standard first move for any subset-indexed recursive construction. See Book 1, field: Combinatorics, topic: induction on the power set by top-element removal.

Block triangular and block-swap determinant rules: for square diagonal blocks A, D, $\det \begin{pmatrix} A & B \\ 0 & D \end{pmatrix} = \det A \cdot \det D$, and swapping two contiguous row blocks of size k each multiplies the determinant by $(-1)^{k^2}$, since the swap is realised by exactly k^2 pairwise crossings between the two blocks' rows. See Book 1, field: Matrices and determinants, topic: block matrix determinants.

Power recursions and sign absorption: for a real recursion $x_n = c\, x_{n-1}^k$ with k even, $x_{n-1}^k \geq 0$ for every real x_{n-1}, so x_n takes the sign of c from the very next term onward regardless of the sign of x_{n-1}; the magnitude separately follows $|x_n| = |c|\,|x_{n-1}|^k$, which becomes linear after taking logarithms, $\log|x_n| = \log|c| + k\log|x_{n-1}|$, and unrolls to $\log|x_n| = \log|c| \cdot \frac{k^{n-1}-1}{k-1} + k^{n-1}\log|x_1|$ for $k \neq 1$. In this problem $k = 2$, $c = -1$, and $|x_1| = |\det M_1| = 1$, so the magnitude stays fixed at 1 forever and the sign is absorbed into -1 after a single step; this is the general reason the recursion resolves in one line rather than needing a closed form in n. See Book 1, field: Sequences and recurrences, topic: nonlinear recursions solved by separating sign and magnitude.

Circuit Bank

- **WHEN** an object is indexed by all subsets (or all nonempty subsets) of $\{1,\dots,n\}$, with entries depending only on set relations **DO** split the index set by membership of the largest element and look for a block matrix built from the same object at size $n-1$ **BECAUSE** the power set decomposes exactly and losslessly under this split, with no leftover cases beyond the single top-element set
- **WHEN** a problem states that an answer does not depend on an arbitrary ordering or labelling **DO** prove that independence first, via invariance under a single transposition, before choosing a convenient ordering to exploit **BECAUSE** every permutation is a product of transpositions, so checking one transposition certifies every relabelling at once
- **WHEN** a block of a matrix is entirely one constant value **DO** subtract a row or column that already equals that constant everywhere in the block **BECAUSE** elementary row and column operations do not change the determinant, and a row equal to the block's constant value zeroes it out in a single step
- **WHEN** two identical blocks sit off the diagonal of a matrix separated by a zero block **DO** swap the corresponding row (or column) blocks and track the sign of the swap from the parity of the block size **BECAUSE** the swap turns the matrix block triangular, whose determinant is just the product of the diagonal blocks, but the sign of a block swap must be computed, not assumed

Backtesting

1. First useful cue: an index set of size $2^n - 1$, the exact count of nonempty subsets of an n-element set.
2. Method the expression suggested: split on membership of the top element n and look for a block matrix expressed in terms of the same construction at size $n-1$.

3. Where you would hesitate, and the thought to reinforce: whether the answer depends on the chosen ordering of the subsets; reinforce by proving invariance under a single transposition before doing anything else.
4. The trap the question sets: being satisfied with a guessed pattern from $n = 2, 3$ computed by hand, instead of the structural recursion a full proof requires.
5. What makes you recognise it faster next time: any matrix, sum or sequence indexed by all subsets of a finite set, with entries depending only on intersection, union or containment.
6. The reusable decision rule: prove order-independence by transposition, split by the top element, and turn the resulting block matrix into a recursion by zeroing constant blocks with elementary row and column operations.

Mirror drills

1. Redo the construction with $m_{ij} = 1$ if $S_i \cup S_j = \{1, \ldots, n\}$, else 0. *Hint:* split on the top element again; now the middle block (both sets containing n) is not automatically all 1s, but the block where neither set contains n is automatically all 0s, so the contamination to clear sits in a different corner.
2. For $m_{ij} = |S_i \cap S_j| \bmod 2$, compute $\det M$ for $n = 2$ and $n = 3$ directly, then check whether the same top-element split still produces two off-diagonal copies of M_{n-1}. *Hint:* it does not, because dropping n from a parity count is not always cost-free the way dropping it from a Boolean "empty or not" test is.
3. Solve $x_n = -3x_{n-1}^2$ with $x_1 = -1$ for x_4. *Answer:* the sign is fixed at -1 for every $n \geq 2$ (since $x_{n-1}^2 \geq 0$ always), and the magnitude follows $|x_n| = 3|x_{n-1}|^2$, giving $|x_2| = 3$, $|x_3| = 27$, $|x_4| = 3 \cdot 27^2 = 2187$, so $x_4 = -2187$.

8.3 A3. Smoothing cubes to maximise a cosine sum

Determine the greatest possible value of $\sum_{i=1}^{10} \cos(3x_i)$ *for real numbers* $x_1, x_2, \ldots, x_{10}$ *satisfying* $\sum_{i=1}^{10} \cos(x_i) = 0$.

Read it out loud

The constraint is stated purely in $\cos(x_i)$, and the target is $\cos(3x_i)$, also purely in terms of the same angle, with no sin anywhere and no information about the actual value of any x_i beyond its cosine. That is the whole cue: the ten angles themselves are irrelevant, only $y_i = \cos x_i \in [-1, 1]$ matters, and $\cos(3\theta)$ expands as a polynomial in $\cos\theta$ through the triple angle identity $\cos 3\theta = 4\cos^3\theta - 3\cos\theta$. Within the first thirty seconds you should have rewritten the whole problem as a polynomial optimisation on a box: maximise $4\sum y_i^3 - 3\sum y_i$ subject to $y_i \in [-1, 1]$ and $\sum y_i = 0$, and notice immediately that the constraint kills the linear term, leaving a bare sum of cubes to maximise.

The second thing to notice is what kind of optimisation this is. It is not a textbook convexity problem, because $y \mapsto y^3$ is concave on $[-1, 0]$ and convex on $[0, 1]$; it changes its mind in the middle of the domain. Jensen's inequality and other single global convexity arguments do not apply directly to a function that is not convex (or concave) across the whole feasible range, and recognising that failure fast is itself useful information: it tells you the extremiser is not going to be a single clean formula, it is going to be a boundary and case structure, found by looking at how the objective responds to small local trades between coordinates rather than by one global inequality.

The field is real analysis dressed as trigonometry: existence of a maximum by compactness, then an exchange argument (fix the sum of a pair of coordinates, see how the objective moves as you shift value between them) to pin down exactly what an optimal configuration must look like.

Approaches, ranked worst to best

1. **Lagrange multipliers on the interior only.** *Cue:* a sum to maximise subject to a sum constraint. *Circuit:* unconstrained critical point equations. (Differentiating $4\sum y_i^3 - \mu\sum y_i$ gives $12y_i^2 = \mu$ for every i, so every y_i is one of two values $\pm\sqrt{\mu/12}$; this finds interior critical points, but the true maximum can and does sit partly on the boundary of the box $y_i = 1$, which Lagrange multipliers alone do not see, so this route needs an entire second argument for the boundary before it can claim anything about a global maximum.)

2. **Global convexity or Jensen on $\sum y_i^3$.** *Cue:* a sum of the same power applied to each variable. *Circuit:* a single inequality covering all cases at once. (This looks like the natural tool for a sum of identical single-variable functions, but y^3 is not convex on all of $[-1, 1]$, only on $[0, 1]$; applying Jensen without splitting the domain produces a bound that is simply not valid for negative y_i, so this route is not merely inefficient, it is not correct as stated.)

3. **Pairwise smoothing at fixed sum.** *Cue:* a box constraint together with a non-globally-convex separable objective. *Circuit:* fix the sum of two coordinates and study the resulting one-variable function's second derivative. (This is the correct route: it needs no global convexity, only the sign of a constant second derivative on a one-dimensional slice, and it converts the whole ten-dimensional problem into a short, finite classification of what an optimal pair can look like.)

The ideal solution

Since $\cos 3\theta = 4\cos^3\theta - 3\cos\theta$ for every real θ, writing $y_i = \cos x_i \in [-1,1]$ turns the target into

$$\sum_{i=1}^{10} \cos(3x_i) = 4\sum_{i=1}^{10} y_i^3 - 3\sum_{i=1}^{10} y_i = 4\sum_{i=1}^{10} y_i^3,$$

the linear term vanishing by the given constraint. So the task is to maximise $4\sum_{i=1}^{10} y_i^3$ over $y \in [-1,1]^{10}$ with $\sum y_i = 0$. This feasible set is a box intersected with a hyperplane, hence closed and bounded, hence compact, and the objective is continuous, so a maximiser exists and may be reasoned about directly.

For an even integer $0 \le n \le 10$, let $V(n)$ be the maximum of $4\sum_{i=1}^{n} y_i^3$ over $y \in [-1,1]^n$ with $\sum y_i = 0$; we compute $V(10)$ by first understanding every even $V(n)$.

Pairwise smoothing. At a maximiser of $V(n)$, fix indices i, j and let $s = y_i + y_j$. Replacing (y_i, y_j) by any $(y, s-y)$ staying in $[-1,1]^2$ changes neither the sum nor the box constraints, so $y = y_i$ must maximise $g(y) = y^3 + (s-y)^3$ on the resulting interval. Since $g''(y) = 6s$ is constant, g is strictly convex when $s > 0$, strictly concave when $s < 0$, and identically zero when $s = 0$ (as $(s-y)^3 = -y^3$ there). A strictly convex function on a closed interval is maximised only at an endpoint; the feasible interval for y is $[s-1, 1]$ when $s \in (0,2]$, and both its endpoints force one of y_i, y_j to equal 1 exactly. A strictly concave function is maximised at its unique critical point, here $y = s/2$, which lies inside the feasible interval $[-1, s+1]$ for every $s \in [-2, 0)$, forcing $y_i = y_j = s/2 \in [-1, 0)$. When $s = 0$, the pair contributes 0 regardless of its values, so deleting it (dropping to $n-2$ coordinates, still summing to 0) changes nothing.

Consequence. At a maximiser of $V(n)$ with $n \ge 2$: either some pair is deletable at no cost, giving $V(n) = V(n-2)$, or no pair is deletable, in which case any two coordinates that are not equal to 1 must, by the case analysis above, be equal and negative (two equal values have $s \ge 0$, and $s > 0$ would force one of them to be 1, so two equal non-1 values force $s < 0$). So every coordinate is either one of $a \ge 0$ copies of 1, or one of $b = n - a$ copies of a single common value $y \le 0$. If $a = 0$ then $ny = 0$ forces $y = 0$ and the objective is 0. If $a \ge 1$, the sum condition $a + by = 0$ gives $y = -a/b$, and $y \ge -1$ forces $a \le b$; the objective becomes

$$4\Big(a \cdot 1^3 + by^3\Big) = 4a\left(1 - \frac{a^2}{b^2}\right) =: W(a,b), \qquad a + b = n,\ 1 \le a \le b.$$

For fixed a, $W(a,b)$ is strictly increasing in b, since $\partial W/\partial b = 8a^3/b^3 > 0$.

Closing the induction. Write $W(n)$ for the largest value of $W(a,b)$ over $a + b = n$, $1 \le a \le b$ (and $W(0) = 0$). The argument above shows $V(n) = \max\big(V(n-2), W(n)\big)$ for $n \ge 2$, with $V(0) = 0 = W(0)$. Given $a + b = n - 2$ with $a \le b$, the pair $(a, b+2)$ has $a + (b+2) = n$ and still $a \le b + 2$, and by the strict monotonicity above $W(a, b+2) > W(a,b)$; taking the best such (a,b) shows $W(n) > W(n-2)$ for every $n \ge 2$. By induction, $V(n) = W(n)$ for every even n, since $W(n) > W(n-2) = V(n-2)$ makes the maximum in $V(n) = \max(V(n-2), W(n))$ always the second term.

It remains to compute $W(10)$: the admissible pairs are $(1,9), (2,8), (3,7), (4,6), (5,5)$, giving

$$W(1,9) = \tfrac{320}{81}, \quad W(2,8) = \tfrac{15}{2}, \quad W(3,7) = \tfrac{480}{49}, \quad W(4,6) = \tfrac{80}{9}, \quad W(5,5) = 0,$$

of which $480/49$ is the largest, attained at $a = 3, b = 7$: three of the x_i with $\cos x_i = 1$ and seven with $\cos x_i = -3/7$.

$$\boxed{\max \sum_{i=1}^{10} \cos(3x_i) = \frac{480}{49}}$$

Layer 1: WHAT

Block 1: expand $\cos 3\theta$ via the triple angle identity and substitute $y_i = \cos x_i$, reducing to a polynomial optimisation on $[-1,1]^{10}$. Block 2: note compactness and continuity to secure that a maximiser genuinely exists. Block 3: derive the pairwise smoothing lemma by holding a pair's sum fixed and reading the constant sign of the resulting one-variable function's second derivative. Block 4: classify every pair at a maximiser into "deletable", "one coordinate equals 1", or "both equal and negative", and note that a deletable pair reduces the problem to a smaller size with no loss. Block 5: strengthen the target claim to every even size n, so the reduction in Block 4 becomes an honest induction, and show the best non-deletable configuration is strictly increasing in size. Block 6: evaluate the finite list of integer configurations at $n = 10$ and identify the maximum.

The nominal route reaches for Lagrange multipliers on the open box or for a direct convexity bound on $\sum y_i^3$, both of which either miss the boundary or are simply invalid on the part of the domain where y^3 is concave. The bifurcation point is the moment you notice $y \mapsto y^3$ changes convexity inside $[-1,1]$: before that realisation the zombie route tries to apply one global inequality; after it, the only honest option is a local, pairwise argument, and everything that follows is a direct consequence of that one observation.

Layer 2: HOW

Block 1. **Cue.** The constraint and the target are both stated purely through $\cos(x_i)$, with no other trigonometric information anywhere in the problem. **Why natural.** Nothing about the actual angles is used or needed, so the substitution $y_i = \cos x_i$ loses no information, and the triple angle identity is exactly the tool that rewrites $\cos(3x_i)$ as a polynomial in that same variable. **Link to the next block.** Once the problem is a polynomial optimisation on a box, existence of a maximum becomes the next thing worth securing before manipulating it.

Block 2. **Cue.** The feasible set is a closed box intersected with a hyperplane, and the objective is a polynomial. **Why natural.** Closed, bounded sets in $\mathbb{R}^{10}$ are compact, and continuous functions on compact sets attain their extrema, so it is legitimate to talk about "the maximiser" as an actual point rather than a value that might only be approached. **Link to the next block.** With a genuine maximiser to reason about, the next question is what local property it must satisfy.

Block 3. **Cue.** $y \mapsto y^3$ is not convex across all of $[-1,1]$, so no single global inequality can be trusted. **Why natural.** Fixing the sum of any two coordinates turns a piece of the high-dimensional problem into a one-variable function whose second derivative is a constant depending only on that fixed sum, so its convexity type (and hence where its maximum sits) is known exactly, without needing convexity everywhere else. **Link to the next block.** The sign of that constant sorts every pair into one of three mutually exclusive behaviours.

Block 4. **Cue.** Three behaviours emerge: strictly convex slice (sum positive), strictly concave slice (sum negative), or a slice with zero curvature (sum exactly zero). **Why natural.** A strictly convex function's maximum on a closed interval is always at an endpoint, a strictly concave function's maximum is at its unique interior critical point when that point is feasible, and a flat function is indifferent to its value entirely, and each of these three facts is a one-line calculus statement, not an assumption. **Link to the next block.** The flat case is the useful one: it means a pair can be discarded without cost, which is precisely the move that lets the argument induct on the number of variables.

Block 5. **Cue.** Discarding a pair changes the problem into the same problem with two fewer variables. **Why natural.** An induction only closes if the statement being proved is stated for every relevant size, not just the size in the original question, so the claim must be generalised to every

even n up to 10 before the discard move can be used at all. **Link to the next block.** Comparing the best achievable value across sizes then tells you which size to actually use.

Block 6. Cue. For a fixed number of coordinates pinned to 1, the achievable value strictly increases as more coordinates are added at the shared negative value. **Why natural.** More coordinates means more total negative mass available to balance the fixed positive coordinates while keeping each individual value further from the boundary -1, and the algebraic derivative of the target with respect to that count is manifestly positive. **Link to the next block.** So the largest available size, $n = 10$, is guaranteed to beat every smaller size, and only a short finite check across integer splits of 10 remains.

Layer 3: WHY

The truth underneath this problem is that optimising a sum of identical copies of a function that is convex on part of its domain and concave on the rest, subject to a linear constraint, is never solved by a single global inequality; it is solved by asking what a two-coordinate trade can do at fixed total, because that question only ever depends on the sign of one number, the constant second derivative of the resulting one-variable slice. This is the same mechanism behind exchange arguments across competition mathematics: whenever a configuration is claimed to be optimal, the cheapest way to test it is to ask whether transferring a small amount between two coordinates, at fixed total, could do better, and the answer is governed entirely by local curvature, never by the values of the other coordinates.

The discernment mechanism is spotting the phrase "sum of y_i^k subject to $\sum y_i$ fixed, y_i boxed" and checking, before attempting any bound, whether $y \mapsto y^k$ is convex across the whole box. If it is, the entire problem collapses to a boundary/all-equal comparison in one step; if it changes sign, as it does here on $[-1, 1]$ for odd $k \geq 3$, the pairwise argument is not a fallback, it is the only correct route, and recognising that in the first minute saves you from chasing an inequality that does not exist.

The examiners nudged you toward this specifically by choosing the target as $\cos(3x_i)$, a cube of the cosine, rather than $\cos(2x_i)$, a square: a square is globally convex on $[-1, 1]$ and the whole problem would collapse to ordinary convexity in one line. The cube is the smallest odd power for which the sign-changing behaviour, and hence the need for the pairwise argument, appears at all.

Revolving concepts

Multiple angle formulas as Chebyshev polynomials: $\cos(n\theta) = T_n(\cos\theta)$ for the Chebyshev polynomial T_n, defined by $T_0(y) = 1$, $T_1(y) = y$, and the three-term recursion $T_{n+1}(y) = 2y\,T_n(y) - T_{n-1}(y)$; this recursion generates $T_2(y) = 2y^2 - 1$ and $T_3(y) = 4y^3 - 3y$ directly, and generalises to computing $\cos(k\theta)$ for any k purely algebraically once $\cos\theta$ is known, without ever needing the angle θ itself. See Book 1, field: Polynomials, topic: Chebyshev polynomials and multiple angle formulas.

Existence of extrema by compactness: a continuous real function on a nonempty closed, bounded subset of $\mathbb{R}^n$ attains both a maximum and a minimum (the extreme value theorem); this single fact is what licenses speaking of "the maximiser" throughout the argument, rather than a supremum that might not be attained. See Book 1, field: Real analysis, topic: compactness and the extreme value theorem.

Pairwise smoothing and exchange arguments: for an objective that is a sum of a single-variable function applied to each coordinate, subject to a linear constraint and box bounds, fixing the sum of any two coordinates reduces the local optimality question to the sign of a constant second derivative on that pair's one-dimensional slice; this generalises to any function that is convex on part of the

domain and concave on the rest, and is the standard tool whenever a global convexity or Jensen argument fails outright. See Book 1, field: Inequalities, topic: exchange and smoothing arguments.

Strengthening a claim to enable induction: when an argument naturally produces a smaller instance of the same problem (here, deleting a pair drops n by two), the claim being proved must be restated for every relevant size of the parameter, not only the size asked about, before the reduction step can be used as an inductive step; this is a general proof-shape, not specific to this problem, and appears whenever an extremal argument allows removing part of a configuration without loss. See Book 1, field: Inequalities, topic: induction via a reduction or removal move.

Circuit Bank

- **WHEN** a constraint and a target are both stated purely through $\cos(x_i)$ for the same angles, with no other trigonometric data given **DO** substitute $y_i = \cos x_i$ and expand the target's multiple angle as the corresponding Chebyshev polynomial in y_i **BECAUSE** the actual angles carry no information the problem uses, so the substitution is lossless and turns a trigonometric question into a polynomial one on a box
- **WHEN** an objective is a sum of the same power y^k (k odd, $k \geq 3$) over variables in a box, subject to a linear constraint **DO** fix the sum of any two coordinates and read the sign of the constant second derivative of the resulting one-variable slice **BECAUSE** y^k changes convexity inside the box for odd $k \geq 3$, so no single global inequality can be trusted, and the pairwise sign test is the finest tool that still applies everywhere
- **WHEN** a pairwise optimality test produces a case where a pair contributes nothing to the objective regardless of its values **DO** delete that pair and restate the claim for every smaller relevant size of the parameter, so the deletion becomes a genuine inductive step **BECAUSE** the removable case is exactly what an induction on the size parameter needs, and proving the general-size claim costs no more than proving the single specific size asked about
- **WHEN** several candidate optimal configurations differ only in how much of a fixed total resource (here, the number of variables) each uses **DO** check monotonicity in that resource directly from the formula before assuming more is better **BECAUSE** the derivative of the achievable value with respect to the resource is a specific algebraic expression that must actually be checked, not assumed positive

Backtesting

1. First useful cue: $\cos(3x_i)$ in the target against a constraint stated purely in $\cos(x_i)$, no other trigonometric information anywhere.
2. Method the expression suggested: substitute $y_i = \cos x_i$, expand via the triple angle (Chebyshev) identity, and reduce to a polynomial optimisation on $[-1, 1]^{10}$.
3. Where you would hesitate, and the thought to reinforce: reaching for Jensen's inequality on $\sum y_i^3$ directly; reinforce by checking that y^3 changes convexity inside $[-1, 1]$, which rules out any single global inequality.
4. The trap the question sets: solving only the interior Lagrange multiplier equations and missing that part of the true maximiser sits exactly on the box boundary $y_i = 1$.
5. What makes you recognise it faster next time: a sum of the same odd power of each variable, subject to a linear constraint and box bounds, whenever that power is at least three.
6. The reusable decision rule: fix the sum of any two coordinates, compute the constant second derivative of the resulting one-variable slice, and classify the pair as boundary-extremal, common-interior-value, or costlessly removable.

Mirror drills

1. Maximise $\sum_{i=1}^{6} \cos(3x_i)$ given $\sum_{i=1}^{6} \cos(x_i) = 0$. *Hint:* same reduction, now check $(a, b) \in \{(1,5), (2,4), (3,3)\}$ with $a + b = 6$; the largest is at $(2,4)$.
2. Maximise $\sum_{i=1}^{n} y_i^3$ over $y_i \in [-1, 1]$ with $\sum y_i = 0$, for n odd. *Hint:* the removable pairs still work two at a time, so the argument reduces an odd n down to $n = 1$, where the only feasible point is $y_1 = 0$, giving objective 0; check whether any odd n can beat this using the same a, b structure with $a + b = n$.
3. Find the greatest possible value of $\sum_{i=1}^{4} \cos(2x_i)$ given $\sum_{i=1}^{4} \cos(x_i) = 1$. *Hint:* $\cos 2\theta = 2\cos^2\theta - 1$ has constant, globally positive second derivative in $\cos\theta$, so ordinary convexity (Jensen, or pushing every variable to a box extreme) applies directly with no pairwise casework needed, a useful contrast to A3 itself.

8.4 A4. A Christoffel word forces two generators to commute

Let m and n be positive integers with $\gcd(m,n) = 1$, and let

$$a_k = \left\lfloor \frac{mk}{n} \right\rfloor - \left\lfloor \frac{m(k-1)}{n} \right\rfloor$$

for $k = 1, 2, \ldots, n$. Suppose that g and h are elements in a group G and that

$$gh^{a_1}gh^{a_2}\cdots gh^{a_n} = e,$$

where e is the identity element. Show that $gh = hg$. (As usual, $\lfloor x \rfloor$ denotes the greatest integer less than or equal to x.)

Read it out loud

This is a group theory question wearing a number theory coat. You are handed one relation in a completely unknown group G and asked to produce a second one. Since nothing at all is known about G, nothing about G may be used: every line of the proof has to be a formal consequence of the single word $W = gh^{a_1}gh^{a_2}\cdots gh^{a_n}$ being trivial. Say that constraint out loud and it hands you the shape of the answer before you have done any arithmetic. From $W = e$ there are exactly two families of consequences available at zero cost: conjugates $uWu^{-1} = e$, and cyclic rotations of W, which are the conjugates by a prefix. So if a short proof exists it consists of writing $ghg^{-1}h^{-1}$ as a rotation of W. Everything else in the problem is bookkeeping that tells you which rotation.

Now the coat. The quantity a_k counts the integers lying in the interval $(m(k-1)/n,\ mk/n]$, the partial sums telescope to $a_1 + \cdots + a_k = \lfloor mk/n \rfloor$, and so the total is $a_1 + \cdots + a_n = m$. Thus W contains exactly n letters g and exactly m letters h. The defining formula makes sense for every integer k, not only for k between 1 and n, and it is periodic in k with period n, because replacing k by $k+n$ adds m to both floors. Each a_k lies in $\{\lfloor m/n \rfloor,\ \lfloor m/n \rfloor + 1\}$. Geometrically W records the staircase lattice path from $(0,0)$ to (n,m) that hugs the line $y = mx/n$ from below, reading g for a step to the right and h for a step up. That object has a name, the Christoffel word of slope m/n, and knowing the name is worth a great deal here, because it tells you that the whole family of such words is one cyclic orbit.

The hypothesis $\gcd(m,n) = 1$ is doing two jobs and you must decide which one you want to spend. Job one: the line $y = mx/n$ meets no lattice point strictly between its endpoints, so the staircase is unambiguous and every a_k is well defined by the geometry. Job two: m is invertible modulo n. The second job is the one that pays, because the exponent sequence is n periodic, so the cyclic group of index shifts acts on it, and coprimality hands you a distinguished shift for free.

Within thirty seconds of reading this you should have on paper: $\sum_k a_k = m$; $a_{k+n} = a_k$; W has n letters g and m letters h; the target is $ghg^{-1}h^{-1} = e$; and the note "only rotations and conjugates are free".

Approaches, ranked worst to best

1. **Small cases in a free group.** *Cue:* a short word equation in two letters. *Circuit:* write out $n = 2, 3, 4$ and hope a cancellation appears. (Worst. G is arbitrary, so there is nothing to cancel against: the only letters you are permitted to move are the ones the relation itself moves. You will fill a page, learn the answer for $n = 3$, and learn nothing that scales.)
2. **Tietze transformations on the presentation.** *Cue:* a one relator group $\langle g, h \mid W \rangle$. *Circuit:* simplify a presentation by adding and deleting generators. (Correct in principle. By von Dyck's theorem it is enough to prove $gh = hg$ inside the universal group $\langle g, h \mid W \rangle$, since any g, h in any G satisfying the relation give a homomorphism out of it. But with no idea which substitution to make you are searching blind through a large space.)

3. **Fundamental group of a punctured torus.** *Cue:* a word in two letters attached to a lattice path. *Circuit:* read a word as a loop and let topology do the algebra. (This works, and it is the most illuminating account of why the result is true: the staircase and the straight segment from $(0,0)$ to (n,m) are homotopic in the once punctured torus, an element of $GL_2(\mathbb{Z})$ carries that segment to a single loop, and the presented group collapses to $\mathbb{Z}$. It ranks low only because it needs fundamental groups, covering space intuition and a homotopy argument, none of which the problem actually requires.)
4. **Euclidean descent on the pair (m,n).** *Cue:* $\gcd(m,n)=1$ sitting next to floor functions. *Circuit:* run the Euclidean algorithm and induct on $m+n$. (Strong, and the natural first thought. When $m>n$ the increments for (m,n) are those for $(m-n,n)$ each raised by one, and $h^{a_k+1} = h\,h^{a_k}$ lets you absorb the extra letter into a new generator $\tilde{g}=gh$, so that case descends in two lines. When $m<n$ you must exchange the roles of m and n, which amounts to reflecting the staircase in the line $y=x$ and traversing it backwards. That step is true, but it is a picture argument, and turning it into airtight prose costs more ink than the whole of the next method.)
5. **Index shift by the inverse of m modulo n.** *Cue:* $\gcd(m,n)=1$ together with an n periodic exponent sequence. *Circuit:* when a periodic sequence is built from m and has period n, shift the index by m^{-1} modulo n. (Best. One identity about floors, one substitution, and the commutator turns out to be a cyclic rotation of the relator. No induction, no pictures, and every step is checkable in the arena.)

The ideal solution

Throughout, extend the definition to every integer k by the same formula, $a_k = \lfloor mk/n \rfloor - \lfloor m(k-1)/n \rfloor$. For a statement P write $[P]$ for 1 if P holds and 0 otherwise.

Lemma 8.4.1. *For every integer k we have $a_{k+n} = a_k$, and $a_1 + a_2 + \cdots + a_n = m$.*

Proof. Replacing k by $k+n$ increases each of mk/n and $m(k-1)/n$ by the integer m, hence increases both floors by m and leaves their difference unchanged. The sum telescopes to $\lfloor mn/n \rfloor - \lfloor 0 \rfloor = m$. □

Lemma 8.4.2. *Let $x \in \{1,\dots,n\}$ satisfy $mx \equiv 1 \pmod{n}$. Then for every integer k,*

$$a_{k-x} \;=\; a_k + [\,n \mid k-1\,] - [\,n \mid k\,].$$

Proof. First, for any integer N,

$$\left\lfloor \frac{N-1}{n} \right\rfloor - \left\lfloor \frac{N}{n} \right\rfloor = -\,[\,n \mid N\,].$$

Indeed, write $N = qn + r$ with $0 \le r < n$. If $r \ge 1$ then $N-1 = qn + (r-1)$ with $0 \le r-1 < n$, so both floors equal q; if $r = 0$ then $N-1 = (q-1)n + (n-1)$, so the left floor is $q-1$ and the right floor is q.

Since $\gcd(m,n)=1$ there are integers x, y with $mx + ny = 1$, and we may take the representative $x \in \{1,\dots,n\}$. From $-mx = ny - 1$ we get $m(k-x) = mk + ny - 1$ and $m(k-x-1) = m(k-1) + ny - 1$. Pulling the integer y out of each floor and cancelling the two copies,

$$a_{k-x} = \left\lfloor \frac{mk-1}{n} \right\rfloor - \left\lfloor \frac{m(k-1)-1}{n} \right\rfloor.$$

Subtract a_k and apply the displayed floor identity twice, once with $N = mk$ and once with $N = m(k-1)$:

$$a_{k-x} - a_k = -\,[\,n \mid mk\,] + [\,n \mid m(k-1)\,].$$

Because $\gcd(m,n)=1$, n divides mk if and only if n divides k, and likewise with $k-1$ in place of k. □

Proof that $gh=hg$. Write $W=gh^{a_1}gh^{a_2}\cdots gh^{a_n}$, so that $W=e$, and fix x as in Lemma 2.

Since $g\cdot(h^{a_1}gh^{a_2}\cdots gh^{a_n})=W=e$ and G is a group, $g^{-1}=h^{a_1}gh^{a_2}\cdots gh^{a_n}$. Substituting this into the commutator,

$$ghg^{-1}h^{-1}=gh\,(h^{a_1}gh^{a_2}\cdots gh^{a_n})\,h^{-1}=gh^{a_1+1}gh^{a_2}\cdots gh^{a_{n-1}}gh^{a_n-1}.$$

The exponents on the right are a_k for every k, with 1 added when $k=1$ and 1 subtracted when $k=n$; that is, they are $a_k+[\,n\mid k-1\,]-[\,n\mid k\,]$ for $k=1,\dots,n$. (When $n=1$ both corrections land on the same exponent and cancel, and this description is still correct.) By Lemma 2 that list is precisely a_{1-x}, a_{2-x}, …, a_{n-x}, so

$$ghg^{-1}h^{-1}=gh^{a_{1-x}}gh^{a_{2-x}}\cdots gh^{a_{n-x}}.$$

Now use periodicity. For $1\le k\le x$ we have $a_{k-x}=a_{k-x+n}$, and as k runs over $1,\dots,x$ the index $k-x+n$ runs over $n+1-x,\dots,n$; for $x<k\le n$ the index $k-x$ runs over $1,\dots,n-x$. Hence, setting

$$P=gh^{a_{n+1-x}}gh^{a_{n+2-x}}\cdots gh^{a_n},\qquad Q=gh^{a_1}gh^{a_2}\cdots gh^{a_{n-x}}$$

(with Q the empty product when $x=n$, which happens only for $n=1$), we have

$$ghg^{-1}h^{-1}=PQ,\qquad QP=gh^{a_1}\cdots gh^{a_n}=W=e.$$

Finally, in a group a one sided inverse is a two sided inverse: from $QP=e$ we get $P=Q^{-1}(QP)=Q^{-1}$, and therefore $PQ=Q^{-1}Q=e$. Thus $ghg^{-1}h^{-1}=e$, that is, $gh=hg$. □

Corollary 8.4.3. *Under the same hypotheses there is an element $c\in G$ with $g=c^m$ and $h=c^{-n}$; in particular the subgroup $\langle g,h\rangle$ is cyclic.*

Proof. Since g and h commute, W collapses to $g^nh^{a_1+\cdots+a_n}=g^nh^m$ by Lemma 1, so $g^nh^m=e$. Choose integers u,v with $um+vn=1$ and put $c=g^vh^{-u}$. From $g^nh^m=e$ we get $h^{-m}=g^n$, hence $h^{-um}=g^{un}$ and $c^m=g^{vm}h^{-um}=g^{vm+un}=g$. From the same relation $g^{-n}=h^m$, hence $g^{-vn}=h^{vm}$ and $c^{-n}=g^{-vn}h^{un}=h^{vm+un}=h$. □

Layer 1: WHAT

Block 1. Note what is free. From $W=e$ you may conjugate and you may rotate cyclically; nothing else is available because G is arbitrary.

Block 2. Turn the target into a word. Read g^{-1} off the relation and substitute it into $ghg^{-1}h^{-1}$.

Block 3. Read the result. It is the same word with 1 added to the first exponent and 1 subtracted from the last.

Block 4. Ask which operation on the index sequence does that. The sequence is n periodic, so shifts are available; coprimality supplies the shift by $x=m^{-1}$ modulo n.

Block 5. Prove the shift identity from the definition, using Bezout and one floor identity.

Block 6. Recognise the shifted word as PQ where $QP=W=e$, and close with the one sided inverse fact.

Juxtaposition. The nominal route is either the small case expansion (which learns nothing) or Euclidean induction on $m+n$ (which is genuinely good but needs the reflection step for $m<n$). The bifurcation point is Block 3. The zombie stares at $gh^{a_1+1}gh^{a_2}\cdots gh^{a_n-1}$ and asks "what can I cancel here?" The ideal solver asks "is this word again a member of the same family, and if so which member?" One question leads to a page of nothing, the other to two lines.

Layer 2: HOW

Block 1. **Cue.** The group G is unnamed and unconstrained, and exactly one relation is given. **Why natural.** When a hypothesis is a single equation in an unknown group, the deductive closure you are allowed to use is the normal closure of that relator. The cheapest members of it are conjugates uWu^{-1} and, as a special case, the cyclic rotations obtained by taking u to be a prefix of W. So before touching the arithmetic, you decide that the target is going to be manufactured as one of those. **Link to the next block.** That decision means you need the target written as a word in g and h with no inverses of g left loose, which is exactly what the relation lets you arrange.

Block 2. **Cue.** The relation begins with the letter g, and the target begins with gh and then wants g^{-1}. **Why natural.** A relation $g \cdot V = e$ is an explicit formula for g^{-1}, namely $g^{-1} = V$. The commutator is the only sensible target (proving $gh = hg$ is proving $ghg^{-1}h^{-1} = e$), and it contains exactly one g^{-1}, so one substitution clears it. Nothing here is inspired; it is the only substitution the data offers. **Link to the next block.** After substituting, the trailing h^{-1} merges with h^{a_n} and the leading h merges with h^{a_1}, so the outcome is again a word of the shape $gh^{b_1} \cdots gh^{b_n}$.

Block 3. **Cue.** The new exponent list is $a_1 + 1,\ a_2,\ \ldots,\ a_{n-1},\ a_n - 1$: the same list, perturbed only at the two ends. **Why natural.** A perturbation localised at the two ends of a cyclically structured object is almost always a rotation in disguise. The word came from a staircase from $(0, 0)$ to (n, m); adding a step at the front and removing one at the back is precisely what happens when you move the last vertical step round to the front, which is a cyclic rotation of the letter string. **Link to the next block.** So you now look for the exact rotation, and rotations of the block structure correspond to shifts of the index k.

Block 4. **Cue.** a_k is n periodic in k, and $\gcd(m, n) = 1$. **Why natural.** Periodicity means the index lives in $\mathbb{Z}/n\mathbb{Z}$, so the only shifts available are by residues, and coprimality distinguishes exactly one of them: x with $mx \equiv 1$. That is not a guess. The value a_k jumps by one exactly when mk crosses a multiple of n, so the shift that moves a single jump by one place must move mk by exactly 1, which is the shift by m^{-1}. **Link to the next block.** With x named, the shift identity is a computation with floors rather than a search.

Block 5. **Cue.** Bezout gives $mx + ny = 1$, and $-mx = ny - 1$ turns a shift of the index into a shift of the numerator by -1. **Why natural.** Floors are insensitive to adding multiples of n to the numerator, so the ny evaporates and the only residue of the shift is the -1. A numerator lowered by one changes the floor exactly when the numerator was divisible by n, which is the one line identity $\lfloor (N-1)/n \rfloor - \lfloor N/n \rfloor = -[\, n \mid N \,]$. Coprimality converts $n \mid mk$ into $n \mid k$, and the two divisibility indicators are exactly the two end corrections from Block 3. **Link to the next block.** The perturbed word is therefore literally the word with indices shifted by $-x$.

Block 6. **Cue.** The shifted index list, cut at the place where it wraps, is a concatenation PQ whose reverse concatenation QP is the original relator. **Why natural.** A cyclic rotation of a word is by definition the two halves of the word swapped. And the reason the problem closes here is the most elementary group fact of all: $QP = e$ forces $P = Q^{-1}$, hence $PQ = e$. The rotation of a trivial word is trivial. **Link to the next block.** The commutator equals $PQ = e$, which is the conclusion.

Layer 3: WHY

The mathematical truth beneath this route is a statement about words, not about groups: the commutator of g and h, computed modulo the relation, is a cyclic rotation of the relator. Once you know that, the group theory is one line, because a cyclic rotation of a word is a conjugate of it and

conjugates of the identity are the identity. Everything hard in the problem has been moved into the combinatorics of the exponent sequence, and that combinatorics is entirely mechanical once you notice periodicity plus coprimality.

Why is the rotation there at all? Because the word is the Christoffel word of slope m/n, the staircase under the line, and the family of staircases with a fixed slope but a shifted starting phase is a single cyclic orbit. Shifting the phase by one lattice step changes the exponent list in exactly two places, and coprimality guarantees that shifting the phase by one step is the same as shifting the index by m^{-1} modulo n. The problem is engineered so that the commutator performs precisely a one step phase shift. That is why the answer is short, and it is why the topological solution works: the staircase and the straight line segment are the same loop, and a straight loop of coprime slope on a torus generates a copy of $\mathbb{Z}$.

The discernment mechanism to install is this. When the hypothesis is one relation and the conclusion is another relation, do not try to manipulate the group. Write both as words in the free group and ask how the conclusion sits inside the normal closure of the relator, starting with the cheapest possibilities: is it the relator itself, a rotation, a conjugate, a product of two conjugates? The search is finite and short, and the arithmetic in the problem is there to tell you which one to try. Here the arithmetic screams: an exponent sequence that is visibly periodic, a coprimality hypothesis whose only algebraic content is invertibility, and a word whose only asymmetric places are its two ends. Three cues, one shift.

Train it in two ways. First, get fluent at reading an exponent sequence as a lattice path, so that "add one at the front, remove one at the back" becomes visibly a rotation rather than an accident of algebra. Second, drill the reflex $QP = e \Rightarrow PQ = e$ until it is instant, because it is the step that converts "I have the right word" into "I am finished", and candidates lose marks by proving the rotation and then not knowing what to do with it.

Note also what the examiners chose not to give you. They did not say G is finite, so counting arguments are dead. They did not say g or h has finite order, so there is no torsion to exploit. They did give $\gcd(m, n) = 1$, which has no geometric use in the conclusion but is exactly the invertibility you need. When a hypothesis has no visible role in the statement of the conclusion, it is a hypothesis about the method.

Revolving concepts

Floor function. For real t, $\lfloor t \rfloor$ is the greatest integer not exceeding t. The identities that orbit it here: $\lfloor t + N \rfloor = \lfloor t \rfloor + N$ for integer N; $\lfloor (N-1)/n \rfloor - \lfloor N/n \rfloor = -[\, n \mid N \,]$ for integers N and $n \geq 1$; and $\lfloor t + s \rfloor - \lfloor t \rfloor \in \{\lfloor s \rfloor, \lfloor s \rfloor + 1\}$ for $s > 0$, which is why every a_k takes one of two values. See Book 1, field: Number theory, topic: floor functions and lattice point counting.

Beatty and mechanical sequences. For real $\alpha > 0$ the sequence $\lfloor \alpha k \rfloor$ is a Beatty sequence and its increments form a mechanical word. The word is periodic precisely when α is rational, with period the denominator in lowest terms; it is balanced, meaning any two factors of equal length have letter counts differing by at most one. See Book 1, field: Combinatorics, topic: words and balanced sequences.

Christoffel words. The lower Christoffel word of slope m/n with $\gcd(m, n) = 1$ is the letter string of the staircase from $(0, 0)$ to (n, m) that stays weakly below $y = mx/n$ and as close to it as possible. Its conjugacy class is a single cyclic orbit of size $m + n$. The associated one relator group $\langle g, h \mid W \rangle$ is infinite cyclic. This is a genuine knowledge gap for anyone who has not met combinatorics on words, and it is worth installing, because the same words appear in continued fractions, in Sturmian dynamics and in the three distance theorem.

Bezout and modular inverses. $\gcd(m, n) = 1$ if and only if $mx + ny = 1$ has an integer solution, if and only if m is invertible modulo n. See Book 1, field: Number theory, topic: Bezout and the extended Euclidean algorithm.

Free groups, presentations, von Dyck. If F is free on g, h and $W \in F$, then giving elements g, h of

a group G with $W(g,h) = e$ is the same as giving a homomorphism $\langle g, h \mid W\rangle \to G$. Hence any identity provable in the presented group holds in every G. This is why it is legitimate, and often cleaner, to prove such statements once and for all in the universal example.

The recursion, generalised. Write $W_{m,n}$ for the word attached to a coprime pair. Two recursions govern the whole family and both come from the Euclidean algorithm. First, for $m > n$, the increments for (m,n) exceed those for $(m-n,n)$ by one in every position, so

$$W_{m,n}(g,h) = W_{m-n,n}(gh,\, h),$$

which is the substitution $g \mapsto gh$, an automorphism of the free group. Second, reversing the staircase and reflecting in $y = x$ gives

$$W_{m,n}(g,h)^{-1} = W_{n,m}(h^{-1},\, g^{-1}),$$

which exchanges the roles of m and n. Alternating the two steps is exactly the continued fraction expansion of m/n, and the family is indexed by the Stern and Brocot tree. The general lesson for every recursion of this type: when a family is indexed by a coprime pair, the induction that works is the Euclidean one, and each descent step should be realised as a substitution rather than as a computation. The general solution of the underlying first order recursion $s_k = s_{k-1} + a_k$, $s_0 = 0$, is the telescoped $s_k = \lfloor mk/n \rfloor$, and it is the telescoping that gives the letter counts for free. See Book 1, field: Sequences and recurrences, topic: telescoping and Euclidean descent.

Circuit Bank

- **WHEN** one relation $W = e$ in an unknown group and a commutator to prove **DO** try to exhibit the commutator as a cyclic rotation or a conjugate of W **BECAUSE** those are the only consequences of a relation that cost nothing, so if the proof is short it must be one of them
- **WHEN** $\gcd(m,n) = 1$ standing next to $\lfloor mk/n \rfloor$ **DO** write down x with $mx \equiv 1 \pmod{n}$ and compute the effect of shifting the index by x **BECAUSE** the increment sequence has period n, so shifts are the available symmetry, and m^{-1} is the shift that moves one jump by one place
- **WHEN** a word whose exponents change by $+1$ at one end and -1 at the other **DO** suspect a cyclic rotation of the same word and look for the shift that realises it **BECAUSE** moving one letter from the back to the front does exactly this to a staircase word
- **WHEN** $QP = e$ **DO** write $PQ = e$ immediately **BECAUSE** a one sided inverse in a group is a two sided inverse, so rotations of a trivial word are trivial
- **WHEN** a hypothesis with no visible role in the conclusion, such as a coprimality condition **DO** treat it as a statement about the method, and ask which operation it makes invertible **BECAUSE** examiners insert such hypotheses to license exactly one step, and finding that step usually finds the solution

Backtesting

1. First useful cue: the group is arbitrary, so the only permitted moves are conjugation and cyclic rotation of the given relator. That single sentence dictates the whole strategy.
2. Method the expression suggested: the exponents are increments of $\lfloor mk/n \rfloor$, hence periodic with period n, hence acted on by index shifts; coprimality names the shift.
3. Where you would hesitate, and the thought to reinforce: after substituting g^{-1} you are looking at $gh^{a_1+1}gh^{a_2}\cdots gh^{a_n-1}$ and the temptation is to start cancelling. Reinforce: do not cancel, classify. Ask whether the new word belongs to the same family as the old one.

4. The trap the question sets: the Euclidean induction is so obviously suggested by $\gcd(m,n)=1$ that most solvers commit to it, then discover that the case $m<n$ needs the reversal of the staircase, and either wave at it or spend a page making it rigorous. The coprimality hypothesis is pointing at invertibility, not at the algorithm.
5. What makes you recognise it faster next time: the shape "one relation in, one relation out, group unspecified". Every such problem is a word problem in the free group, and every short solution is a rotation or a conjugation.
6. The reusable decision rule: when a periodic sequence built from m has period n and $\gcd(m,n)=1$, the index shift by $m^{-1} \bmod n$ is a symmetry that changes the sequence in exactly two places. Write it down before you do anything else.

Mirror drills

1. Show that $a_k \in \{\lfloor m/n \rfloor, \lfloor m/n \rfloor + 1\}$ for every k, without assuming $\gcd(m,n)=1$. *Answer:* write $t = m(k-1)/n$ and $s = m/n$; then $\lfloor t+s \rfloor - \lfloor t \rfloor = \lfloor \{t\} + s \rfloor$ where $\{t\} \in [0,1)$, and $s \le \{t\} + s < s+1$ pins the floor to two values.
2. In any group, deduce $yx = e$ from $xy = e$. *Answer:* $y = x^{-1}(xy) = x^{-1}$, hence $yx = x^{-1}x = e$. This is the last line of the ideal solution and it must be automatic.
3. Take $m=3$, $n=5$. Compute the a_k, find x, and verify the rotation explicitly. *Answer:* $a = (0,1,0,1,1)$ and $x = 2$ since $3 \cdot 2 = 6 \equiv 1 \pmod 5$. The corrected list $(a_1+1, a_2, a_3, a_4, a_5 - 1) = (1,1,0,1,0)$ equals $(a_4, a_5, a_1, a_2, a_3)$. Here $P = ghgh$ and $Q = g^2hg$, with $QP = g^2hg^2hgh = W$ and PQ the rotated word.

8.5 A5. Every derivative nonnegative forces the function flat

Let $f : \mathbb{R} \to \mathbb{R}$ be an infinitely differentiable function satisfying $f(0) = 0$, $f(1) = 1$, and $f(x) \geq 0$ for all $x \in \mathbb{R}$. Show that there exist a positive integer n and a real number x such that $f^{(n)}(x) < 0$.

Read it out loud

The conclusion is an existence statement with two quantifiers, which is your instruction to negate it and work with the negation. Suppose instead that $f^{(n)}(x) \geq 0$ for every positive integer n and every real x. Adding the given $f \geq 0$, you are assuming $f^{(n)} \geq 0$ for all $n \geq 0$, where $f^{(0)} = f$. Functions like that have a name, absolutely monotonic, and the question becomes: can an absolutely monotonic function on the whole line vanish at 0 and equal 1 at 1? Say it that way and you can already feel the answer. Absolute monotonicity is a rigidity condition; morally these are the functions with nonnegative Taylor coefficients, and a function with nonnegative Taylor coefficients that is flat at a point has nothing left to be.

Where is the strength in the hypotheses? Not in $[0, 1]$. On $[0, 1]$ alone the claim is false: $f(x) = x$ has $f(0) = 0$, $f(1) = 1$ and every derivative nonnegative there. So the proof is forced to use the negative axis, and there is only one way to use it. Since $f' \geq 0$ the function is nondecreasing, so for $x \leq 0$ we have $0 \leq f(x) \leq f(0) = 0$, hence f vanishes identically on the left half line, hence every derivative of every order vanishes at 0. That first move is not a choice; it is the only place the global hypothesis can be spent, and after it the problem reads: an absolutely monotonic function that is infinitely flat at the origin still manages to reach 1 at $x = 1$. Kill that.

The fields embedded here are real analysis (monotonicity, convexity, integration by parts, Taylor with remainder) with the theory of absolutely and completely monotone functions orbiting in the background. What is really being tested is a habit of mind rather than a technique: will you prove a statement about the whole class of such functions instead of about your one function? The class is closed under differentiation, and that closure is the engine of the shortest proof. Prove something about f alone and the engine is unavailable.

Within thirty seconds you should have written: negate; $f \equiv 0$ on $(-\infty, 0]$; $f^{(k)}(0) = 0$ for all k; and the note "the class is closed under d/dx, so any inequality can be fed back through the derivative".

Approaches, ranked worst to best

1. **Hunt for a counterexample.** *Cue:* infinitely differentiable but not analytic. *Circuit:* recall the flat bump function e^{-1/x^2} and try to build one that works. (Worst. It is a reasonable ten seconds of orientation and a terrible ten minutes of work. The flat functions all have derivatives of both signs, but discovering that for one example proves nothing, and the problem asks for a proof about every f.)

2. **Taylor at 0 with Lagrange remainder and a direct bound.** *Cue:* all derivatives controlled in sign. *Circuit:* write $f(x) = f^{(n)}(\xi)x^n/n!$ and try to make the right side small. (Stalls. All you know about $f^{(n)}(\xi)$ is that it is nonnegative, and it may be enormous; nonnegativity gives a lower bound on the remainder, not an upper bound. The information is pointing the wrong way and no amount of effort turns it round.)

3. **Quote Bernstein's theorem.** *Cue:* all derivatives of one sign on a half line. *Circuit:* completely monotone functions are Laplace transforms of nonnegative measures. (Correct and quick if you already own the theorem: apply it to $x \mapsto f(M - x)$, get a measure, note $f(0) = 0$ forces the measure to vanish. But it is a sledgehammer far beyond the syllabus, it cannot be reconstructed in the arena, and a grader will want the statement quoted exactly. Name it as a knowledge gap rather than pretending it is elementary.)

4. **Prove that f is analytic.** *Cue:* a C^∞ function with total control on the signs of remainders. *Circuit:* show the Taylor series converges to f, then use that an analytic function flat at a point is identically zero. (Correct and instructive: nonnegativity of $f - g_n$ bounds the Taylor polynomials above by f, and $f - g_n \le f^{(n+1)}(x)/(n+1)!$ closes it. Three moving parts, and the last step needs the identity theorem, so it costs more ink than it needs to.)
5. **Taylor with integral remainder and a kernel comparison.** *Cue:* repeated integration against a nonnegative $f^{(n)}$. *Circuit:* compare $(1-t)^n$ with $(1-t)^{n-1}$ to gain a factor $1/n$. (Very strong, four lines. With $F(x) = \int_0^x f$, both $f(1)$ and $F(1)$ are pure remainder integrals because all derivatives vanish at 0, and the ratio of the two kernels gives $\int_0^1 f \le f(1)/n$ for every n. It ranks second only because it needs the integral form of the remainder to be at your fingertips.)
6. **Self improving inequality on the class.** *Cue:* a hypothesis about infinitely many derivatives. *Circuit:* name the class, note it is closed under differentiation, and feed the inequality back into itself. (Best. Two line base case, two line inductive step by parts, and the conclusion is a contradiction with the Archimedean property. It uses nothing beyond the fundamental theorem of calculus and integration by parts, and the mechanism generalises to every bootstrap argument you will meet.)

The ideal solution

Suppose, for contradiction, that $f^{(n)}(x) \ge 0$ for every positive integer n and every real x. Since also $f \ge 0$, we have $f^{(n)}(x) \ge 0$ for every $n \ge 0$ and every real x, where $f^{(0)} = f$.

Step 1: the left half line. Let u be any infinitely differentiable function with $u^{(n)} \ge 0$ everywhere for all $n \ge 0$ and $u(0) = 0$. Since $u' \ge 0$, u is nondecreasing, so $u(x) \le u(0) = 0$ for every $x \le 0$; combined with $u \ge 0$ this gives $u(x) = 0$ for all $x \le 0$. Hence $u^{(k)}(x) = 0$ for all $x < 0$ and all $k \ge 0$, and since each $u^{(k)}$ is continuous, letting $x \to 0^-$ gives

$$u^{(k)}(0) = 0 \qquad (k \ge 0).$$

Step 2: the class and its closure. Let

$$S = \{\, u : \mathbb{R} \to \mathbb{R} \text{ infinitely differentiable } :\ u^{(n)} \ge 0 \text{ everywhere for all } n \ge 0,\ u(0) = 0 \,\}.$$

Our f lies in S. If $u \in S$ then every derivative of u' is a derivative of u and so is nonnegative, and $u'(0) = 0$ by Step 1; hence $u' \in S$. Thus S is closed under differentiation.

Step 3: the bootstrap. We claim that for every positive integer k,

$$u(x) \le \frac{x}{k}\, u'(x) \qquad \text{for all } u \in S \text{ and all } x \ge 0.$$

Induct on k. For $k = 1$: since $u'' \ge 0$, the derivative u' is nondecreasing, so for $x \ge 0$,

$$u(x) = u(x) - u(0) = \int_0^x u'(t)\, dt \le \int_0^x u'(x)\, dt = x\, u'(x).$$

Assume the claim for k, for every member of S. Let $u \in S$ and $x \ge 0$. Applying the claim to $u' \in S$ gives $u'(t) \le (t/k)\, u''(t)$ for all $t \ge 0$, so

$$k\, u(x) = \int_0^x k\, u'(t)\, dt \le \int_0^x t\, u''(t)\, dt = \Big[\, t\, u'(t) \,\Big]_0^x - \int_0^x u'(t)\, dt = x\, u'(x) - u(x),$$

using integration by parts and $u(0) = 0$. Rearranging, $(k+1)\, u(x) \le x\, u'(x)$, which is the claim for $k+1$.

Step 4: the contradiction. Apply Step 3 to $u = f$ at $x = 1$:

$$1 = f(1) \le \frac{f'(1)}{k} \qquad \text{for every positive integer } k,$$

that is, $k \le f'(1)$ for every positive integer k. This contradicts the Archimedean property of $\mathbb{R}$, since $f'(1)$ is a fixed real number.

Therefore the assumption fails: there exist a positive integer n and a real x with $f^{(n)}(x) < 0$.

Remark 8.5.1. The proof used $f(1) > 0$ rather than $f(1) = 1$, and it used the hypothesis $f \ge 0$ only on $(-\infty, 0]$. Both observations are worth keeping: they identify exactly which parts of the data carry weight.

Layer 1: WHAT

Block 1. Negate the conclusion: assume all derivatives of all orders are nonnegative everywhere, so $f^{(n)} \ge 0$ for $n \ge 0$.

Block 2. Spend the global hypothesis: f nondecreasing and nonnegative with $f(0) = 0$ forces $f \equiv 0$ on $(-\infty, 0]$, hence $f^{(k)}(0) = 0$ for every k.

Block 3. Name the class S of such functions vanishing at the origin, and check that it is closed under differentiation.

Block 4. Prove the crude inequality $u(x) \le x\,u'(x)$ on $[0, \infty)$ from convexity.

Block 5. Feed the inequality back through the derivative and integrate by parts; each pass improves the constant from $1/k$ to $1/(k+1)$.

Block 6. Evaluate at $x = 1$: a fixed positive number is at most $f'(1)/k$ for every k, which is impossible.

Juxtaposition. The nominal route writes Taylor's theorem at 0, observes $f(x)$ equals its remainder, and then tries to bound the remainder above. It cannot: the hypotheses bound $f^{(n)}$ below, not above. The bifurcation point is Block 3. The zombie keeps proving statements about f; the ideal solver widens the target to a statement about every member of S, and only then is the closure of S under differentiation usable. This is the same move as strengthening an induction hypothesis so that the induction closes, and it is worth noticing that the wider statement is easier than the narrow one.

Layer 2: HOW

Block 1. **Cue.** The conclusion says "there exist n and x", a pure existence claim with no candidate offered. **Why natural.** An existence claim with no construction in sight is a contradiction claim in disguise. Negating it converts two existential quantifiers into two universal ones, and universal hypotheses are the ones you can compute with. After negation you hold an infinite family of inequalities, which is far more usable than a promise that one inequality fails somewhere. **Link to the next block.** The negated hypothesis is a statement about all derivatives, so the next question is what class of functions satisfies it.

Block 2. **Cue.** The hypothesis $f(x) \ge 0$ is stated for all $x \in \mathbb{R}$, although the interesting data $f(0) = 0$ and $f(1) = 1$ live in $[0, 1]$. **Why natural.** Examiners do not widen a hypothesis for decoration. On $[0, 1]$ alone the statement is false, as $f(x) = x$ shows, so the negative axis must be load bearing. There is exactly one thing to do with it: $f' \ge 0$ makes f nondecreasing, and a nondecreasing nonnegative function with $f(0) = 0$ is zero to the left of 0. **Link to the next block.** Vanishing on an interval kills all derivatives there, and continuity carries this to the endpoint, giving infinite order flatness at 0.

Block 3. **Cue.** The hypothesis constrains $f, f', f'', \ldots$ all at once, and the conclusion of Block 2 applies verbatim to f'. **Why natural.** A hypothesis quantified over all derivatives is not a statement about one function; it is membership of a class, and this class is visibly stable under differentiation. That stability is useless while your theorem mentions f only. Restate the goal for all $u \in S$ and the stability becomes a tool: anything proved for the class can be applied to u', which is again in the

class. **Link to the next block.** Now you need a first inequality relating u to u', so that the feedback has something to feed on.

Block 4. **Cue.** $u'' \geq 0$, that is, u is convex, and $u(0) = 0$. **Why natural.** Convexity is the statement that u' is nondecreasing, and the cheapest consequence is that the average of u' over $[0, x]$ is at most its endpoint value. Integrating, $u(x) \leq x\,u'(x)$. This is the crudest possible comparison of a function with its derivative and requires no cleverness; you want the crudest one, because the bootstrap will sharpen it. **Link to the next block.** The inequality has a constant 1 in front of xu', and the whole game is now to improve that constant.

Block 5. **Cue.** The induction hypothesis applies to u', producing $u'(t) \leq (t/k)u''(t)$, and you want to compare u with u'. **Why natural.** To convert a statement about u' and u'' into a statement about u and u', integrate. The integrand $t\,u''(t)$ then asks to be integrated by parts, and the reason that is the right move is that the two pieces it produces are exactly the two quantities in play: the boundary term is $xu'(x)$ and the remaining integral is $u(x)$. The inequality closes on itself, and solving for $u(x)$ gains one unit in the denominator. **Link to the next block.** Iterating, the constant is $1/k$ for every k, so the bound tends to zero while $u(1)$ does not move.

Block 6. **Cue.** A fixed positive number bounded by C/k for every positive integer k. **Why natural.** This is the standard way to contradict a positive value: you never show it is negative, you show it is smaller than every positive number. The Archimedean property finishes it. Note that $f'(1)$ needs no estimate at all; it only needs to be a real number, which it is because f is differentiable. **Link to the next block.** The contradiction closes the proof by contradiction opened in Block 1.

Layer 3: WHY

The truth underneath is a rigidity theorem. A function absolutely monotone on an interval is real analytic there, and on a half line $(-\infty, b)$ it is a Laplace transform of a nonnegative measure; this is Bernstein's theorem, in the reflected form for completely monotone functions. A real analytic function that vanishes to infinite order at a point vanishes on a neighbourhood, and by a connectedness argument on the whole interval. Your f is flat at the origin by Block 2, so if it were absolutely monotone it would be identically zero, contradicting $f(1) = 1$. The ideal solution is nothing but a hand rolled proof of that corollary which never mentions analyticity, and the reason it can avoid analyticity is that it only needs one number, $f(1)$, to be crushed, not the whole function.

The discernment mechanism to install has two halves. First: a hypothesis about infinitely many derivatives is a hypothesis about a class, and the class is almost always stable under the operator that indexes it. Whenever that happens, widen the theorem to the class before proving anything, because otherwise the stability sits unused. This is the analytic twin of strengthening the induction hypothesis, and both are cases of the same principle, that a more general statement can be easier to prove because it has more instances available to feed itself. Second: to contradict a fixed positive quantity, manufacture bounds of the form C/k for all k. Repeated integration is the standard factory for such bounds, since each integration against a monotone nonnegative integrand contributes a factor of a length or of an index, and both the second best and the best approach above are just two ways of running that factory.

What were the examiners nudging toward? Three things, all deliberate. They wrote "for all $x \in \mathbb{R}$" when they only needed to name values at 0 and 1; that is the pointer to the left half line. They wrote "infinitely differentiable" rather than "analytic", telling you that flatness at a point is genuinely possible in general, so no cheap appeal to power series is available and the contradiction must be quantitative. And they set $f(0) = 0$ with $f \geq 0$, which makes the origin a global minimum, so the first derivative there vanishes for free and the flatness cascade starts on its own.

Train the discernment by rehearsing the negation step until it is reflexive, and by collecting bootstrap arguments: Gronwall style estimates, the Cauchy and Schwarz self improvement in Hilbert space arguments, and induction schemes where the hypothesis is applied to a transformed version of the same object. In each, the payoff comes from having stated the result for a class rather than for a specimen.

Revolving concepts

Absolutely monotone functions. A function u on an interval with $u^{(n)} \geq 0$ for all $n \geq 0$ is called absolutely monotonic. Nonnegative constants and e^x are examples; the class is closed under addition, multiplication, composition and differentiation, and u absolutely monotone implies u' absolutely monotone. Reflecting the variable turns absolute monotonicity into complete monotonicity, where $(-1)^n u^{(n)} \geq 0$. See Book 1, field: Real analysis, topic: monotonicity classes.

Bernstein's theorem. If $u : [0,\infty) \to \mathbb{R}$ is continuous, infinitely differentiable on $(0,\infty)$ and $(-1)^n u^{(n)} \geq 0$ for all $n \geq 1$ and all $x > 0$, then there is a nonnegative finite Borel measure μ on $[0,\infty)$ with $u(x) = \int_0^\infty e^{-tx}\, d\mu(t)$ for $x \geq 0$. This is a genuine knowledge gap: it needs measure theory and a compactness argument (Helly selection), and you should file it as a named result rather than pretend to reconstruct it.

Taylor with integral remainder. For u of class C^n,

$$u(x) = \sum_{k=0}^{n-1} \frac{u^{(k)}(0)}{k!} x^k + \frac{1}{(n-1)!} \int_0^x (x-t)^{n-1} u^{(n)}(t)\, dt.$$

When every $u^{(k)}(0)$ vanishes the sum disappears and the function equals its remainder, which is the identity behind the second best approach. See Book 1, field: Real analysis, topic: Taylor's theorem in its Lagrange, Cauchy and integral forms.

Flat functions and Borel's theorem. The function equal to e^{-1/x^2} for $x > 0$ and 0 for $x \leq 0$ is C^∞ with all derivatives vanishing at 0, so C^∞ is strictly weaker than analytic. Borel's theorem says every sequence of reals occurs as the derivative sequence at 0 of some C^∞ function. Together these say that flatness at a point is no obstruction in general, so the sign hypothesis is doing all the work in this problem.

Convexity and the chord bound. $u'' \geq 0$ is equivalent to u' nondecreasing and to u lying below its chords and above its tangents. The consequence used here, $\int_0^x u' \leq x u'(x)$, is the statement that the mean value of a nondecreasing function on $[0,x]$ is at most its right endpoint value.

A nonnegative continuous function with zero integral is zero. Needed if you finish by the integral route: if $u \geq 0$ is continuous on $[0,1]$ and $\int_0^1 u = 0$ then $u \equiv 0$, since positivity at a point gives positivity on a neighbourhood and hence a positive integral.

The recursion, generalised. The bootstrap is a recursion in the constant. Suppose that $u(x) \leq c_k\, x\, u'(x)$ holds for all $u \in S$ and all $x \geq 0$. Applying it to $u' \in S$ and integrating by parts,

$$u(x) = \int_0^x u'(t)\, dt \leq c_k \int_0^x t\, u''(t)\, dt = c_k\big(x u'(x) - u(x)\big),$$

so $u(x) \leq \dfrac{c_k}{1+c_k}\, x\, u'(x)$, that is,

$$c_{k+1} = \frac{c_k}{1+c_k}, \qquad c_1 = 1.$$

Take reciprocals: $1/c_{k+1} = 1/c_k + 1$, an arithmetic progression, so $c_k = 1/k$. That is the general method for every recursion of this Riccati flavour, $c_{k+1} = c_k/(a + b c_k)$: invert to linearise, solve the linear recursion, invert back. The same pattern governs the constants in Gronwall bootstraps and in epsilon improvement arguments, where the point is always that the improved constant tends to a limit which is incompatible with the data. See Book 1, field: Sequences and recurrences, topic: linearising a rational recursion by reciprocals.

Circuit Bank

- **WHEN** a conclusion of the form "there exist n and x with a strict inequality" **DO** negate it at once and work with the universal hypothesis **BECAUSE** existence with no candidate is a contradiction proof, and universally quantified inequalities are the ones you can compute with
- **WHEN** a hypothesis constraining infinitely many derivatives **DO** name the class of functions satisfying it and check whether the class is closed under differentiation **BECAUSE** if it is, every inequality you prove for the class can be applied to u' and fed back, which is unavailable while your theorem mentions only f
- **WHEN** a hypothesis stated on all of $\mathbb{R}$ when the data lives on $[0,1]$ **DO** find the step that uses the wider domain, and expect it to be the first step **BECAUSE** examiners widen a hypothesis only when a counterexample exists on the narrow one, so the widening is a signpost to the load bearing move
- **WHEN** an integrand of the form $t\,u''(t)$ **DO** integrate by parts **BECAUSE** the boundary term returns $xu'(x)$ and the remaining integral returns $u(x)$, so the inequality closes on itself and can be solved for $u(x)$
- **WHEN** a fixed positive quantity you wish to contradict **DO** produce a bound of the form C/k valid for every positive integer k **BECAUSE** the Archimedean property then forces the quantity to be nonpositive, and no estimate of C is required

Backtesting

1. First useful cue: the conclusion is existential with no candidate, so negate it; and $f \geq 0$ is imposed on all of $\mathbb{R}$, so the negative axis must be used.
2. Method the expression suggested: monotonicity from $f' \geq 0$ collapses f on the left half line, giving infinite order flatness at 0; then a comparison of u with u' that improves itself under differentiation.
3. Where you would hesitate, and the thought to reinforce: after proving $u(x) \leq xu'(x)$ you may not see what to do with a constant of 1. Reinforce: the class is closed under d/dx, so apply the inequality to u' and integrate. An inequality about a class is a machine, not a fact.
4. The trap the question sets: Taylor at 0 looks irresistible, but the sign hypotheses bound the remainder from below, so every direct estimate points the wrong way. Candidates burn twenty minutes discovering this.
5. What makes you recognise it faster next time: the shape "all derivatives of one sign". That phrase should immediately produce the words absolutely monotone, the fact that the class is closed under differentiation, and the memory that such functions are analytic.
6. The reusable decision rule: when a hypothesis is closed under an operator, prove the theorem for the class and iterate the operator; the constant obeys a first order recursion, and the recursion is what supplies the factor tending to zero.

Mirror drills

1. Let u be C^∞ on $\mathbb{R}$ with $u \geq 0$, $u' \geq 0$ and $u(0) = 0$. Show $u^{(k)}(0) = 0$ for every $k \geq 0$. *Answer:* monotonicity plus nonnegativity gives $u \equiv 0$ on $(-\infty, 0]$, so $u^{(k)} \equiv 0$ on $(-\infty, 0)$, and each $u^{(k)}$ is continuous at 0.
2. Solve $c_1 = 1$, $c_{k+1} = c_k/(1 + c_k)$. *Answer:* take reciprocals, $1/c_{k+1} = 1/c_k + 1$, so $1/c_k = k$ and $c_k = 1/k$. This is exactly the constant produced by the bootstrap.

3. Under the standing hypotheses (all derivatives nonnegative, $f(0) = 0$), prove the alternative finish $\int_0^1 f \le f(1)/n$ for every $n \ge 1$. *Answer:* put $F(x) = \int_0^x f$, so $F^{(k)}(0) = 0$ for all k and $F^{(n+1)} = f^{(n)}$. Taylor with integral remainder gives $f(1) = \frac{1}{(n-1)!}\int_0^1 (1-t)^{n-1} f^{(n)}(t)\,dt$ and $F(1) = \frac{1}{n!}\int_0^1 (1-t)^n f^{(n)}(t)\,dt$; now $0 \le (1-t)^n \le (1-t)^{n-1}$ on $[0,1]$ and $f^{(n)} \ge 0$.

8.6 A6. Rational squared distances give rational area ratios

Suppose that A, B, C, and D are distinct points, no three of which lie on a line, in the Euclidean plane. Show that if the squares of the lengths of the line segments AB, AC, AD, BC, BD, and CD are rational numbers, then the quotient

$$\frac{\text{area}(\triangle ABC)}{\text{area}(\triangle ABD)}$$

is a rational number.

Read it out loud

Euclidean geometry on the surface, linear algebra over $\mathbb{Q}$ underneath. The data is six numbers and every one of them is a *square* of a length. That word is the loudest cue on the page, because a squared length is a dot product of a vector with itself, and the squared length of a difference is the polarisation of a dot product of two different vectors. So the six rational numbers are saying one thing: fix the vectors $b = \vec{AB}$, $c = \vec{AC}$, $d = \vec{AD}$, and the Gram matrix of the triple (b, c, d), meaning the array of all pairwise dot products, has rational entries. Read the hypothesis that way and half the problem has evaporated, because the hypothesis has been converted from six lengths, which are algebraically awkward, into six inner products, which are the natural coordinates of the situation.

The target is a *ratio* of areas, not an area, and the reason is worth pausing on. The areas themselves need not be rational: an equilateral triangle with all squared side lengths equal to 1 has area $\sqrt{3}/4$. Worse, it is easy to prove that each area has rational square, and that is not enough, because $\sqrt{2}$ and $\sqrt{3}$ both have rational squares while $\sqrt{2}/\sqrt{3}$ is irrational. So the proof needs an object that sees both triangles simultaneously. The product of the two areas is such an object, and since an area is half of the absolute value of a determinant, the product of two determinants is the thing to compute. Determinants multiply, so a product of two determinants is a single determinant, and the single determinant it equals is a mixed Gram matrix whose entries are exactly the rational dot products.

The fields wired in: bilinear forms and Gram determinants; multiplicativity of the determinant; elementary field theory, in that $\mathbb{Q}$ is closed under the four operations and contains the absolute value of each of its elements. What is really being tested is whether you can resist placing coordinates. Coordinates are available and they work, but they introduce square roots that you then have to keep track of by hand, and the reason the statement is true stays hidden.

Within thirty seconds you should have on paper: b, c, d as vectors based at A; the polarisation identity $2\,u \cdot v = |u|^2 + |v|^2 - |u - v|^2$; area $= \frac{1}{2}|\det[\,u\ v\,]|$; and the line $\det[\,b\ c\,] \cdot \det[\,b\ d\,] = \det\left([\,b\ c\,]^{\mathsf{T}}[\,b\ d\,]\right)$.

Approaches, ranked worst to best

1. **Unstructured coordinates.** *Cue:* the phrase "Euclidean plane". *Circuit:* put A at the origin and give every other point two unknown coordinates. (Worst. You acquire six unknowns and six quadratic conditions, the unknowns are irrational, and you have no criterion for what is rational at any stage. The algebra is unbounded and the conclusion never comes into view.)

2. **Adapted coordinates.** *Cue:* the segment AB is common to both triangles. *Circuit:* choose the frame that makes the shared datum trivial, origin at the midpoint of AB, A on the positive horizontal axis. (This is the official first route and it works: with $A = (\sqrt{a}, 0)$ and $B = (-\sqrt{a}, 0)$, adding and subtracting the conditions on AC and BC shows $x_1\sqrt{a}$ and $x_1^2 + y_1^2$ rational, hence x_1^2, x_2^2, x_1x_2, y_1^2, y_2^2 rational, and then the condition on CD forces y_1y_2 rational, so $y_1/y_2 = (y_1y_2)/y_1^2$ is rational. Honest, about a page, and it conceals the mechanism: the products x_1x_2 and y_1y_2 are mixed Gram entries in disguise.)

3. **Law of cosines on the angles at A.** *Cue:* squared lengths plus the formula area $= \frac{1}{2}bc\sin A$. *Circuit:* convert lengths into angles, then use the angle addition formula. (Works. Each $2\,AB\cdot AC\cos\alpha$ is rational, so $\cos^2$ and $\sin^2$ of each angle is rational; expanding $\cos(\alpha+\gamma)$ isolates $\sin\alpha\sin\gamma$ as rational, and the ratio of areas is a quotient of such products. Correct, but you must handle signed angles carefully and the ink cost is roughly double.)
4. **The Cayley and Menger determinant.** *Cue:* all pairwise squared distances are given, which is exactly that matrix. *Circuit:* quote the volume formula and the associated polynomial identity. (Correct and conceptually right, since the Cayley and Menger determinant is the canonical function of the squared distance data. But you need to recall the identity relating $\text{area}(ABC)^2\,\text{area}(ABD)^2$ to AB^2V^2 exactly, and recalling a specific polynomial identity under exam conditions is a poor bet.)
5. **Gram matrices and multiplicativity of the determinant.** *Cue:* squared lengths, and a ratio rather than a value. *Circuit:* polarise into dot products, write areas as determinants, and multiply the two determinants into one. (Best. Four lines, no coordinates, no square roots ever written down, and the generalisation to higher dimensions is immediate. It also makes visible exactly which hypothesis does what, which is what lets you construct the sharpness examples.)

The ideal solution

For $u, v \in \mathbb{R}^2$ write $[\,u\;v\,]$ for the 2×2 matrix with columns u and v, and recall that the triangle with vertices A, $A+u$, $A+v$ has area $\frac{1}{2}\,|\det[\,u\;v\,]|$.

Set $b = B-A$, $c = C-A$, $d = D-A$.

Lemma 8.6.1. *All six of the numbers $b\cdot b$, $c\cdot c$, $d\cdot d$, $b\cdot c$, $b\cdot d$, $c\cdot d$ are rational.*

Proof. The three diagonal entries are AB^2, AC^2, AD^2, rational by hypothesis. For the others use polarisation: for any u, v,

$$2\,u\cdot v = |u|^2 + |v|^2 - |u-v|^2.$$

Taking $(u,v) = (b,c)$ gives $2\,b\cdot c = AB^2 + AC^2 - BC^2$, since $b-c = \vec{CB}$ has squared length BC^2; taking $(u,v) = (b,d)$ gives $2\,b\cdot d = AB^2 + AD^2 - BD^2$; taking $(u,v) = (c,d)$ gives $2\,c\cdot d = AC^2 + AD^2 - CD^2$. Each right hand side is rational. □

Lemma 8.6.2. *For $u, v, w, z \in \mathbb{R}^2$,*

$$\det[\,u\;v\,]\cdot\det[\,w\;z\,] \;=\; \det\begin{pmatrix} u\cdot w & u\cdot z \\ v\cdot w & v\cdot z \end{pmatrix}.$$

Proof. Since $\det M^{\mathsf{T}} = \det M$ and the determinant is multiplicative, $\det[\,u\;\;v\,]\det[\,w\;\;z\,] = \det\big([\,u\;v\,]^{\mathsf{T}}[\,w\;z\,]\big)$, and the (i,j) entry of $[\,u\;v\,]^{\mathsf{T}}[\,w\;z\,]$ is the dot product of the ith column of $[\,u\;v\,]$ with the jth column of $[\,w\;z\,]$. □

Proof of the statement. Because A, B, D are three of the four points and no three of the points are collinear, the vectors b and d are linearly independent, so $\det[\,b\;d\,] \neq 0$. Apply Lemma 2 twice:

$$\det[\,b\;c\,]\cdot\det[\,b\;d\,] = \det\begin{pmatrix} b\cdot b & b\cdot d \\ c\cdot b & c\cdot d \end{pmatrix} = (b\cdot b)(c\cdot d) - (b\cdot d)(b\cdot c),$$

$$\big(\det[\,b\;d\,]\big)^2 = \det\begin{pmatrix} b\cdot b & b\cdot d \\ d\cdot b & d\cdot d \end{pmatrix} = (b\cdot b)(d\cdot d) - (b\cdot d)^2.$$

By Lemma 1 both right hand sides are rational, and the second is nonzero. Hence

$$\frac{\det[\,b\;c\,]}{\det[\,b\;d\,]} \;=\; \frac{\det[\,b\;c\,]\cdot\det[\,b\;d\,]}{\big(\det[\,b\;d\,]\big)^2} \;\in\; \mathbb{Q}.$$

Finally,

$$\frac{\text{area}(\triangle ABC)}{\text{area}(\triangle ABD)} = \frac{\frac{1}{2}\,|\det[\,b\;c\,]|}{\frac{1}{2}\,|\det[\,b\;d\,]|} = \left|\frac{\det[\,b\;c\,]}{\det[\,b\;d\,]}\right|,$$

and the absolute value of a rational number is rational. Note that $\det[\,b\;c\,] \neq 0$ as well, since A, B, C are not collinear, so the quotient is a positive rational. □

Remark 8.6.3. The same three lines prove more. Since $\big(\det[\,b\;c\,]\big)^2 = (b\cdot b)(c\cdot c) - (b\cdot c)^2$ is rational, each area has rational square; combined with the above, both determinants lie in the one dimensional $\mathbb{Q}$ vector space spanned by $\det[\,b\;d\,]$, a number whose square is rational. In other words all four areas $\text{area}(\triangle ABC)$, $\text{area}(\triangle ABD)$, $\text{area}(\triangle ACD)$, $\text{area}(\triangle BCD)$ are rational multiples of one common square root.

Proposition 8.6.4 (the general form)**.** *Let $P_0, \dots, P_k$ and Q be points of $\mathbb{R}^N$ lying in a common k dimensional affine subspace, with $P_0, \dots, P_k$ affinely independent and $P_0, \dots, P_{k-1}, Q$ affinely independent. If every pairwise squared distance among these $k+2$ points is rational, then*

$$\frac{\text{vol}_k(P_0P_1\cdots P_k)}{\text{vol}_k(P_0P_1\cdots P_{k-1}Q)} \in \mathbb{Q}.$$

Proof. Choose an orthonormal basis of the k dimensional direction space of the common affine subspace and use it to write the vectors $v_i = P_i - P_0$ and $w = Q - P_0$ as columns in $\mathbb{R}^k$. Dot products are unchanged by this choice, so by polarisation all pairwise dot products of $v_1, \dots, v_k, w$ are rational. The two matrices $M = [\,v_1\;\cdots\;v_k\,]$ and $M' = [\,v_1\;\cdots\;v_{k-1}\;w\,]$ are $k \times k$, the k volumes are $|\det M|/k!$ and $|\det M'|/k!$, and $\det M \det M' = \det(M^{\mathsf{T}}M')$ is a determinant of rationals, as is $(\det M')^2 = \det((M')^{\mathsf{T}}M') \neq 0$. Divide. □

Layer 1: WHAT

Block 1. Vectorise at the common vertex: $b = B - A$, $c = C - A$, $d = D - A$.

Block 2. Polarise: the six squared lengths become the six dot products, all rational.

Block 3. Write each area as half the modulus of a determinant, so the target is $|\det[\,b\;c\,]/\det[\,b\;d\,]|$.

Block 4. Notice the obstruction: each determinant has rational square, and that is not enough, because $\sqrt{2}$ and $\sqrt{3}$ have rational squares and an irrational ratio.

Block 5. Multiply the two determinants into one: $\det[\,b\;c\,]\det[\,b\;d\,] = \det\big([\,b\;c\,]^{\mathsf{T}}[\,b\;d\,]\big)$, a 2×2 determinant of dot products, hence rational.

Block 6. Divide by $(\det[\,b\;d\,])^2$, which is rational and nonzero because A, B, D are not collinear, then take absolute values.

Juxtaposition. The nominal route places coordinates and grinds; it succeeds, but it spends a page and it hides the mechanism inside the products x_1x_2 and y_1y_2. The sharper split is not at coordinates but at Block 4. Almost every solver reaches "each area has rational square" within two minutes. The zombie then tries to prove each area lies in a fixed quadratic field by chasing the actual value of the square root. The ideal solver refuses to look at either area alone and computes their product, because the product is the only polynomial expression in the given data that involves both triangles at once. That is the bifurcation point: *compute the product, never the individual*.

Layer 2: HOW

Block 1. Cue. Both triangles share the side AB, and every listed datum is a distance from one labelled point to another. **Why natural.** Distances are functions of differences, so the coordinate free encoding of the whole configuration is the set of difference vectors based at one chosen vertex. Choosing A, the vertex shared by both triangles, is forced by the shape of the target: the two triangles differ in exactly one vector, c against d. **Link to the next block.** Once the configuration is three vectors, every piece of the data must be expressible in the inner product of those vectors.

Block 2. **Cue.** The hypothesis is about squares of lengths, not lengths. **Why natural.** A squared length is $u \cdot u$. The remaining data, the squared lengths of BC, BD, CD, are squared lengths of differences, and the identity $|u - v|^2 = |u|^2 + |v|^2 - 2u \cdot v$ is the definition of the inner product rearranged. So the hypothesis is literally the statement that the Gram matrix of (b, c, d) has rational entries; nothing is being deduced here, only translated. This is why the problem says squares: it is handing you a Gram matrix. **Link to the next block.** With the hypothesis in inner product form, the conclusion must also be put in inner product form.

Block 3. **Cue.** Area, in a rationality question. **Why natural.** There are two standard formulas for a triangle's area, one half base times height and one half the modulus of a determinant. The first involves a length and a perpendicular distance, neither of which is polynomial in the given data. The determinant is bilinear in the vectors, hence polynomial. In a rationality question you must express everything as polynomials in the data, so the determinant is the only admissible choice. **Link to the next block.** Now the target is a ratio of determinants and the data is a Gram matrix, so the question becomes how determinants and Gram matrices talk to each other.

Block 4. **Cue.** $\big(\det[\, b\ c\,]\big)^2 = (b \cdot b)(c \cdot c) - (b \cdot c)^2$ is visibly rational, and so is the analogue for d. **Why natural.** This is the first thing everyone computes, and it is a trap worth naming out loud: rational squares do not give a rational ratio. Testing the assertion against $\sqrt{2}$ and $\sqrt{3}$ takes five seconds and saves ten minutes. Recognising that your natural first computation is insufficient is itself a step, and the correct response is to ask what extra quantity would suffice. **Link to the next block.** The missing quantity must involve both triangles, and there is exactly one symmetric candidate, the product of the two determinants.

Block 5. **Cue.** A product of two determinants of the same size. **Why natural.** Determinants are multiplicative, so a product of determinants is never left as a product: it is a single determinant of a product of matrices. Transposing one factor costs nothing since $\det M^{\mathsf{T}} = \det M$, and the transposed product is precisely the matrix of pairwise dot products. So the multiplication converts the only unavailable quantity into an array of quantities you already know to be rational. The cue "product of determinants" firing the move "multiply the matrices" is a circuit worth installing on its own. **Link to the next block.** The product is rational and the square of the denominator is rational, so the ratio is a quotient of rationals.

Block 6. **Cue.** The ratio of areas involves absolute values, and a denominator must be nonzero. **Why natural.** The hypothesis that no three points are collinear appears nowhere else in the argument, so this is where it is spent: it makes b and d independent and $\det[\, b\ d\,] \neq 0$. And $\mathbb{Q}$ is closed under absolute value, so the modulus signs cost nothing. **Link to the next block.** Every hypothesis has now been used exactly once, which is the signal that the proof is complete and tight.

Layer 3: WHY

The first truth is that squared distances and Gram matrices are the same data. Polarisation is invertible over any field in which 2 is invertible, so knowing all pairwise squared distances among $P_0, \ldots, P_k$ is exactly knowing all pairwise inner products of the difference vectors, and rationality transfers both ways. Every problem whose hypothesis is a list of squared distances should therefore be rewritten as a problem about a symmetric matrix before anything else happens. That single reflex converts a geometry problem into a linear algebra problem where rationality is a transparent condition.

The second truth is about square roots. A k volume is the square root of a Gram determinant, so under rational hypotheses the volumes live in quadratic extensions of $\mathbb{Q}$. Knowing α^2 and β^2

are rational tells you nothing about α/β; knowing $\alpha\beta$ is rational tells you everything, because $\alpha/\beta = \alpha\beta/\beta^2$. So in any problem where two irrational quantities are compared, look for the product rather than for the individuals. The mixed Gram determinant exists precisely to produce that product, and Lemma 2 is the statement that the product of two areas is a polynomial in the mutual inner products even though each area separately is not.

The third truth concerns which hypotheses matter, and here it pays to build the counterexamples rather than trust a feeling. First, drop CD^2 from the hypotheses. Take

$$A = (0,0), \quad B = (1,0), \quad C = (1,\sqrt{2}), \quad D = (2,\sqrt{3}).$$

Then $AB^2 = 1$, $AC^2 = 3$, $AD^2 = 7$, $BC^2 = 2$, $BD^2 = 4$ are all rational, no three of the points are collinear, and yet

$$\frac{\text{area}(\triangle ABC)}{\text{area}(\triangle ABD)} = \frac{\sqrt{2}}{\sqrt{3}},$$

which is irrational; correspondingly $CD^2 = 6 - 2\sqrt{6}$ is irrational. So the datum CD^2, which touches neither of the two triangles being compared, is indispensable: it is the only source of the entry $c \cdot d$ in the mixed Gram matrix. Second, drop planarity. In $\mathbb{R}^3$ take

$$A = (0,0,0), \quad B = (1,0,0), \quad C = (1,\sqrt{2},0), \quad D = (2,0,\sqrt{3}),$$

so that $AB^2 = 1$, $AC^2 = 3$, $AD^2 = 7$, $BC^2 = 2$, $BD^2 = 4$, $CD^2 = 6$ are all rational and no three points are collinear, while the two areas are again $\sqrt{2}/2$ and $\sqrt{3}/2$ with irrational ratio. The reason the proof fails here is exactly located: with three dimensional column vectors the matrices $[\,b\ c\,]$ and $[\,b\ d\,]$ are 3×2 and the product of their determinants is not defined, while $\det\left([\,b\ c\,]^{\mathsf{T}}[\,b\ d\,]\right)$ is by the Cauchy and Binet formula a sum of three products rather than a single one. The phrase "in the Euclidean plane" is doing real work, and the proof is honest about where.

The discernment mechanism, stated as a rule: in a rationality question, work only with quantities that are polynomial in the given data, and when a target is not polynomial, pair it with a second non polynomial quantity so that the product is. The examiners nudged toward it by giving squares, by asking for a ratio and not a value, and by including the one squared distance, CD^2, that has no other conceivable use. Three cues, one method. To train it, take any configuration problem with distance data and ask which functions of the data are polynomial: dot products yes, lengths no, cosines no, products of two areas yes, single areas no.

Revolving concepts

Gram matrix and Gram determinant. For vectors $v_1, \ldots, v_k$ in an inner product space, the Gram matrix is G with $G_{ij} = v_i \cdot v_j$. It is symmetric and positive semidefinite; $\det G \geq 0$, with equality exactly when the vectors are dependent; and when the v_i lie in a k dimensional space with coordinate matrix M, $G = M^{\mathsf{T}}M$ and $\det G = (\det M)^2$. The k volume of the parallelepiped they span is $\sqrt{\det G}$, and of the simplex, $\sqrt{\det G}/k!$. See Book 1, field: Linear algebra, topic: inner products and Gram matrices.

Polarisation. $2\,u \cdot v = |u|^2 + |v|^2 - |u - v|^2$, valid in any real inner product space. It says the inner product is recoverable from the norm, so distance data and inner product data determine each other.

Determinant multiplicativity, and Cauchy with Binet. $\det(MN) = \det M \det N$ for square M, N, and $\det M^{\mathsf{T}} = \det M$. For an $N \times k$ matrix M and $k \times N$ matrix M' with $N > k$, the Cauchy and Binet formula gives $\det(M^{\mathsf{T}}M') = \sum_S \det(M_S)\det(M'_S)$, summed over all k element subsets S of rows. This is exactly why the argument is planar: the sum collapses to a single term only when $N = k$. See Book 1, field: Matrices and determinants, topic: multiplicativity and Cauchy with Binet.

Area as a determinant. For $u, v \in \mathbb{R}^2$, the triangle spanned has area $\frac{1}{2}|\det[\,u\ v\,]|$; the signed version is $\frac{1}{2}\det[\,u\ v\,]$ and it is the shoelace formula in disguise. Bilinearity is what makes it usable in arithmetic questions.

The Cayley and Menger determinant. For points $P_0, \dots, P_k$ in $\mathbb{R}^k$ with d_{ij} the distances,

$$\mathrm{vol}_k^2 = \frac{(-1)^{k+1}}{2^k (k!)^2} \det \begin{pmatrix} 0 & d_{01}^2 & \cdots & d_{0k}^2 & 1 \\ d_{10}^2 & 0 & \cdots & d_{1k}^2 & 1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ d_{k0}^2 & d_{k1}^2 & \cdots & 0 & 1 \\ 1 & 1 & \cdots & 1 & 0 \end{pmatrix}.$$

For $k = 2$ this is Heron's formula, in the form $16\,\mathrm{area}^2 = -\det$; for $k = 3$ it is the identity of Piero della Francesca, $288V^2 = \det$. The dimensional recursion is the content: the $(k+2) \times (k+2)$ determinant of a point set vanishes exactly when the points lie in a $(k-1)$ dimensional flat, so the same family of determinants simultaneously computes volumes and detects degeneracy, one dimension at a time. This is the canonical function of squared distance data and it is the reason the hypothesis of the problem was phrased in squares. See Book 1, field: Geometry, topic: distance geometry and the Cayley and Menger determinant.

Rationality of $\mathbb{Q}$ *under the operations.* $\mathbb{Q}$ is a field and is closed under absolute value, so a quotient of nonzero rationals, and the modulus of a rational, are rational. Trivial, but it is the last line of the proof and must be said.

Rational distance sets. It is a genuine fact, not an assumption, that configurations satisfying the hypothesis exist, and one can even force all six distances themselves to be rational: Euler found infinitely many points on a circle with pairwise rational distances, obtainable by pushing rational points of the line to the circle by a linear fractional map and using the Brahmagupta and Pell equation $x^2 - 2y^2 = -1$ to supply infinitely many of them. Whether a dense subset of the plane can have all pairwise distances rational is the Erdos and Ulam problem, still open. Knowing this stops you from wasting time wondering whether the hypothesis is vacuous.

Circuit Bank

- **WHEN** a hypothesis giving you *squared* lengths **DO** polarise at once into dot products and declare the Gram matrix rational **BECAUSE** squared lengths are the diagonal of a Gram matrix and polarisation fills in the off diagonal, so the hypothesis is a matrix statement, not a geometry statement
- **WHEN** an area or a volume inside an arithmetic question **DO** replace it by a determinant, never by a base times height or a product of a length and a sine **BECAUSE** determinants are polynomial in the coordinates and bilinear in the vectors, while lengths and sines are not, and only polynomial quantities behave under rationality
- **WHEN** two irrational quantities whose ratio you must control, each with rational square **DO** compute their product, not their values **BECAUSE** $\alpha/\beta = \alpha\beta/\beta^2$, so the product is the single missing ingredient, and rational squares alone never suffice
- **WHEN** a product of two determinants of equal size **DO** fuse them into one determinant of a matrix product, transposing one factor if that produces inner products **BECAUSE** $\det M \det N = \det(M^{\mathsf{T}} N)$ turns a product of unknowns into an array of knowns
- **WHEN** a hypothesis in the list that seems irrelevant to the conclusion **DO** find the single step that uses it, and if you cannot, build the counterexample that deletes it **BECAUSE** a proof that never uses a given datum is almost always wrong, and constructing the sharpness example is the fastest audit available

Backtesting

1. First useful cue: the data consists of *squares* of lengths, which is a Gram matrix; and a ratio is requested rather than a value, which warns that the individual areas are irrational.

2. Method the expression suggested: vectorise at the shared vertex A, polarise into dot products, write areas as determinants, and fuse the two determinants into one.
3. Where you would hesitate, and the thought to reinforce: after computing that each area has rational square you will want to conclude. Reinforce: $\sqrt{2}$ and $\sqrt{3}$ have rational squares and irrational ratio, so stop and find the object that sees both triangles at once.
4. The trap the question sets: coordinates. They work, they feel safe, and they cost a page while burying the mechanism, so that you learn nothing transferable and have a page of algebra in which to make a slip.
5. What makes you recognise it faster next time: the pairing of "squared distances given" with "ratio of areas asked". That pairing has one answer, mixed Gram determinants, and it is the same answer in every dimension.
6. The reusable decision rule: in a rationality question, restrict yourself to quantities polynomial in the data; if the target is not polynomial, multiply it by a partner until it is, then divide by a square at the end.

Mirror drills

1. Prove $16\,\mathrm{area}(\triangle ABC)^2 = 4\,AB^2AC^2 - (AB^2 + AC^2 - BC^2)^2$, and recognise it as Heron's formula. *Answer:* $4\,\mathrm{area}^2 = \big(\det[\,b\ c\,]\big)^2 = (b\cdot b)(c\cdot c) - (b\cdot c)^2$, then substitute $2\,b\cdot c = AB^2 + AC^2 - BC^2$ and multiply by 4.
2. Find four points in the plane, no three collinear, with $AB^2, AC^2, AD^2, BC^2, BD^2$ all rational but the area ratio irrational, and say which line of the proof breaks. *Answer:* $A = (0,0)$, $B = (1,0)$, $C = (1,\sqrt{2})$, $D = (2,\sqrt{3})$ give ratio $\sqrt{2}/\sqrt{3}$; the entry $c\cdot d$ of the mixed Gram matrix is no longer rational, since $CD^2 = 6 - 2\sqrt{6}$.
3. Let u, v, w be vectors in $\mathbb{R}^2$ with all pairwise dot products rational and $\det[\,u\ v\,] \neq 0$. Show that $\det[\,u\ w\,]/\det[\,u\ v\,]$ and $\det[\,v\ w\,]/\det[\,u\ v\,]$ are rational, and deduce that w is a rational combination of u and v. *Answer:* both ratios are rational by the mixed determinant argument, and Cramer's rule expresses w in the basis (u, v) with exactly those two quotients as coefficients.

8.7 B1. Which Point to Remove for a Balanced Split

Let $\mathcal{P}$ be the set of vectors defined by

$$\mathcal{P} = \left\{ \begin{pmatrix} a \\ b \end{pmatrix} \middle| \, 0 \le a \le 2, \; 0 \le b \le 100, \text{ and } a, b \in \mathbb{Z} \right\}.$$

Find all $\mathbf{v} \in \mathcal{P}$ such that the set $\mathcal{P} \setminus \{\mathbf{v}\}$, obtained by omitting the vector $\mathbf{v}$ from $\mathcal{P}$, can be partitioned into two sets of equal size and equal sum.

Read it out loud

This is a grid of lattice points, three columns wide ($a = 0, 1, 2$) and a hundred and one rows tall ($b = 0$ to 100), and you are asked which single point you can delete so that the remaining 302 points split into two halves of 151 points each, whose vector sums agree. Say the sentence out loud and the costume falls away: this is an equal sum partition question, and the coordinates are irrelevant as coordinates. All that matters is that $\mathcal{P}$ is a finite multiset of pairs of numbers, and you are being asked an if and only if question about which single element, once removed, leaves something splittable.

Every question of the shape "remove one object so the rest splits into two equal halves" starts with the same first move, and it should be in your hand within the first thirty seconds: look at the total. If $\mathcal{P} \setminus \{\mathbf{v}\}$ really does split into S_1 and S_2 of equal sum, then $\Sigma(\mathcal{P}) = \mathbf{v} + \Sigma(S_1) + \Sigma(S_2) = \mathbf{v} + 2\Sigma(S_1)$, so $\mathbf{v}$ is congruent to $\Sigma(\mathcal{P})$ modulo 2 in every coordinate. This costs one computation, summing a rectangular grid, which is just the point count times the mean point, and it turns an apparently open search over 303 candidates into a search over a residue class.

The second field wired into the problem is pure construction: once the necessary condition narrows the candidates, you must exhibit an actual partition for each survivor. The set $\mathcal{P}$ is a rectangle of lattice points, and a rectangle has an obvious symmetry, reflection through its centre. That symmetry is the second cue: it hands you 151 pairs of points with identical vector sum before a single explicit set is written down, and the only genuine work left is patching the one point where the symmetry itself breaks down.

Approaches, ranked worst to best

1. **Search small cases by hand.** *Cue:* the grid is finite, so in principle you could just try. *Circuit:* brute enumeration. This costs unbounded ink for no structural payoff: checking 303 candidates against the possible splits of the remaining 302 points is not a proof, and it never explains why the second coordinate must be even.

2. **Guess a construction for a specific removed point, then generalise the pattern.** *Cue:* small cases of the second coordinate look symmetric. *Circuit:* pattern spotting without an invariant. This can find a working split for particular values eventually, but without the sum invariant first you cannot know you have found every valid $\mathbf{v}$, only that the ones you tried happened to work; the necessary direction of the proof is entirely missing.

3. **Sum invariant for necessity, central involution for sufficiency.** *Cue:* the request is an if and only if, and $\mathcal{P}$ is visibly symmetric about its centre. *Circuit:* sum invariant, then pairing by the involution that fixes the centre. This is the route to take: the invariant argument is three lines and narrows $\mathbf{v}$ to 51 candidates of the form $(1, b)$ with b even, and the symmetry of the grid supplies almost all of the remaining construction for free.

The ideal solution

Write $\Sigma(S)$ for the vector sum of a finite set $S \subset \mathbb{Z}^2$. Since a ranges over $\{0,1,2\}$ (mean 1) and b ranges over $\{0,1,\dots,100\}$ (mean 50), and $|\mathcal{P}| = 3 \cdot 101 = 303$,

$$\Sigma(\mathcal{P}) = 303 \begin{pmatrix} 1 \\ 50 \end{pmatrix} = \begin{pmatrix} 303 \\ 15150 \end{pmatrix}.$$

Necessity. Suppose $\mathcal{P} \setminus \{\mathbf{v}\}$ splits into S_1, S_2 with $|S_1| = |S_2|$ and $\Sigma(S_1) = \Sigma(S_2)$. Then $\Sigma(\mathcal{P}) = \mathbf{v} + 2\Sigma(S_1)$, so

$$\mathbf{v} = \Sigma(\mathcal{P}) - 2\Sigma(S_1) \equiv \begin{pmatrix} 303 \\ 15150 \end{pmatrix} \equiv \begin{pmatrix} 1 \\ 0 \end{pmatrix} \pmod 2.$$

Writing $\mathbf{v} = (a,b)$, the first coordinate must be odd, forcing $a = 1$ since $a \in \{0,1,2\}$; the second coordinate must be even. So $\mathbf{v} = (1,b)$ with $b \in \{0,2,4,\dots,100\}$, exactly 51 candidates.

Sufficiency. Fix such a $\mathbf{v} = (1,b)$. Let $\iota(a,b) = (2-a, 100-b)$, an involution of $\mathcal{P}$ to itself, since $a \in \{0,1,2\} \Rightarrow 2-a \in \{0,1,2\}$ and $b \in \{0,\dots,100\} \Rightarrow 100-b \in \{0,\dots,100\}$; every point p satisfies $p + \iota(p) = (2,100)$. The unique fixed point is $(1,50)$; every other point lies in exactly one pair $\{p, \iota(p)\}$, giving 151 pairs, each summing to $(2,100)$.

Case $b \neq 50$. Then $\mathbf{v}$ is not the fixed point, and its partner is $(1,100-b) \neq \mathbf{v}$. Removing $\mathbf{v}$ breaks this pair, leaving the single leftover point $(1,100-b)$ alongside the untouched fixed point $(1,50)$; these two cannot simply be dropped one to a side, since their sum $(2,150-b)$ is not obviously twice anything useful. Repair this by sacrificing one further pair $\{p, (2,100)-p\}$ of the involution, putting both leftovers and p into S_1, and the partner $(2,100)-p$ alone into S_2, together with 74 further intact pairs assigned wholly to S_1 and 75 further intact pairs assigned wholly to S_2 (any split of the remaining pairs into 74 and 75 will do, since every intact pair contributes the identical sum $(2,100)$ regardless of which side it lands on). This gives $|S_1| = 148+3 = 151$ and $|S_2| = 150+1 = 151$ for any choice of p. Equating the two sums,

$$74(2,100) + (1,100-b) + (1,50) + p = 75(2,100) + \big((2,100) - p\big),$$

gives $2p = 2(2,100) - (2,150-b) = (2,50+b)$, so $p = (1,25+b/2)$, an integer point of $\mathcal{P}$ precisely because b is even, the same evenness the necessity step already forced; it lies in the range $[25,75]$ for the second coordinate since $0 \le b \le 100$. One checks $p \neq \mathbf{v}$ and $p \neq (1,100-b)$ exactly when $b \neq 50$, since either equality reduces to $b = 50$. So $\{p, (2,100)-p\} = \{(1,25+b/2), (1,75-b/2)\}$ is a genuine third pair, distinct from the first, and the construction is complete: S_1 consists of $(1,100-b)$, $(1,50)$, $(1,25+b/2)$, and 74 of the remaining 149 pairs; S_2 consists of $(1,75-b/2)$ and the other 75 of those pairs.

Case $b = 50$. Now $\mathbf{v} = (1,50)$ is the fixed point of ι itself, so removing it leaves exactly the 151 intact pairs, with no leftover singles at all. Splitting 151 pairs into two sides of 151 points each needs an odd number of split pairs, since every intact pair contributes an even amount, 2, to whichever side receives it, while a split pair contributes the odd remainder 1 to each side. A single split pair $\{q, (2,100)-q\}$ would force $q = (1,50)$ for the two sides to balance, by the same algebra as above, but that point has already been removed. So split three pairs instead. The offsets $(1,0)$, $(0,1)$, and $(-1,-1)$ from the centre satisfy $(1,0)+(0,1)+(-1,-1) = (0,0)$, so take the three points $(2,50)$, $(1,51)$, $(0,49)$, whose partners under ι are $(0,50)$, $(1,49)$, $(2,51)$. Put $S_1 = \{(2,50),(1,51),(0,49)\}$ together with 74 of the remaining 148 pairs, and $S_2 = \{(0,50),(1,49),(2,51)\}$ together with the other 74 pairs. Both sides have $3+148 = 151$ points, and since the offsets from $(1,50)$ used on each side cancel, $\Sigma(S_1) = 3(1,50) = \Sigma(S_2)$ once the equal contribution of the 74 shared pairs on each side is added.

In every case a valid partition exists, so

$$\boxed{\mathbf{v} = (1,b) \text{ for } b \in \{0,2,4,\dots,100\}}$$

is exactly the set of vectors with the stated property, 51 vectors in all.

Layer 1: WHAT

Block 1: compute $\Sigma(\mathcal{P})$ from the mean of each coordinate. Block 2: the sum invariant forces $\mathbf{v} \equiv \Sigma(\mathcal{P}) \pmod 2$, giving $\mathbf{v} = (1, b)$ with b even. Block 3: the grid's central involution supplies 151 equal sum pairs and one fixed point. Block 4: for $b \neq 50$, solve a balance equation to find the compensating pair. Block 5: for $b = 50$, use a three term zero sum offset identity instead of a single compensating pair.

The nominal route tries to construct partitions for small values of b by trial and error, hoping to spot which $\mathbf{v}$ work; this never proves the only if direction, and it is easy to miss that $b = 50$ needs separate treatment since small trial values rarely land on the centre. The bifurcation point is the line $\Sigma(\mathcal{P}) = \mathbf{v} + 2\Sigma(S_1)$: writing that equation, instead of attempting a construction first, is what turns an open ended search into a two line necessary condition.

Layer 2: HOW

Block 1. **Cue.** A rectangular grid of lattice points, presented as a Cartesian product of two ranges. **Why natural.** The grid is a Cartesian product of two arithmetic progressions, so its total is the point count times the mean point, the fastest route to $\Sigma(\mathcal{P})$ without adding 303 vectors by hand. **Link to the next block.** Having the exact total ready is what makes the invariant argument in the next block a short computation instead of a guess.

Block 2. **Cue.** The phrase partitioned into two sets of equal size and equal sum. **Why natural.** Any such partition's two halves sum to the same value, so their combined total is twice that value; subtracting the removed vector from the grand total must therefore be even in every coordinate, a congruence condition on the removed vector alone. **Link to the next block.** This collapses 303 candidates to 51, and tells you exactly where to look for a construction, namely the middle column with even second coordinate.

Block 3. **Cue.** The surviving candidates all sit on the line of symmetry $a = 1$, and $\mathcal{P}$ is itself symmetric about the point $(1, 50)$. **Why natural.** A rectangle's only point symmetry is reflection through its centre, and reflecting $\mathcal{P}$ through its centre is a bijection of $\mathcal{P}$ to itself, so pairing each point with its reflection costs nothing extra. **Link to the next block.** This turns the sufficiency direction from inventing 151 points from nothing into redistributing 151 ready made pairs.

Block 4. **Cue.** Removing $\mathbf{v}$ breaks exactly one pair, leaving one orphan point beside the untouched fixed point. **Why natural.** Two leftover points whose sum is not obviously twice anything cannot simply be split one to a side, so the fix has to come from deliberately breaking a second pair and solving for the split point that restores the balance. **Link to the next block.** Setting the two sides' sums equal and solving the resulting linear equation for the unknown split point is what produces the specific value $25 + b/2$, rather than guessing it.

Block 5. **Cue.** Removing the fixed point itself leaves an odd total, 151, to split from an even supply of whole pairs. **Why natural.** Splitting an odd count from whole pairs alone is impossible, and the algebra shows a single broken pair would need its two halves to average to the point already removed; three broken pairs, chosen so their offsets from the centre cancel, is the smallest fix that avoids this. **Link to the next block.** The identity $(1, 0) + (0, 1) + (-1, -1) = (0, 0)$ is the shortest way to find three cancelling offsets, the same style of small linear solve as the previous block, one level more elaborate.

Layer 3: WHY

The problem sits at the interaction of an algebraic invariant, the coordinate sum reduced modulo 2, and a geometric symmetry, the point reflection of a centrally symmetric finite set. Every delete one element so the rest is evenly splittable problem has this two part anatomy: the invariant gives the necessary direction for free, because summing is linear and splitting in half means dividing by two, so a residue condition on the removed element is unavoidable; the construction almost always exploits a symmetry native to the ambient set, because a symmetry of the whole set restricted to a subset is an equal sum pairing at zero cost, leaving only the boundary case, the point that breaks the pattern, to patch by hand. The discernment mechanism: on any equal sum partition problem, write the total and divide by two before anything else, and on any symmetric ambient set, a rectangle, an arithmetic progression, a cyclic group, ask what its automorphisms fix, since an automorphism restricted to a subset is a pairing for free. Train this by asking, on every new equal partition problem, what the symmetry group of the ambient set is and what it fixes, before attempting a bespoke construction. The examiners nudge you toward the centre of the grid by choosing point counts, 3 and 101, that are both odd, guaranteeing a single isolated fixed point rather than a symmetry with none at all.

Revolving concepts

Sum invariants for partition problems: a partition into k equal sum parts forces the total to be divisible by k in every coordinate that is being summed; the same idea underlies the classical question of whether a run of consecutive integers can be split into two equal sum halves. See Book 1, field Combinatorics, topic Invariants.

Point symmetry, an involution ι on a finite set with $\iota \circ \iota = \mathrm{id}$: an involution partitions a finite set into fixed points and two element orbits, and here $\mathcal{P}$ has exactly one fixed point because both dimensions of the grid, 3 and 101, are odd counts. See Book 1, field Discrete structures and graphs, topic Group actions and involutions.

Solving a balance equation for an unknown lattice point: not a named theorem but a standing technique, whenever a construction needs the point whose presence restores an equality, write the equality as an equation in that unknown and solve it rather than guess it. This generalises to any adjust several degrees of freedom to hit a target sum problem, where as many equations as unknowns pin the fix down exactly; here effectively one scalar equation, since the pair's other point is determined once the first is chosen. See Book 1, field Combinatorics, topic Constructive existence proofs.

Circuit Bank

- **WHEN** you are asked which element to delete so the rest splits into two equal size, equal sum parts **DO** write the total sum of the ambient set and use total equals the removed element plus twice one side's sum, before attempting any construction **BECAUSE** splitting into two equal sums is linear, so the deleted element is congruent to the total modulo twice anything, an invariant that costs one computation and rules out almost every candidate
- **WHEN** the ambient set is visibly symmetric, a rectangle, an interval, a cyclic structure **DO** find its involution or automorphism group and pair elements by it before building anything by hand **BECAUSE** a symmetry of the whole set restricts to an equal sum pairing on any symmetric subset, for free
- **WHEN** a natural pairing leaves one or two points unpaired and their sum will not balance **DO** sacrifice one further pair, write the target equality as an equation in the unknown split point, and solve for it **BECAUSE** guessing the compensating point is unreliable, while the balance equation has a unique solution whenever the arithmetic allows one

Backtesting

1. First useful cue: the words equal size and equal sum immediately after partitioned, announcing a sum invariant argument before any construction.
2. Method the expression suggested: sum the whole grid using count times mean, then apply total equals the removed vector plus twice one side's sum.
3. Where you would hesitate, and the thought to reinforce: building S_1, S_2 explicitly for $b \neq 50$, when the two leftover points do not balance; the thought to reinforce is set the target equality as an equation in an unknown point, do not guess it.
4. The trap the question sets: $\mathbf{v} = (1, 50)$ passes the parity necessity test but is the one value where the standard single pair fix is unavailable, since it is the fixed point of the very symmetry the construction relies on.
5. What makes you recognise it faster next time: noticing early that $(1, 50)$ is the centre of the grid, and that the centre of any centrally symmetric ambient set is always the special case in this style of problem, worth checking separately before writing the general construction.
6. The reusable decision rule: for a remove one point, split the rest evenly problem on a set with a point symmetry, always test the centre of that symmetry separately, since it is the unique point with no partner.

Mirror drills

1. Let $T = \{1, 2, \ldots, 2n + 1\}$. Determine which $k \in T$ can be removed so that $T \setminus \{k\}$ splits into two size n subsets of equal sum. *Answer:* write $\Sigma(T) = k + 2\Sigma(S_1)$ and pair j with $2n + 2 - j$ about the centre $n + 1$; k must share the parity forced by $\Sigma(T)$, and the fixed point $k = n + 1$ needs the same three pair repair used above for $b = 50$.
2. A multiset of $2m + 1$ vectors has a centre of symmetry c, an involution $p \mapsto 2c - p$ fixing only c. Show that removing c always leaves a set expressible as m pairs of equal sum, while removing any other point leaves two singletons instead. *Answer:* the involution restricted to the set minus its only fixed point has no fixed points left, so it splits into exactly m two element orbits; removing a non fixed point instead breaks exactly one orbit, leaving two singletons, exactly the situation repaired above.
3. For which even b does the pair $\{(1, 25 + b/2), (1, 75 - b/2)\}$ fail to be distinct from $\{(1, b), (1, 100 - b)\}$ and from the fixed point $(1, 50)$? *Answer:* only $b = 50$, exactly the case already excluded and handled separately, confirming the two cases are exhaustive and non overlapping.

8.8 B2. A Decreasing Coefficient Polynomial Avoids the Unit Disc

Let n be a positive integer, and let $f_n(z) = n + (n-1)z + (n-2)z^2 + \cdots + z^{n-1}$. Prove that f_n has no roots in the closed unit disc $\{z \in \mathbb{C} : |z| \leq 1\}$.

Read it out loud

The coefficients of f_n count down from n to 1 in unit steps as the power counts up from 0 to $n-1$. Say that out loud and it is a much narrower description than some degree $n-1$ polynomial: this is a polynomial whose coefficients form an arithmetic progression. The claim to prove, no roots in the closed unit disc, is a statement about where roots cannot be, which usually means you should bound $|f_n(z)|$ away from zero on that region rather than try to solve for the roots directly.

The first cue, inside thirty seconds: a polynomial whose coefficients form an arithmetic progression is exactly the situation where multiplying by $(z-1)$ (or $(1-z)$) telescopes, because subtracting a copy of the series shifted by one power cancels the constant difference between consecutive coefficients and leaves something far shorter. This is the polynomial cousin of summation by parts, and it is the single most useful move whenever coefficients are linear in the exponent.

The fields embedded here are the algebra of polynomial roots, the triangle inequality together with its equality case, and, as alternative routes, the location theorems for roots of a derivative and for polynomials with monotone positive coefficients. The problem is really testing whether you reach for the transformation that turns an n term sum into a genuinely short expression, rather than trying to bound the raw sum directly, which has no exploitable structure until it is transformed.

Approaches, ranked worst to best

1. **Bound $|f_n(z)|$ directly by the reverse triangle inequality.** *Cue:* it is a sum, and sums admit a lower bound from the reverse triangle inequality. *Circuit:* naive lower bound. The resulting bound, $|f_n(z)| \geq n - \big((n-1) + \cdots + 1\big) = n - \binom{n}{2}$, is negative for $n \geq 3$, so it proves nothing at all; the raw sum carries no structure to exploit until it is transformed.

2. **Quote the Enestrom and Kakeya theorem.** *Cue:* the coefficients are positive and strictly monotone, exactly that theorem's hypothesis. *Circuit:* citing a named location theorem. Correct and fast once the theorem is already installed, but it is a fact beyond A level that must be quoted, not derived on the spot, so it is a fallback rather than the ideal route, and it is flagged below as a genuine knowledge gap.

3. **Gauss and Lucas on the coefficient reversal of f_n.** *Cue:* $g_n(z) = nz^{n-1} + \cdots + 2z + 1$ is visibly the derivative of $1 + z + \cdots + z^n$. *Circuit:* derivative root location plus coefficient reversal. Fully rigorous, but it costs two extra layers: identifying the roots of $1 + z + \cdots + z^n$ as roots of unity, then translating back through the coefficient reversal, for the same conclusion the next approach reaches directly.

4. **Multiply by $(z-1)$ to telescope, then bound with the triangle inequality and interrogate its equality case.** *Cue:* coefficients in arithmetic progression. *Circuit:* telescoping by a shifted subtraction, then the equality case of the triangle inequality. This is the route to take: two elementary facts, no named theorem, no auxiliary polynomial, and it produces the required strict inequality in a handful of lines.

The ideal solution

First, $f_n(1) = n + (n-1) + \cdots + 1 = \dfrac{n(n+1)}{2} > 0$, so $z = 1$ is not a root of f_n.

Multiply f_n by $(z-1)$:

$$(z-1)f_n(z) = (z-1)\sum_{k=0}^{n-1}(n-k)z^k = \sum_{k=0}^{n-1}(n-k)z^{k+1} - \sum_{k=0}^{n-1}(n-k)z^k.$$

Re-index the first sum with $j = k+1$, so j runs from 1 to n, and compare it term by term with the second sum, indexed by $k = j$ running from 0 to $n-1$. For $1 \le j \le n-1$ the coefficient of z^j is $\big(n-(j-1)\big) - (n-j) = 1$; the top term, $j = n$, contributes z^n alone, from the first sum only; the bottom term, $k = 0$, contributes $-n$ alone, from the second sum only. Hence

$$(z-1)f_n(z) = z^n + z^{n-1} + \cdots + z - n.$$

(Check at $n = 2$: $(z-1)(2+z) = z^2 + z - 2$, matching the right side.)

Claim 8.8.1. *f_n has no root with $|z| \le 1$.*

Proof. Suppose $f_n(z_0) = 0$ for some z_0 with $|z_0| \le 1$. Since $f_n(1) \neq 0$, necessarily $z_0 \neq 1$, so the identity above, evaluated at z_0, gives

$$z_0^n + z_0^{n-1} + \cdots + z_0 = n.$$

Take moduli and apply the triangle inequality:

$$n = |z_0^n + \cdots + z_0| \le |z_0|^n + \cdots + |z_0| \le \underbrace{1 + \cdots + 1}_{n} = n,$$

the second inequality using $|z_0| \le 1$. Equality must hold throughout both inequalities. Equality in $|z_0|^k \le 1$ for every $k = 1, \ldots, n$ forces $|z_0| = 1$. Equality in $|w_1 + \cdots + w_n| \le |w_1| + \cdots + |w_n|$ for the nonzero terms $w_k = z_0^k$ forces every w_k to share the argument of $w_1 = z_0$; in particular $\arg(z_0^2) \equiv \arg(z_0) \pmod{2\pi}$, that is $2\arg(z_0) \equiv \arg(z_0)$, so $\arg(z_0) \equiv 0$. Combined with $|z_0| = 1$, this forces $z_0 = 1$, contradicting $z_0 \neq 1$. So no such z_0 exists. □

Hence f_n has no root in the closed unit disc, as required. ■

Layer 1: WHAT

Block 1: multiply by $(z-1)$ to telescope the arithmetic coefficients into $z^n + \cdots + z - n$. Block 2: rule out $z = 1$ directly, needed before dividing the argument by the very factor just introduced. Block 3: bound the telescoped expression's modulus by n using $|z| \le 1$. Block 4: interrogate the equality case of both inequalities and show it forces $z = 1$, already excluded.

The nominal route attempts to bound $f_n(z)$ itself with the reverse triangle inequality; this fails outright, since the resulting lower bound is negative once $n \ge 3$. The bifurcation point is the decision to transform the polynomial, multiplying by $z-1$, before attempting any inequality at all, rather than inequality bashing the given expression as it stands: a coefficient sequence that decreases steadily to a vanishing point is never the shape you bound directly, it is the shape you telescope first.

Layer 2: HOW

Block 1. **Cue.** Coefficients $n, n-1, \ldots, 1$, differing by the constant 1 at every step. **Why natural.** Multiplying by $(z-1)$ and shifting one copy of the series against the other cancels every interior coefficient difference, because that difference is the same constant throughout; a non arithmetic coefficient sequence would not collapse this cleanly. **Link to the next block.** Having a two term expression, $z^n + \cdots + z - n$, in hand is what makes an inequality worth attempting at all; the original n term sum was never tight enough to bound usefully.

Block 2. **Cue.** You are about to divide an equation by the factor $(z-1)$ you just introduced. **Why natural.** Multiplying by $(z-1)$ can manufacture a spurious root at $z=1$ that was never a root of f_n; the only safe way to use the telescoped identity is to check $z=1$ separately first, using $f_n(1)$ directly, an easy positive number. **Link to the next block.** Once $z=1$ is excluded, the implication that $f_n(z_0)=0$ forces $z_0^n+\cdots+z_0=n$ is valid for exactly the values of z_0 still to be ruled out.

Block 3. **Cue.** The hypothesis $|z_0|\le 1$, sitting unused until now. **Why natural.** The triangle inequality converts a sum you cannot evaluate into a bound you can compute, and $|z_0|\le 1$ is exactly what caps each term $|z_0|^k$ at 1, giving the clean bound n. **Link to the next block.** The bound matches the required value n exactly, and an exact match is the signal to look at the equality case rather than declare the matter closed.

Block 4. **Cue.** The chain $n\le n$ is not itself a contradiction, it is an equality, and an equality inside an inequality always encodes extra information. **Why natural.** The triangle inequality is tight only when every term points the same way in the complex plane, and $|z_0|^k=1$ for every k only when $|z_0|=1$; combining both equality conditions pins z_0 down to the single point $z_0=1$. **Link to the next block.** That single point was already excluded, so the chain closes into a contradiction, which is the entire content of the proof.

Layer 3: WHY

The telescoping route is the ideal one because it is the unique single algebraic move that turns a coefficient sequence with constant difference into a sequence with only two nonzero terms; any other single move, differentiating, substituting z by $1/z$, splitting into real and imaginary parts, leaves an n term expression, and the triangle inequality can bound n terms but never bound them tightly, exactly as the naive first approach showed. The discernment mechanism: look at consecutive coefficients, and if their difference is constant, the polynomial is a piece of the derivative of a geometric series, so multiplying by $(z-1)$ or differentiating a geometric sum are the two doors into that structure. Once the expression is down to two terms, the triangle inequality is worth trying, and whenever the bound obtained matches the target value exactly, chase the equality case rather than stop, since an exact match is either the whole proof, if equality turns out to be impossible, or a genuine extra root you have missed. The examiners nudge you here by letting the coefficients run all the way down to 1 rather than stopping early, which is exactly what makes $f_n(1)>0$ a clean, separate fact worth checking before anything else; a coefficient pattern that stopped short would not offer this free exclusion of $z=1$.

Revolving concepts

Polynomials with coefficients in arithmetic progression, and telescoping under multiplication by $z-1$: the general statement, for any sequence c_k, is that $(z-1)\sum c_k z^k$ equals $\sum(c_{k-1}-c_k)z^k$ plus boundary terms, the polynomial analogue of summation by parts. Whenever the difference $c_{k-1}-c_k$ is itself simple, constant, geometric, or otherwise short, the same multiply and telescope move applies, not only to arithmetic sequences. See Book 1, field Polynomials, topic Coefficient transforms.

The triangle inequality for complex numbers and its equality case, all terms sharing a common argument: this orbits every problem where a sum of complex numbers must be bounded and the bound is claimed to be tight or not, and the two sided use here, bounding then interrogating equality, is the standard pattern for such problems. See Book 1, field Inequalities, topic Triangle inequality in the complex plane.

Roots of unity as the roots of $1+z+\cdots+z^n$, the Gauss and Lucas theorem locating the roots of a derivative inside the convex hull of the roots of the original polynomial, coefficient reversal and

reciprocal roots, and the Enestrom and Kakeya theorem for polynomials with monotone positive coefficients. These four facts power the two alternative routes above; the Gauss and Lucas theorem and the Enestrom and Kakeya theorem both sit beyond A level and are flagged as knowledge gaps, the first because it is a genuinely useful, frequently quotable location theorem for the roots of a derivative, the second because it answers exactly this shape of question, monotone positive coefficients, in one line once memorised, and deserves to be installed even though the ideal solution above does not need it. See Book 1, field Complex numbers, topic Root location theorems.

Circuit Bank

- **WHEN** a polynomial's coefficients form an arithmetic progression, or any sequence with a short, simple difference pattern **DO** multiply by $(z-1)$ (or $(1-z)$) and telescope before attempting any inequality **BECAUSE** the shifted subtraction cancels the interior structure of the coefficients and leaves a short expression that an inequality can actually bite on
- **WHEN** you are about to multiply an equation by a factor such as $(z-1)$ to simplify it **DO** check separately, first, whether the value that factor vanishes at is already excluded **BECAUSE** multiplying by a vanishing factor can manufacture roots that were never there, and the simplified identity is only valid once that value is ruled out on its own
- **WHEN** a bound obtained from the triangle inequality exactly matches the target value **DO** do not stop; write down the precise equality condition of every inequality used and solve for what it forces **BECAUSE** an exact match is only a proof once equality is shown impossible, and the only way to know that is to chase the equality case to its end

Backtesting

1. First useful cue: coefficients running down from n to 1 in unit steps, the signature of an arithmetic progression.
2. Method the expression suggested: multiply by $(z-1)$ to telescope, then bound the result with the triangle inequality.
3. Where you would hesitate, and the thought to reinforce: on reaching $|z_0^n + \cdots + z_0| \leq n$ and seeing it match the required value n exactly, when it is tempting to call the bound sufficient; the thought to reinforce is that an exact match means chase the equality case, it is not yet a contradiction.
4. The trap the question sets: multiplying by $(z-1)$ is only valid once $z=1$ has been excluded separately, and it is easy to forget this and treat the telescoped identity as fully equivalent to the original one.
5. What makes you recognise it faster next time: seeing that the reverse triangle inequality applied to the raw, untransformed sum gives a useless negative bound is itself the signal that the polynomial needs transforming before any inequality is worth writing down.
6. The reusable decision rule: whenever consecutive coefficients differ by a constant, or any short and simple pattern, multiply by $(z-1)$ and telescope before reaching for any inequality on the original expression.

Mirror drills

1. Show that $g(z) = 1 + 2z + 3z^2 + \cdots + nz^{n-1}$ has no root with $|z| \leq \frac{n-1}{n+1}$. *Hint:* g is the derivative of $1 + z + \cdots + z^n$; either telescope directly by a shifted subtraction, or reduce to the Gauss and Lucas theorem on the roots of unity, as in the third approach above.

2. For which z with $|z| = 1$ does $1 + z + z^2 + \cdots + z^{n-1}$ attain $\left|1 + z + \cdots + z^{n-1}\right| = n$ exactly? *Answer:* only $z = 1$, by the identical equality case argument used above.

3. Derive the general identity $(z-1)\sum_{k=0}^{n-1} c_k z^k = c_{n-1}z^n - c_0 + \sum_{k=1}^{n-1}(c_{k-1} - c_k)z^k$ for an arbitrary coefficient sequence $c_0, \ldots, c_{n-1}$, and check it reduces to the identity used above when $c_k = n - k$. *Hint:* shift the index in one of the two sums exactly as in the ideal solution, and match coefficients power by power.

8.9 B3. The Power of Two Tower Divisibility Chain

Find all positive integers $n < 10^{100}$ for which, simultaneously, n divides 2^n, $n-1$ divides $2^n - 1$, and $n-2$ divides $2^n - 2$.

Read it out loud

Write the three conditions uniformly as $(n-j) \mid (2^n - j)$ for $j = 0, 1, 2$. Since $(2^n - n) - (2^n - j) = j - n = -(n-j)$, each condition is equivalent to $(n-j) \mid (2^n - n)$. So the question, read out loud, is not three unrelated facts: it is asking for the n such that three consecutive integers, n, $n-1$, $n-2$, all divide the single fixed quantity $2^n - n$. The field wired into this is elementary number theory, factorisation for the condition depending on n alone, and the multiplicative order of 2 for the two that involve arithmetic modulo a shifted value of n.

The first cue, inside thirty seconds: of the three conditions, $n \mid 2^n$ is far more restrictive than the other two, because it is a statement about n's prime factorisation alone, with no exponential arithmetic required. A number dividing a pure power of 2 can itself have no odd prime factor, so $n \mid 2^n$ forces n to be a power of 2 outright. That is the condition to resolve first: always resolve the condition that pins down the unknown's shape before touching a condition that needs arithmetic modulo the unknown.

Once $n = 2^m$, the remaining two conditions both take the shape $2^k - 1$ divides $2^\ell - 1$, governed by exactly one lemma, that the order of 2 modulo $2^k - 1$ is exactly k. That lemma is applied twice, once to pin down m, once more, after cancelling a common factor of 2 from the third condition, to pin down the exponent ℓ with $m = 2^\ell$. The bound $n < 10^{100}$ looks like it wants heavy machinery, but it is arithmetic dressing: one logarithm converts it into a bound on m small enough to finish by listing candidates.

Approaches, ranked worst to best

1. **Search directly for n by trial division.** *Cue:* the bound 10^{100} looks like it invites a computer search. *Circuit:* brute enumeration. Hopeless on its own terms: 10^{100} candidates cannot be tested one at a time, and even a sieve gains nothing without first knowing n must be a power of 2.
2. **Analyse $(n-1) \mid (2^n - 1)$ or $(n-2) \mid (2^n - 2)$ before pinning down the shape of n.** *Cue:* these two look more special, since they subtract 1 and 2. *Circuit:* multiplicative order modulo an arbitrary integer. Technically possible but far harder: the order of 2 modulo a general integer has no clean formula, whereas the order modulo a Mersenne number $2^k - 1$ is exactly k; tackling these first throws away the simplification the first condition supplies for free.
3. **Resolve $n \mid 2^n$ first, then apply the Mersenne order lemma twice, peeling one layer of the power tower at each remaining condition, then convert the bound by a logarithm.** *Cue:* the three conditions are visibly nested in restrictiveness. *Circuit:* power of two factorisation, then the recurring order lemma, then a logarithm estimate. This is the route to take: each step uses the cheapest tool available for that layer, and the recursive self similarity of the three conditions is used explicitly rather than fought.

The ideal solution

Lemma 8.9.1. *A positive integer k divides 2^k if and only if k is a power of 2, including $k = 1 = 2^0$.*

Proof. If $k = 2^r$ then $2^r \mid 2^{2^r}$, since $r \leq 2^r$ for every $r \geq 0$. Conversely, if k has an odd prime factor p, then $p \mid k \mid 2^k$ would force $p \mid 2^k$, impossible, since 2^k has no prime factor other than 2. □

Lemma 8.9.2. *For positive integers k, ℓ, $2^k - 1$ divides $2^\ell - 1$ if and only if k divides ℓ.*

Proof. Write $\ell = qk + r$ with $0 \le r < k$. Modulo $2^k - 1$, $2^k \equiv 1$, so $2^\ell = (2^k)^q 2^r \equiv 2^r$, giving $2^\ell - 1 \equiv 2^r - 1 \pmod{2^k - 1}$. If $k \mid \ell$ then $r = 0$ and $2^\ell - 1 \equiv 0$. Conversely if $2^k - 1 \mid 2^\ell - 1$ then $2^k - 1 \mid 2^r - 1$; but $0 \le 2^r - 1 < 2^k - 1$ since $0 \le r < k$, forcing $2^r - 1 = 0$, that is $r = 0$, that is $k \mid \ell$. □

Now solve the problem. By the power of two lemma applied with $k = n$, the first condition forces $n = 2^m$ for some integer $m \ge 0$. Since $2^{10} > 10^3$, $2^{340} = (2^{10})^{34} > (10^3)^{34} = 10^{102} > 10^{100}$, so $n < 10^{100}$ forces $m < 340$, that is $m \le 339$. The case $m = 0$, that is $n = 1$, already fails the second condition, since $n - 1 = 0$ and 0 divides only 0, while $2^n - 1 = 1 \ne 0$; so in fact $1 \le m \le 339$.

For the second condition, $n - 1 = 2^m - 1$, so the Mersenne order lemma (with $k = m$, $\ell = n = 2^m$) shows $(n - 1) \mid (2^n - 1)$ holds if and only if $m \mid 2^m$, which by the power of two lemma (with $k = m$) holds if and only if m is itself a power of 2. Write $m = 2^p$ for some integer $p \ge 0$.

For the third condition, $n - 2 = 2^m - 2 = 2(2^{m-1} - 1)$ and $2^n - 2 = 2(2^{n-1} - 1)$, both even since $m \ge 1$ makes $n = 2^m$ even; cancelling the common factor 2, $(n - 2) \mid (2^n - 2)$ is equivalent to $(2^{m-1} - 1) \mid (2^{n-1} - 1)$. If $m = 1$ (that is $p = 0$, $n = 2$), this must be checked directly rather than through the lemma, since $m - 1 = 0$: here $n - 2 = 0$ and $2^n - 2 = 2 \ne 0$, so the condition fails, and $p = 0$ is excluded. For $m \ge 2$ (that is $p \ge 1$), the Mersenne order lemma (with $k = m - 1$, $\ell = n - 1 = 2^m - 1$) shows the condition holds if and only if $(m - 1) \mid (2^m - 1)$, that is, since $m = 2^p$, if and only if $(2^p - 1) \mid (2^{2^p} - 1)$. Applying the Mersenne order lemma once more (with $k = p$, $\ell = 2^p$) this holds if and only if $p \mid 2^p$, which by the power of two lemma (with $k = p$) holds if and only if p is itself a power of 2. Write $p = 2^t$ for some integer $t \ge 0$.

So all three conditions together force

$$n = 2^m = 2^{2^p}, \qquad p = 2^t \ge 1.$$

The bound $m \le 339$ becomes $2^p \le 339$; since $2^8 = 256 \le 339 < 512 = 2^9$, this restricts p to the powers of 2 not exceeding 8, namely $p \in \{1, 2, 4, 8\}$ (the next power, $p = 16$, gives $2^{16} = 65536 > 339$). The four resulting values of n are

$$n = 2^{2^1} = 4, \qquad n = 2^{2^2} = 16, \qquad n = 2^{2^4} = 65536, \qquad n = 2^{2^8} = 2^{256}.$$

Each satisfies $n < 10^{100}$: the largest, $2^{256} = (2^{10})^{25} \cdot 2^6 < (10^3)^{25} \cdot 100 = 10^{77} < 10^{100}$. Direct verification confirms each value satisfies all three original conditions: for instance $n = 4$ gives $4 \mid 16$, $3 \mid 15$, $2 \mid 14$; $n = 16$ gives $16 \mid 65536$, $15 \mid 65535$, $14 \mid 65534$; the same chain of reasoning run forward verifies $n = 65536$ and $n = 2^{256}$.

$$\boxed{n \in \{4,\ 16,\ 65536,\ 2^{256}\}}$$

Layer 1: WHAT

Block 1: state and prove that an integer divides a power of 2 exactly when it is itself a power of 2. Block 2: state and prove that $2^k - 1$ divides $2^\ell - 1$ exactly when k divides ℓ. Block 3: apply Block 1 to the first condition, fixing $n = 2^m$, and bound m by a logarithm. Block 4: apply Block 2 then Block 1 to the second condition, fixing $m = 2^p$. Block 5: cancel a factor of 2 in the third condition, then apply Block 2 twice and Block 1, fixing $p = 2^t$. Block 6: intersect with the bound on m to get the finite list $p \in \{1, 2, 4, 8\}$ and the four values of n.

The nominal route analyses $(n - 1) \mid (2^n - 1)$ or $(n - 2) \mid (2^n - 2)$ directly, without first fixing $n = 2^m$, which forces reasoning about the order of 2 modulo an arbitrary integer, a genuinely hard, unstructured problem with no clean formula. The bifurcation point is the decision to resolve $n \mid 2^n$, the condition depending on n alone with no shift, before either of the other two, because it is the tightest, cheapest constraint available.

Layer 2: HOW

Block 1. **Cue.** The condition $n \mid 2^n$. **Why natural.** A number dividing a pure power of 2 can itself carry no other prime factor, so n's entire structure collapses to a single exponent, $n = 2^m$; this is the cheapest possible reduction, using only unique factorisation, before any exponential arithmetic is needed. **Link to the next block.** Having fixed $n = 2^m$, the other two conditions can now be rephrased purely in terms of m.

Block 2. **Cue.** $(n-1) \mid (2^n - 1)$, and $n - 1 = 2^m - 1$ is now a Mersenne type number. **Why natural.** Powers of 2 modulo $2^m - 1$ repeat with period exactly m, since $2^m \equiv 1$ and no smaller positive power can be congruent to 1, so $2^n \equiv 1 \pmod{2^m - 1}$ exactly when $m \mid n$. **Link to the next block.** Since $n = 2^m$, the condition $m \mid n$ becomes $m \mid 2^m$, the same test as Block 1 applied one level down, to m instead of n.

Block 3. **Cue.** $m \mid 2^m$. **Why natural.** This is the Block 1 lemma again, verbatim, with m in the role of n; recognising the repetition saves re-deriving the factorisation argument from scratch. **Link to the next block.** Writing $m = 2^p$ produces a new unknown, p, and the third condition must now be re-expressed in terms of it.

Block 4. **Cue.** $(n-2) \mid (2^n - 2)$, and both sides are visibly even once $m \geq 1$. **Why natural.** Dividing a divisibility statement by a common factor is always legitimate and always worth doing when both sides share one; here it strips the condition to $(2^{m-1} - 1) \mid (2^{n-1} - 1)$, the same Mersenne shape as Block 2, shifted down by one throughout. **Link to the next block.** Applying the Block 2 lemma twice in a row, once relating $m - 1$ and $n - 1$, once more, using $n - 1 = 2^m - 1$ and $m = 2^p$, to relate p and 2^p, forces p itself to be a power of 2, the same test a third time.

Block 5. **Cue.** The bound $n < 10^{100}$, sitting untouched since the problem statement. **Why natural.** An astronomical bound on n is only useful once translated, by one logarithm estimate, into a bound on the much smaller exponent m, since the finite list of candidates actually needed is a list of values of p, not of n. **Link to the next block.** Intersecting $p \in \{1, 2, 4, 8, 16, \ldots\}$ with $2^p \lesssim 339$ leaves exactly four values, and the problem is finished by exhibiting n for each.

Layer 3: WHY

This problem resolves into a clean finite list rather than an intractable search because all three conditions, stripped of their surface differences, are instances of the identical arithmetic fact applied at nested depths: an integer divides a power of 2 exactly when it is itself a power of 2, and a Mersenne number $2^k - 1$ divides another exactly when the exponents are in a divisibility relation, itself the multiplicative cousin of the first fact, since the greatest common divisor of $2^k - 1$ and $2^\ell - 1$ is $2^{\gcd(k,\ell)} - 1$, mirroring $\gcd(k, \ell)$ directly. Once the three given conditions are rewritten in the uniform shifted form $(n - j) \mid (2^n - n)$ for $j = 0, 1, 2$, the recursive self similarity stops being a coincidence: the problem is manufactured by nesting the same test three times, at n, then at the exponent m that test produces, then at the exponent p that test produces again. The discernment mechanism: whenever a family of divisibility conditions involves the same base raised to the same exponent at several shifted moduli, look for the order of that base modulo each modulus, and whenever an integer condition looks like a power of two test, suspect the same test recurring one level down once the previous answer is substituted in. Train this by writing each condition in a uniform shifted form before analysing any of them separately, since the uniform form is what reveals whether conditions are genuinely nested or only superficially similar. The examiners nudge you toward peeling one layer at a time by choosing three conditions of visibly increasing algebraic

distance from n, namely n itself, then $n-1$, then $n-2$, which all but announces that each should be resolved before the next is attempted.

Revolving concepts

Power of two divisibility: an integer k divides 2^k exactly when k is a power of 2. This one fact recurs three times in this problem, at n, then at m, then at p; the recursion to flag is that whenever the same structural test must be satisfied by a value and then by the exponent that value produces, the answer comes out as a power tower, with one level of the tower per recurrence of the test. See Book 1, field Number theory, topic Divisors of powers.

The multiplicative order of 2 modulo a Mersenne number: 2^k-1 divides $2^\ell-1$ exactly when k divides ℓ. The orbiting generalisation is $\gcd(2^k-1, 2^\ell-1) = 2^{\gcd(k,\ell)}-1$, proved by the same division algorithm argument, run to produce a greatest common divisor rather than a yes or no answer; replacing 2 by any integer $a > 1$ gives the same equivalence, a^k-1 divides $a^\ell-1$ exactly when k divides ℓ, and this generalises further to the order of an element in any group where that order is finite. See Book 1, field Number theory, topic Multiplicative order.

Converting an astronomical bound into a bound on an exponent by taking a logarithm: not a theorem so much as a standing habit, whenever a bound is given as $n < 10^K$ and n is known to equal b^m for a fixed base b, take $\log_b$ of both sides to get a bound on m small enough to enumerate; the exact value of K almost never matters beyond fixing how many candidates survive. See Book 1, field Real analysis, topic Logarithmic estimates.

Circuit Bank

- **WHEN** several structural conditions are imposed simultaneously on the same unknown **DO** resolve the condition that pins the unknown's shape down most tightly, using the least machinery, before touching any condition that needs arithmetic modulo the unknown itself **BECAUSE** substituting the resolved shape into the remaining conditions turns them from statements about an arbitrary integer into statements about one new parameter, almost always far easier
- **WHEN** a divisibility statement has the shape 2^k-1 divides $2^\ell-1$, or the same with any fixed base in place of 2 **DO** invoke, or re-derive on the spot, the order lemma: this holds exactly when k divides ℓ **BECAUSE** the powers of the base modulo 2^k-1 cycle with period exactly k, by the division algorithm applied to the exponent
- **WHEN** a divisibility statement's two sides share an obvious common factor **DO** cancel it immediately, before analysing the original, unreduced statement **BECAUSE** ca divides cb exactly when a divides b, for nonzero c, and the reduced statement is always at least as easy, usually revealing the same structure one level down
- **WHEN** a bound is given as an enormous power of ten applied to a quantity already known to be a power of a fixed base **DO** take the logarithm in that base to convert the bound into a small, enumerable bound on the exponent **BECAUSE** the exact numerical bound almost never matters beyond determining how many candidates in a short, structured list survive

Backtesting

1. First useful cue: n divides 2^n is a condition on n alone with no shift, visibly more restrictive than the other two.
2. Method the expression suggested: unique factorisation resolves the first condition instantly; the multiplicative order of 2 modulo a Mersenne number resolves the other two once the first has fixed n's shape.

3. Where you would hesitate, and the thought to reinforce: at the third condition, when $n - 2 = 2^m - 2$ does not immediately look like a Mersenne number; the thought to reinforce is factor out the common power of 2 first, then compare shapes.
4. The trap the question sets: the small cases $n = 1$ and $n = 2$ pass the power of two style test for their own condition but fail the next condition, because zero divides only zero; both must be checked and excluded explicitly, not waved away.
5. What makes you recognise it faster next time: noticing that all three conditions can be rewritten uniformly as $(n - j) \mid (2^n - j)$ for $j = 0, 1, 2$, which announces that the same test must recur at nested depths before a single line of casework is written.
6. The reusable decision rule: when a problem imposes the same kind of condition at several shifted arguments, rewrite all of them in one uniform shape first, resolve the most restrictive instance, and substitute forward; expect the answer to come out as a tower, one layer per condition.

Mirror drills

1. Prove the Mersenne order lemma again from scratch, then use it to find all n with $n \mid 2^n$ and $(n-1) \mid (2^n - 1)$ only, dropping the third condition. *Answer:* exactly $n = 2^{2^p}$ for every integer $p \geq 0$, an infinite family, since only the third condition in the original problem cuts this down further.
2. If $n < 10^{50}$ and n is known to equal 3^m for some integer $m \geq 0$, what is the largest possible value of m? *Hint:* take $\log_3$ of 10^{50}; since $\log_3 10$ is a little above 2.09, $m \leq 104$, the same logarithm to exponent translation used to bound m above.
3. Find all positive integers n with $n \mid 2^n$ and $n \mid 3^n$ simultaneously. *Hint:* the first condition forces n to be a power of 2, the second forces n to be a power of 3; only $n = 1$ can be both, the same resolve the most restrictive shape first circuit applied to two conditions that turn out jointly very restrictive.

8.10 B4. Chebyshev disguise turns Fibonacci angles periodic

Given a real number a, we define a sequence by $x_0 = 1$, $x_1 = x_2 = a$, and

$$x_{n+1} = 2x_n x_{n-1} - x_{n-2} \qquad (n \geq 2).$$

Prove that if $x_n = 0$ for some n, then the sequence is periodic.

Read it out loud

Say the recursion aloud before you write anything: two, times a term, times the term before it, minus the term three places back. Not a sum of multiples of earlier terms, so it is not a linear recursion and no characteristic equation is coming. The only nonlinearity in sight is a single product of two consecutive terms, and it arrives with a factor of 2 bolted to the front. There is exactly one place in your installed mathematics where a doubled product of two things equals a sum of two other things of the same species: the product to sum identity

$$2\cos A \cos B = \cos(A + B) + \cos(A - B).$$

Rearranged, that reads $\cos(A + B) = 2\cos A \cos B - \cos(A - B)$, which is the given recursion with $A + B$, A, B, $A - B$ in the four slots. The factor of 2 is not decoration. It is the examiner's fingerprint.

Now check the initial conditions against that reading. If $x_n = \cos\theta_n$, the recursion demands $\theta_{n+1} = \theta_n + \theta_{n-1}$ and $\theta_{n-2} = \theta_n - \theta_{n-1}$, which is the same statement twice. So $\theta_n = F_n b$ for a Fibonacci-type sequence F_n and a single free angle b. Test it: $x_0 = 1$ wants $\theta_0 = 0$, so $F_0 = 0$; $x_1 = x_2 = a$ wants $\theta_1 = \theta_2$, so $F_1 = F_2$. That is precisely the standard Fibonacci sequence $0, 1, 1, 2, 3, 5, \ldots$. The problem has handed you $x_0 = 1$ and the doubled equality $x_1 = x_2$ for no reason other than to make the Fibonacci indexing come out exactly right. Two given values, two confirmations.

The fields wired into this problem: sequences and recurrences (a nonlinear recursion linearised by a change of coordinates), trigonometry and Chebyshev polynomials (the linearising map), and number theory (the Pisano period, that is, the Fibonacci sequence read modulo an integer). The word *periodic* in the conclusion is the number theory cue: real sequences are almost never periodic by accident, so periodicity has to come from a finite state space somewhere, and the only finite object in this problem will be $\mathbb{Z}/d\mathbb{Z}$.

Within thirty seconds you should have written on your paper: $2\cos A \cos B = \cos(A + B) + \cos(A - B)$; the guess $x_n = \cos(F_n b)$ with $a = \cos b$; and the caveat that $a = \cos b$ needs $|a| \leq 1$, so the case $|a| > 1$ must be disposed of separately. That caveat is the only real bookkeeping in the whole problem, and candidates who forget it lose points for an incomplete case analysis rather than for missing the idea.

Approaches, ranked worst to best

1. **Polynomial brute force.** *Cue:* every x_n is a polynomial in a, so compute them. *Circuit:* expand and hunt for a pattern. This is the zombie route. You get $x_3 = 2a^2 - 1$, $x_4 = 4a^3 - 3a$, $x_5 = 16a^5 - 20a^3 + 5a$, and then x_6 has degree 8, x_7 degree 13: the degrees are the Fibonacci numbers, so the ink cost grows exponentially and you never reach a general statement. It ranks last as a plan, but notice that it is not worthless as a diagnostic: those three polynomials are T_2, T_3 and T_5, the Chebyshev polynomials, and recognising them hands you the same substitution the fast route gets for free. Brute force here is the slow road to the correct cue.

2. **Pigeonhole on the state vector.** *Cue:* "periodic" means finitely many states. *Circuit:* state plus finiteness gives eventual periodicity. The recursion is a map on triples, $(x_{n-2}, x_{n-1}, x_n) \mapsto (x_{n-1}, x_n, 2x_n x_{n-1} - x_{n-2})$, so if the triples lived in a finite set you would be done. They do

not; they live in $\mathbb{R}^3$. This route stalls immediately because you have no boundedness and, even with boundedness, no finiteness. It ranks above brute force only because the instinct is correct: periodicity will come from a finite set, and your job is to find which one.

3. **Conserved cubic.** *Cue:* a three term nonlinear recursion of Markov type usually hides an invariant. *Circuit:* look for a symmetric function of consecutive terms that the map preserves. Set $I_n = x_{n-1}^2 + x_n^2 + x_{n+1}^2 - 2x_{n-1}x_nx_{n+1}$. Substituting $x_{n+2} = 2x_{n+1}x_n - x_{n-1}$ gives

$$x_{n+2}^2 - 2x_nx_{n+1}x_{n+2} = x_{n+2}\left(x_{n+2} - 2x_nx_{n+1}\right) = -x_{n-1}x_{n+2} = x_{n-1}^2 - 2x_{n-1}x_nx_{n+1},$$

so $I_{n+1} = I_n$, and $I_1 = 1 + a^2 + a^2 - 2a^2 = 1$. Thus $x_{n-1}^2 + x_n^2 + x_{n+1}^2 - 2x_{n-1}x_nx_{n+1} = 1$ always. This is correct, it is the Cayley cubic surface, and it is the algebraic shadow of the identity $\cos^2 A + \cos^2 B + \cos^2(A+B) - 2\cos A\cos B\cos(A+B) = 1$. It ranks third because it proves the right kind of rigidity but not the conclusion: an invariant confines the orbit to a surface, and a surface is not a finite set. Keep it in your pocket as confirmation that the cosine parametrisation is the truth and not a guess.

4. **Trace coordinates in SL_2.** *Cue:* the conserved cubic is a Fricke trace identity. *Circuit:* model x_n as half the trace of a word in two matrices. Every relation above is the shadow of $\mathrm{tr}(MN) + \mathrm{tr}(MN^{-1}) = \mathrm{tr}(M)\mathrm{tr}(N)$ for $M, N \in SL_2$. Correct, general, and far heavier machinery than a competition answer needs. Ranked fourth: right church, wrong pew.

5. **Cosine parametrisation with Fibonacci angles.** *Cue:* $2\times$ product minus a third term, plus $x_0 = 1$ and $x_1 = x_2$. *Circuit:* product to sum linearises the recursion, turning multiplication of values into addition of angles. Best. It converts the nonlinear recursion into $\theta_{n+1} = \theta_n + \theta_{n-1}$, converts the hypothesis $x_N = 0$ into the statement that b is a rational multiple of 2π, and converts periodicity of (x_n) into periodicity of $(F_n \bmod d)$, which is free because a bijection of a finite set has purely periodic orbits. Every hypothesis in the problem gets used exactly once.

The ideal solution

Step 1: the case $|a| > 1$ never has a zero term. We claim $1 = |x_0| \le |x_1| \le |x_2| \le \cdots$. The first two inequalities hold because $|x_1| = |x_2| = |a| > 1 = |x_0|$. Suppose $n \ge 2$ and $1 = |x_0| \le |x_1| \le \cdots \le |x_n|$. Then, using $|x_{n-2}| \le |x_n|$ and $|x_{n-1}| \ge 1$,

$$|x_{n+1}| = |2x_nx_{n-1} - x_{n-2}| \ge 2|x_n||x_{n-1}| - |x_{n-2}| \ge 2|x_n||x_{n-1}| - |x_n| = |x_n|\left(2|x_{n-1}| - 1\right) \ge |x_n|.$$

By induction $|x_n| \ge 1$ for every n, so $x_n \ne 0$ for every n and the hypothesis of the problem is never satisfied. The implication we must prove is therefore vacuously true when $|a| > 1$, and we may assume $|a| \le 1$ from here on.

Step 2: parametrise. Since $|a| \le 1$ there is $b \in [0, \pi]$ with $a = \cos b$. Let $F_0 = 0$, $F_1 = F_2 = 1$ and $F_{n+1} = F_n + F_{n-1}$ for $n \ge 1$ be the Fibonacci numbers.

Claim 8.10.1. *$x_n = \cos(F_n b)$ for every $n \ge 0$.*

Proof. For $n = 0$, $\cos(F_0 b) = \cos 0 = 1 = x_0$; for $n = 1, 2$, $\cos(F_n b) = \cos b = a = x_n$. Let $m \ge 2$ and suppose the formula holds for all indices up to m. Since $m \ge 2$ we have $F_m - F_{m-1} = F_{m-2}$ and $F_m + F_{m-1} = F_{m+1}$, so

$$2x_mx_{m-1} = 2\cos(F_m b)\cos(F_{m-1}b) = \cos((F_m - F_{m-1})b) + \cos((F_m + F_{m-1})b) = \cos(F_{m-2}b) + \cos(F_{m+1}b).$$

Hence $x_{m+1} = 2x_mx_{m-1} - x_{m-2} = \cos(F_{m+1}b)$, which closes the induction. □

Step 3: turn the hypothesis into rationality. Suppose $x_N = 0$ for some N. Since $x_0 = 1$ we have $N \ge 1$, so $F_N \ge 1$. From $\cos(F_N b) = 0$ we get $F_N b = \frac{(2j+1)\pi}{2}$ for some integer $j \ge 0$, hence

$$b = \frac{c}{d}(2\pi), \qquad c = 2j + 1 \in \mathbb{Z}, \quad d = 4F_N \in \mathbb{Z}_{>0}.$$

This is the only place the hypothesis is used, and it is used to buy one thing: an integer denominator d.

Step 4: the terms depend only on F_n modulo d. If $F_m \equiv F_n \pmod d$ then $\frac{cF_m}{d} - \frac{cF_n}{d} = c \cdot \frac{F_m - F_n}{d}$ is an integer, so

$$x_m = \cos\left(\frac{cF_m}{d}\,2\pi\right) = \cos\left(\frac{cF_n}{d}\,2\pi\right) = x_n.$$

Step 5: Fibonacci modulo d is purely periodic. Work in the finite set $(\mathbb{Z}/d\mathbb{Z})^2$ and let $v_n = (F_n, F_{n+1}) \bmod d$. Then $v_{n+1} = T(v_n)$ where $T(u,v) = (v, u+v)$. The map T is a bijection of $(\mathbb{Z}/d\mathbb{Z})^2$, with inverse $T^{-1}(u,v) = (v-u, u)$. Since $(\mathbb{Z}/d\mathbb{Z})^2$ is finite, the sequence $v_0, v_1, v_2, \ldots$ must repeat a value, say $v_{n_1} = v_{n_2}$ with $n_1 < n_2$; applying T^{-1} exactly n_1 times gives $v_0 = v_\ell$ where $\ell = n_2 - n_1 \geq 1$. Applying T repeatedly then gives $v_{n+\ell} = v_n$ for all $n \geq 0$, so in particular

$$F_{n+\ell} \equiv F_n \pmod d \qquad (n \geq 0).$$

Step 6: conclude. By Steps 4 and 5, $x_{n+\ell} = x_n$ for every $n \geq 0$ with $\ell \geq 1$ fixed. The sequence is periodic. ■

The invertibility of T in Step 5 is not a formality. Without it you would only get *eventual* periodicity, and the problem asks for periodicity of the sequence, meaning from the start. State it.

Layer 1: WHAT

Block 1. Split on $|a| > 1$ against $|a| \leq 1$, because the parametrisation you are about to use only exists in the second case.

Block 2. Kill $|a| > 1$ by proving $|x_n|$ is nondecreasing and starts at 1: the hypothesis $x_n = 0$ is then never met.

Block 3. Write $a = \cos b$ and guess $x_n = \cos(F_n b)$, forced by the shape $2 \cdot (\text{product}) - (\text{third term})$.

Block 4. Verify the guess by induction, using $F_m - F_{m-1} = F_{m-2}$ to make the product to sum identity land on the right indices.

Block 5. Convert $x_N = 0$ into $b/(2\pi) = c/d$ with $d = 4F_N$ an integer.

Block 6. Observe x_n depends only on F_n mod d.

Block 7. Fibonacci modulo d is purely periodic because the shift is a bijection of a finite set. Done.

The nominal route runs Block 1, then expands $x_3, x_4, x_5, \ldots$ as polynomials in a, then tries to solve $x_N(a) = 0$ for a and check periodicity for each root. It dies at the moment the degrees start growing like F_n: a general argument is impossible from there because you would need to control the roots of infinitely many polynomials of unbounded degree.

The bifurcation point is one line: the line where you look at $2x_n x_{n-1} - x_{n-2}$ and decide whether it is an instruction to multiply out or a name for an identity you already own. Everything downstream is determined by that decision.

Layer 2: HOW

Block 1. Cue. The substitution you are reaching for is $a = \cos b$, and cosine has range $[-1, 1]$. **Why natural.** You never start a case split for its own sake. You start it because the tool you have chosen has a domain, and you must check the input lies in it. Naming the excluded case first, before you use the tool, is what stops a grader writing "incomplete" on an otherwise perfect script. **Link to the next block.** Having isolated $|a| > 1$, you now need to kill it, and killing it means showing no term can be zero.

Block 2. **Cue.** You must prove a term is never 0, that is, bounded away from 0. The natural quantity is $|x_n|$, and the recursion has $2x_nx_{n-1}$ in it, a product of two things you are already trying to bound below. **Why natural.** If all previous $|x_k| \geq 1$, then the product term $2|x_n||x_{n-1}|$ is at least twice the size of either factor, and the triangle inequality lets the subtracted $|x_{n-2}|$ eat at most one copy of $|x_n|$. So growth beats subtraction, with the exact bookkeeping $2|x_n||x_{n-1}| - |x_n| = |x_n|(2|x_{n-1}| - 1) \geq |x_n|$. Notice that the induction hypothesis has to be the whole chain $|x_0| \leq \cdots \leq |x_n|$, not just the last inequality, because you use $|x_{n-2}| \leq |x_n|$ and $|x_{n-1}| \geq 1$ at the same time. Strong induction, not ordinary induction. **Link to the next block.** With that case closed, $|a| \leq 1$ is now a standing assumption and the substitution is legal.

Block 3. **Cue.** Doubled product of two consecutive terms, minus one earlier term. Plus $x_0 = 1$ and $x_1 = x_2$. **Why natural.** This is the definition-level reason and it is worth saying exactly: cos is the real part of the character $\theta \mapsto e^{i\theta}$, so multiplying two cosines mixes the sum and the difference of the angles, and $2\cos A \cos B = \cos(A+B) + \cos(A-B)$ is nothing more than $\frac{1}{2}(e^{iA} + e^{-iA})(e^{iB} + e^{-iB})$ expanded. A recursion that says "value at index $n+1$ equals twice the product of the values at n and $n-1$, minus the value at $n-2$" is therefore an instruction that the indices behave additively: $\theta_{n+1} = \theta_n + \theta_{n-1}$ and $\theta_{n-2} = \theta_n - \theta_{n-1}$. Those two conditions are the same condition, which is why the guess is consistent rather than overdetermined. The initial data then pins the angle sequence to $F_n b$. **Link to the next block.** Once the guess exists, verification is a routine induction, and you should do it explicitly because the index arithmetic is where errors hide.

Block 4. **Cue.** An explicit formula proposed for all n, with a three term recursion behind it. **Why natural.** The induction needs $F_m - F_{m-1} = F_{m-2}$, which requires $m \geq 2$, exactly the range in which the recursion is given. That alignment is a sanity check on your indexing: if the given recursion had started at $n \geq 3$ you would have a different Fibonacci offset. Check the three base cases $n = 0, 1, 2$ separately; do not wave at them. **Link to the next block.** Now the sequence is completely understood as a function of one real number b, and the hypothesis can be translated.

Block 5. **Cue.** $x_N = 0$ means $\cos(\text{something}) = 0$. **Why natural.** Zeros of cosine are the half-odd multiples of π. That is a rigidity statement: an equation of the form $\cos\theta = 0$ does not merely constrain θ, it forces θ/π to be a half-odd-integer, hence forces θ to be a rational multiple of π. Rational means there is a denominator, and a denominator is an integer, and an integer is the finiteness you needed in Block 7. This is the whole reason the problem gives you a vanishing term rather than, say, a bounded sequence. **Link to the next block.** The denominator $d = 4F_N$ is the finite modulus. Now push everything into $\mathbb{Z}/d\mathbb{Z}$.

Block 6. **Cue.** $x_n = \cos(2\pi c F_n/d)$ and cosine has period 2π. **Why natural.** The value only depends on cF_n/d modulo 1, hence only on F_n modulo d. In other words, the map "integer $\mapsto$ term" factors through $\mathbb{Z}/d\mathbb{Z}$. Factoring an infinite index set through a finite quotient is the standard way to manufacture periodicity, and you should recognise it as the same manoeuvre as proving that decimal expansions of rationals recur. **Link to the next block.** All that is left is periodicity of Fibonacci modulo d.

Block 7. **Cue.** A sequence in a finite set defined by a fixed one-step rule on pairs. **Why natural.** Two facts, both needed. Finiteness gives a repeat by pigeonhole. Invertibility of the shift $T(u,v) = (v, u+v)$, whose inverse is $(u,v) \mapsto (v-u, u)$, upgrades that repeat from "eventually periodic" to "purely periodic", which is what lets you claim $x_{n+\ell} = x_n$ for all $n \geq 0$ including $n = 0$. The determinant of T as a matrix over $\mathbb{Z}/d\mathbb{Z}$ is -1, a unit, which is the structural reason invertibility holds for every modulus. **Link to the next block.** Combine with Block 6 and the proof closes.

Layer 3: WHY

The mathematical truth under this problem is that the recursion is an addition law written in a bad chart. On the circle, angles add. The function cos is a two-to-one chart from the circle to the interval $[-1, 1]$, and when you push the addition law through that chart it stops looking like addition and starts looking like $2xy - z$. Every "nonlinear recursion with a mysterious pattern" of this family is the same phenomenon: $x_{n+1} = 2x_n x_{n-1} - x_{n-2}$, $x_{n+1} = x_n^2 - 2$, $x_{n+1} = 2x_n x_{n-1} - x_{n-1}$ and their cousins are all the group law $\theta \mapsto \theta + \varphi$ in disguise. So the correct instinct on seeing such a recursion is not "find a pattern" but "find the chart".

Which chart? The functions f satisfying $f(A+B) + f(A-B) = 2f(A)f(B)$ for all real A, B are exactly $f = \cos(\lambda\cdot)$, $f = \cosh(\lambda\cdot)$, the constant $f \equiv 1$ and the degenerate $f \equiv 0$. That is d'Alembert's functional equation, and it explains both halves of the case analysis at once: for $|a| \le 1$ the chart is cos, and for $|a| > 1$ it is cosh, since $2\cosh A \cosh B = \cosh(A+B) + \cosh(A-B)$ is the same identity. Indeed, with $a = \varepsilon \cosh t$ and $\varepsilon = \pm 1$ you can check that $x_n = \varepsilon^{F_n} \cosh(F_n t)$, so $|x_n| = \cosh(F_n t) \ge 1$. That is the conceptual version of Step 1, and it is worth knowing even though the three line induction is faster to write in the arena. The lesson is that the case split is not an annoyance bolted onto the problem; it is the two branches of the same parametrisation, separated by whether the group is compact.

The discernment mechanism, stated so you can train it: count the nonlinearity and count the degrees of freedom. Here the nonlinearity is a single bilinear term with a coefficient of exactly 2, and there is exactly one free parameter a in the whole problem. One parameter means the answer is a one-parameter family, and one-parameter families that satisfy quadratic addition rules are trigonometric or hyperbolic. If the coefficient had been 3 instead of 2, no identity would fit and you would be in a different problem entirely. So read coefficients as fingerprints, not as noise.

The examiners nudged in three places, and you should be able to name all three after the fact. First, $x_0 = 1$, which is $\cos 0$ and pins $F_0 = 0$. Second, $x_1 = x_2$, which pins $F_1 = F_2$ and is otherwise a strange thing to impose. Third, the conclusion says *periodic*, not *bounded* or *eventually periodic*, and a real sequence is periodic only when it factors through something finite, which tells you in advance that an integer modulus is coming. Three nudges, one method.

Training protocol. Take ten nonlinear recursions with small integer coefficients, compute four terms of each as polynomials in the seed, and try to identify the polynomial family: Chebyshev T_n, Chebyshev U_n, Fibonacci-like, or none. You are not training the algebra, you are training the recognition that $2a^2 - 1$ and $4a^3 - 3a$ are not random cubics but T_2 and T_3. Recognition of small named polynomials is a memory task, and memory tasks are the cheap part of the Putnam.

Revolving concepts

Chebyshev polynomials. T_n is defined by $T_n(\cos\theta) = \cos(n\theta)$, equivalently by $T_0 = 1$, $T_1 = x$, $T_{n+1} = 2xT_n - T_{n-1}$. The orbiting identities are $T_m T_n = \frac{1}{2}(T_{m+n} + T_{|m-n|})$ and $T_m \circ T_n = T_{mn}$. In this problem $x_n = T_{F_n}(a)$, which is why the computed terms were T_2, T_3, T_5. Learn the first five by sight: 1, x, $2x^2 - 1$, $4x^3 - 3x$, $8x^4 - 8x^2 + 1$, $16x^5 - 20x^3 + 5x$. See Book 1, field: Polynomials, topic: Chebyshev families.

d'Alembert's functional equation. The equation $f(A+B) + f(A-B) = 2f(A)f(B)$ with f continuous and not identically zero has solutions $\cos(\lambda x)$, $\cosh(\lambda x)$ and 1. This is the theorem that turns "I guessed cosine" into "cosine is forced". See Book 1, field: Functional equations, topic: cosine functional equation.

The generalised recursion, and how to solve any member of the family. Suppose a sequence satisfies $x_{n+1} = 2x_n x_{n-1} - x_{n-2}$ with $x_0 = 1$. Then $x_n = f(\theta_n)$ where f solves d'Alembert and θ satisfies the *linear* recursion $\theta_{n+1} = \theta_n + \theta_{n-1}$. That is the general principle and it is worth stating in full generality, because it applies to every recursion in this family:

(1) Detect the shape $x_{n+1} = 2x_n x_{n-k} - x_{n-2k}$ or similar, in which the four index positions satisfy

$p + q = r + s$ in the sense that the outer pair sums to the inner pair.

(2) Substitute $x_n = \cos\theta_n$; the recursion becomes the linear recursion on angles obtained by reading the index arithmetic.

(3) Solve the linear recursion by its characteristic equation. For $\theta_{n+1} = \theta_n + \theta_{n-1}$ the solution is $\theta_n = F_n\theta_1 + F_{n-1}\theta_0$, and with $\theta_0 = 0$ this is $\theta_n = F_n b$. For $\theta_{n+1} = 2\theta_n$ (which is the recursion $x_{n+1} = 2x_n^2 - 1$) it is $\theta_n = 2^n b$.

(4) A term vanishes if and only if the corresponding angle is an odd multiple of $\pi/2$, which forces b to be a rational multiple of 2π with a computable denominator d.

(5) Periodicity of (x_n) then reduces to periodicity of the integer sequence (θ_n/b) modulo d. For a linear recursion with integer coefficients and invertible transfer matrix over $\mathbb{Z}/d\mathbb{Z}$, that periodicity is automatic and pure. For Fibonacci the transfer matrix is $\begin{pmatrix} 0 & 1 \\ 1 & 1 \end{pmatrix}$ with determinant -1, a unit modulo every d.

Pisano period. The Fibonacci sequence modulo m is purely periodic; its period $\pi(m)$ is the Pisano period. Facts worth carrying: $\pi(2) = 3$, $\pi(4) = 6$, $\pi(8) = 12$, $\pi(10) = 60$; $\pi(\mathrm{lcm}(m, n)) = \mathrm{lcm}(\pi(m), \pi(n))$ for coprime m, n; and $\pi(m) \leq 6m$ always. You never need the exact value on a Putnam, only that it exists and is finite. See Book 1, field: Number theory, topic: linear recurrences modulo m.

The conserved cubic. $x_{n-1}^2 + x_n^2 + x_{n+1}^2 - 2x_{n-1}x_n x_{n+1} = 1$ for this sequence. Recognise the surface $x^2 + y^2 + z^2 - 2xyz = 1$: it is the Cayley cubic, the character variety of the free group on two generators mapped to SL_2, and the identity $\cos^2 A + \cos^2 B + \cos^2(A + B) - 2\cos A \cos B \cos(A + B) = 1$ is its trigonometric parametrisation. The Markov equation $x^2 + y^2 + z^2 = 3xyz$ is its close relative and the "Vieta jumping" technique lives on the same idea: a quadratic in one variable with the other two fixed has two roots, and the map swapping them is an involution on solutions. See Book 1, field: Number theory, topic: Vieta jumping and Markov triples.

Pure versus eventual periodicity. A sequence produced by iterating a map T on a finite set is always eventually periodic; it is purely periodic if and only if the starting state lies in a cycle, which is guaranteed when T is a bijection. This distinction is worth points on the Putnam more often than it looks. See Book 1, field: Discrete structures and graphs, topic: functional graphs, rho shape and cycles.

Circuit Bank

- **WHEN** a recursion containing $2\,x_n x_{n-1}$ minus an earlier term **DO** substitute $x_n = \cos\theta_n$ and read off the linear recursion on the angles **BECAUSE** $2\cos A \cos B = \cos(A + B) + \cos(A - B)$ is the only identity in which a doubled product of two values equals a sum of two values of the same function, so the coefficient 2 identifies the chart
- **WHEN** the substitution you want has a restricted domain, such as cos needing $|a| \leq 1$ **DO** open with the excluded case and dispose of it before using the substitution **BECAUSE** a solution that silently assumes its parametrisation exists is incomplete, and the excluded case is usually the easy one: here $|a| > 1$ gives a growth induction in three lines
- **WHEN** a hypothesis of the form "some term equals zero" applied to a trigonometric parametrisation **DO** convert it into "the angle is a rational multiple of π" and extract the integer denominator **BECAUSE** zeros of cos are rigid, at odd multiples of $\pi/2$, so vanishing is a rationality statement, and rationality is where the finite modulus comes from
- **WHEN** you need periodicity of a real sequence **DO** find a finite set the sequence factors through, then use pigeonhole on a bijection **BECAUSE** real sequences are never periodic by accident; the periodicity must be inherited from a finite quotient such as $\mathbb{Z}/d\mathbb{Z}$
- **WHEN** pigeonhole gives you a repeated state **DO** check whether the step map is invertible

before claiming pure periodicity **BECAUSE** a noninvertible map gives a rho shaped orbit with a tail, so you would only earn eventual periodicity, and the question asked for periodicity from the start

Backtesting

1. First useful cue: the coefficient 2 in front of the product $x_n x_{n-1}$, reinforced by $x_0 = 1$ and $x_1 = x_2$. Those three data points say cosine, Fibonacci indexing, and nothing else.
2. Method the expression suggested: linearise by parametrisation. Replace values by angles so that a quadratic recursion becomes an additive one, then do all the work on the angles.
3. Where you would hesitate, and the thought to reinforce: at the end, after proving $x_n = \cos(F_n b)$, it is tempting to say "and clearly the sequence repeats". It does not clearly repeat; b is a general real number and $(F_n b \bmod 2\pi)$ is equidistributed for almost every b. The hypothesis $x_N = 0$ is what forces b into the rational multiples of 2π. Reinforce the thought: *use every hypothesis, and if a hypothesis has not been used yet, that is where the remaining difficulty lives*.
4. The trap the question sets: two traps. Forgetting that $a = \cos b$ requires $|a| \leq 1$, which costs a case; and claiming eventual periodicity when the question asked for periodicity, which costs the invertibility sentence in Step 5.
5. What makes you recognise it faster next time: memorise the first six Chebyshev polynomials by sight. If $x_3 = 2a^2 - 1$ appears on your page and you do not immediately think $\cos 2b$, you have already lost ten minutes.
6. The reusable decision rule: when a nonlinear recursion has a doubled product and small integer coefficients, look for a one-parameter group whose addition law it encodes, and do the whole problem on the parameter, not on the values.

Mirror drills

1. Let $y_0 = a$ and $y_{n+1} = y_n^2 - 2$. Find a closed form and describe when the sequence is periodic. *Answer:* write $a = t + t^{-1}$ (allowing $|t| = 1$ exactly when $|a| \leq 2$); then $y_n = t^{2^n} + t^{-2^n}$. With $t = e^{i\theta}$, $y_n = 2\cos(2^n\theta)$, periodic exactly when $\theta/2\pi$ is rational with odd denominator times a power of two handled by the doubling map.
2. Prove that $x_{n-1}^2 + x_n^2 + x_{n+1}^2 - 2x_{n-1}x_n x_{n+1}$ is constant for the sequence of this problem, without using the cosine formula. *Answer:* substitute $x_{n+2} = 2x_{n+1}x_n - x_{n-1}$ into the expression at index $n+1$ and factor $x_{n+2}(x_{n+2} - 2x_n x_{n+1}) = -x_{n-1}x_{n+2}$; the expression collapses to its value at index n.
3. Show that the Fibonacci sequence modulo m is purely periodic for every $m \geq 1$, and compute the period for $m = 8$. *Answer:* the pair map $(u, v) \mapsto (v, u + v)$ has matrix of determinant -1, hence is invertible modulo m, so orbits are pure cycles. Modulo 8 the sequence runs $0, 1, 1, 2, 3, 5, 0, 5, 5, 2, 7, 1$ and then repeats, so the period is 12.

8.11 B5. Symmetrised Jacobian forces global injectivity

Let $f = (f_1, f_2)$ be a function from $\mathbb{R}^2$ to $\mathbb{R}^2$ with continuous partial derivatives $\frac{\partial f_i}{\partial x_j}$ that are positive everywhere. Suppose that

$$\frac{\partial f_1}{\partial x_1}\frac{\partial f_2}{\partial x_2} - \frac{1}{4}\left(\frac{\partial f_1}{\partial x_2} + \frac{\partial f_2}{\partial x_1}\right)^2 > 0$$

everywhere. Prove that f is one-to-one.

Read it out loud

A map from the plane to the plane, continuously differentiable, all four partial derivatives positive, and one extra inequality. Prove it is injective. Injectivity is a global statement about two arbitrary points, so before anything else write down what you are actually going to prove: for all $p \neq q$ in $\mathbb{R}^2$, $f(p) \neq f(q)$. Write the two points down as symbols now, because the entire solution is going to be built on the segment between them.

Now read the extra inequality out loud, slowly. It says: (entry 11) times (entry 22), minus the square of the *average* of entries 12 and 21. Abbreviate $f_{ij} = \partial f_i/\partial x_j$ and put the Jacobian on the page:

$$Df = \begin{pmatrix} f_{11} & f_{12} \\ f_{21} & f_{22} \end{pmatrix}, \qquad S := \tfrac{1}{2}\left(Df + (Df)^{\mathsf{T}}\right) = \begin{pmatrix} f_{11} & \frac{f_{12}+f_{21}}{2} \\ \frac{f_{12}+f_{21}}{2} & f_{22} \end{pmatrix}.$$

The hypothesis is exactly $\det S > 0$. It is not $\det Df > 0$, which would be $f_{11}f_{22} - f_{12}f_{21}$, and the difference between those two expressions is the whole problem. The examiners went out of their way to write $\frac{1}{4}(f_{12} + f_{21})^2$ rather than $f_{12}f_{21}$, which is a strictly larger quantity by $\frac{1}{4}(f_{12} - f_{21})^2 \geq 0$, so the hypothesis you are given is strictly stronger than positivity of the Jacobian determinant. When an examiner hands you a hypothesis that is deliberately stronger than the obvious one, the extra strength is load bearing, and your job is to find the argument that uses it.

Together with $f_{11} > 0$, the condition $\det S > 0$ says that S is positive definite (Sylvester's criterion: leading principal minors positive). Positive definiteness of the symmetric part of Df is a named condition: it says f is a *strictly monotone* map, the multivariable analogue of "has positive derivative". In one variable, positive derivative gives strictly increasing gives injective, and the middle step is the mean value theorem. So the shape of the solution is fixed before you have done any work: manufacture a function of one real variable whose derivative is $v^{\mathsf{T}}Sv$, and apply one-variable calculus to it.

Fields wired in: multivariable differential calculus (chain rule along a path, and the fact that continuous partials imply total differentiability), quadratic forms and definiteness from linear algebra, and the theory of monotone operators, which is the correct general home for this statement. What is really being tested is whether you know that local information does not become global information for free. Within thirty seconds you should have written Df, its symmetric part S, the remark that the hypothesis is $\det S > 0$ with $f_{11} > 0$ hence S positive definite, and the two arbitrary points p and q.

Approaches, ranked worst to best

1. **Coordinates and elimination.** *Cue:* $f(p) = f(q)$ is two equations, so try to solve them. *Circuit:* set up simultaneous equations and eliminate. There are no formulas for f_1 and f_2; only their derivatives are constrained. Nothing can be eliminated. Ranked last because it does not even start.

2. **Inverse function theorem.** *Cue:* positive partials, positive determinant, smooth map. *Circuit:* Jacobian nonsingular gives a local diffeomorphism. This one is dangerous, because it is true

and it feels like a solution. Since $\frac{1}{4}(f_{12}+f_{21})^2 \geq f_{12}f_{21}$ by the arithmetic mean and geometric mean inequality applied to the two positive numbers f_{12} and f_{21}, the hypothesis gives

$$\det Df = f_{11}f_{22} - f_{12}f_{21} \geq f_{11}f_{22} - \tfrac{1}{4}(f_{12}+f_{21})^2 > 0,$$

so f is a local diffeomorphism at every point. That establishes *local* injectivity and stops. It does not imply global injectivity, and the standard counterexample is one you must have loaded: $F(x,y) = (e^x \cos y, e^x \sin y)$, the complex exponential, has $\det DF = e^{2x} > 0$ everywhere and satisfies $F(x, y+2\pi) = F(x,y)$. A script that says "the Jacobian is nonzero, hence f is injective" scores zero. Ranked second precisely so that you can see the trap and step over it.

3. **Monotonicity in each variable separately.** *Cue:* all four partials are positive, so each f_i is increasing in each argument. *Circuit:* use the one-variable mean value theorem coordinate by coordinate. Suppose $f(p) = f(q)$ with $v = q - p \neq 0$. If $v_1 \geq 0$ and $v_2 \geq 0$, then moving from p to q increases x_1 weakly, increases x_2 weakly, and at least one strictly, so $f_1(q) > f_1(p)$: contradiction. The same argument with signs reversed handles $v_1 \leq 0$, $v_2 \leq 0$. So the only surviving case is v_1 and v_2 strictly of opposite sign. This is a genuine reduction and it earns partial credit, and more importantly it tells you what the strange hypothesis is for: it exists to handle the mixed directions, where the increase in one coordinate fights the decrease in the other. Ranked third because it is correct but incomplete, and the completion turns out to subsume it.

4. **Convexity via a potential.** *Cue:* positive definite symmetric matrix of second derivatives is a Hessian condition. *Circuit:* if $f = \nabla\varphi$ with φ strictly convex then f is injective. If Df happened to be symmetric, then f would be the gradient of some φ with positive definite Hessian, so φ would be strictly convex and $\nabla\varphi$ injective. Here Df need not be symmetric, so this does not apply directly; but it is the right picture, and the proof of "gradient of a strictly convex function is injective" is exactly the proof we want, with the potential deleted. Ranked fourth: correct instinct, needs an unavailable hypothesis.

5. **Strict monotonicity along the joining segment.** *Cue:* a global conclusion about two arbitrary points, plus a hypothesis that is a quadratic form. *Circuit:* pair the difference of images with the difference of points and differentiate along the straight path. Best. Define $g(t) = v \cdot f(p + tv)$ with $v = q - p$. Then $g'(t) = v^{\mathsf{T}} Df\, v = v^{\mathsf{T}} S v > 0$, so $g(1) > g(0)$, so $v \cdot f(q) \neq v \cdot f(p)$, so $f(q) \neq f(p)$. Every hypothesis is used, nothing is wasted, and the argument is five lines. It also generalises verbatim to $\mathbb{R}^n$.

The ideal solution

Throughout write $f_{ij} = \partial f_i / \partial x_j$, and for a point $p \in \mathbb{R}^2$ and a vector $v = (v_1, v_2)$ set

$$Q_p(v) = f_{11}(p)\, v_1^2 + \big(f_{12}(p) + f_{21}(p)\big)\, v_1 v_2 + f_{22}(p)\, v_2^2.$$

Lemma 8.11.1. *For every $p \in \mathbb{R}^2$ and every $v \neq 0$ we have $Q_p(v) > 0$.*

Proof. Fix p and abbreviate $A = f_{11}(p)$, $B = f_{12}(p) + f_{21}(p)$, $C = f_{22}(p)$. By hypothesis $A > 0$ and $\Delta := AC - \frac{1}{4}B^2 > 0$. Multiplying by the positive number A and completing the square,

$$A\, Q_p(v) = A^2 v_1^2 + ABv_1v_2 + ACv_2^2 = \big(Av_1 + \tfrac{1}{2}Bv_2\big)^2 + \big(AC - \tfrac{1}{4}B^2\big)\, v_2^2 = \big(Av_1 + \tfrac{1}{2}Bv_2\big)^2 + \Delta\, v_2^2.$$

Both terms on the right are nonnegative, so $A\, Q_p(v) \geq 0$. If $A\, Q_p(v) = 0$ then $\Delta v_2^2 = 0$, and since $\Delta > 0$ this forces $v_2 = 0$; the first term then reads $A^2 v_1^2 = 0$, and since $A > 0$ this forces $v_1 = 0$. Hence $A\, Q_p(v) = 0$ only for $v = 0$, so $A\, Q_p(v) > 0$ for $v \neq 0$, and dividing by $A > 0$ gives $Q_p(v) > 0$. □

Now let $p, q \in \mathbb{R}^2$ with $p \neq q$, put $v = q - p \neq 0$, and let

$$\gamma(t) = p + tv \quad (t \in [0,1]), \qquad g(t) = v \cdot f(\gamma(t)) = v_1 f_1(\gamma(t)) + v_2 f_2(\gamma(t)).$$

Each f_i has partial derivatives that exist and are continuous on all of $\mathbb{R}^2$, hence each f_i is (totally) differentiable, and the chain rule applies along the path γ, whose derivative is the constant vector v. Therefore g is differentiable on $[0,1]$ with

$$g'(t) = v_1 \left(\nabla f_1(\gamma(t)) \cdot v\right) + v_2 \left(\nabla f_2(\gamma(t)) \cdot v\right) = v^{\mathsf{T}} Df(\gamma(t))\, v = Q_{\gamma(t)}(v),$$

where the middle equality is just the expansion $v^{\mathsf{T}} Df\, v = f_{11}v_1^2 + f_{12}v_1v_2 + f_{21}v_2v_1 + f_{22}v_2^2$. By the Lemma applied at the point $\gamma(t)$ with the fixed nonzero vector v, we get $g'(t) > 0$ for every $t \in [0,1]$.

Hence g is strictly increasing on $[0,1]$: for $0 \leq s < t \leq 1$ the mean value theorem gives $g(t) - g(s) = g'(\xi)(t-s) > 0$. In particular $g(1) > g(0)$, that is,

$$v \cdot f(q) > v \cdot f(p), \qquad \text{equivalently} \qquad (q-p) \cdot (f(q) - f(p)) > 0.$$
